GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

"Materials and Methods" S&S sets the standard

Key reasons researchers prefer S&S nitrocellulose, such as BA85, are its versatility and the fact that it is the material upon which the *entire* hybridization field is based. The first published report, in 1963, specified S&S nitrocellulose for filter hybridization. S&S nitrocellulose is still the accepted standard.

Now S&S nitrocellulose is used extensively in Southern (DNA) transfers, RNA transfers, bi-directional transfers, electrophoretic transfers, protein transfers, as well as plaque and colony hybridization studies. No other transfer medium has stood the test of time so well.

Another important factor behind the preeminence of S&S in the genetics field is the S&S policy of *total* commitment to the user. S&S understands the applications of nitrocellulose and provides technical assistance, comprehensive applications literature and the "Sequences" newsletters.

Photographed at the Institute of Cancer Research, Columbia University, Dr. Philip Feigelson's laboratory.

Moreover, 18 years of experience as a manufacturer of nitrocellulose enables S&S to guarantee product quality, lot after lot.

Publication of the basic transfer methods (as shown) is the latest example of S&S total commitment. Written by a team of leading molecular biologists, this 8-page guide details DNA, RNA and protein transfer techniques using nitrocellulose and Transa-Bind™ diazotized media. It is available free upon request from S&S, manufacturer of the recognized standard.

MACMILLAN JOURNALS

MEETING THE CHALLENGE OF

Space-age explorations of the heavens, using astronomical satellites to compile systematic catalogues of radio, infrared, ultraviolet and X-ray radiations, have fundamentally changed man's existing picture of the universe.

An example of such pioneering sky maps was the inventory of X-ray and ultraviolet cosmic sources made by the Astronomical Netherlands Satellite, ANS, a few years ago. The celestial map drawn on the basis of the measurements made is still being used for detailed observations.

The technological lead gained by ANS will soon be followed-up by placing another Dutch astronomical satellite, IRAS, into a 900 km orbit around the earth. Basically, the task of IRAS is to compile a sky map covering all infrared radiation between 8 and 120 μm, as well as to measure the intensity of radiation from the infrared sources.

Having made an important contribution to the success of the ANS space platform, Philips has again been chosen to provide technological assistance for this new, equally ambitious astronomical project. Responsibilities include IRAS's on-board computer, power supply, communication system and sub-systems integration and testing.

The requirements of satellite technology, both for in space and on the ground, represent a formidable challenge to the technical and organisational abilities of the participating industries. And, by integrating the experience, expertise and technological resources of its specialized divisions and member companies, Philips is continuing to meet this challenge – as the following examples illustrate.

MACMILLAN JOURNALS

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

Breakthrough in biotechnology

Just when research needed it, NENZYMES™ provided it. Now more and more people doing DNA-RNA studies are using these enzymes — because they are ultra pure. NENZYMES eliminate one variable from the many in molecular biology.

NENZYMES are tested for biological purity in two stages: First, in numerous specific assays of each produced lot (which are recorded for customer inspection); and again when used as integral components in our pre-packaged systems for DNA/RNA research. They have to be trouble-free before they go to you.

RNA Ligase is the latest addition to our line of DNA/RNA modifying enzymes. We also offer restriction enzymes as well as selected nucleic acids — all of the highest quality. Call us toll free for complete information on any of these products.

The New Way of Separating

- *plasmids*
- *DNA fragments*
- *viruses*
- *sub-cellular particles*
- *large proteoglycans and polysaccharides*

– by gel filtration

Sephacryl® S-1000 Superfine is a unique new gel which offers a rapid, inexpensive and mild method for the separation of large molecules by gel filtration. A combination of extremely high porosity and good rigidity allows you to separate large molecules and particles up to 300–400 nm in diameter.

Put Sephacryl S-1000 in your lab and reduce your time spent in the centrifuge room! Technical information and detailed instructions are available upon request from Pharmacia Fine Chemicals.

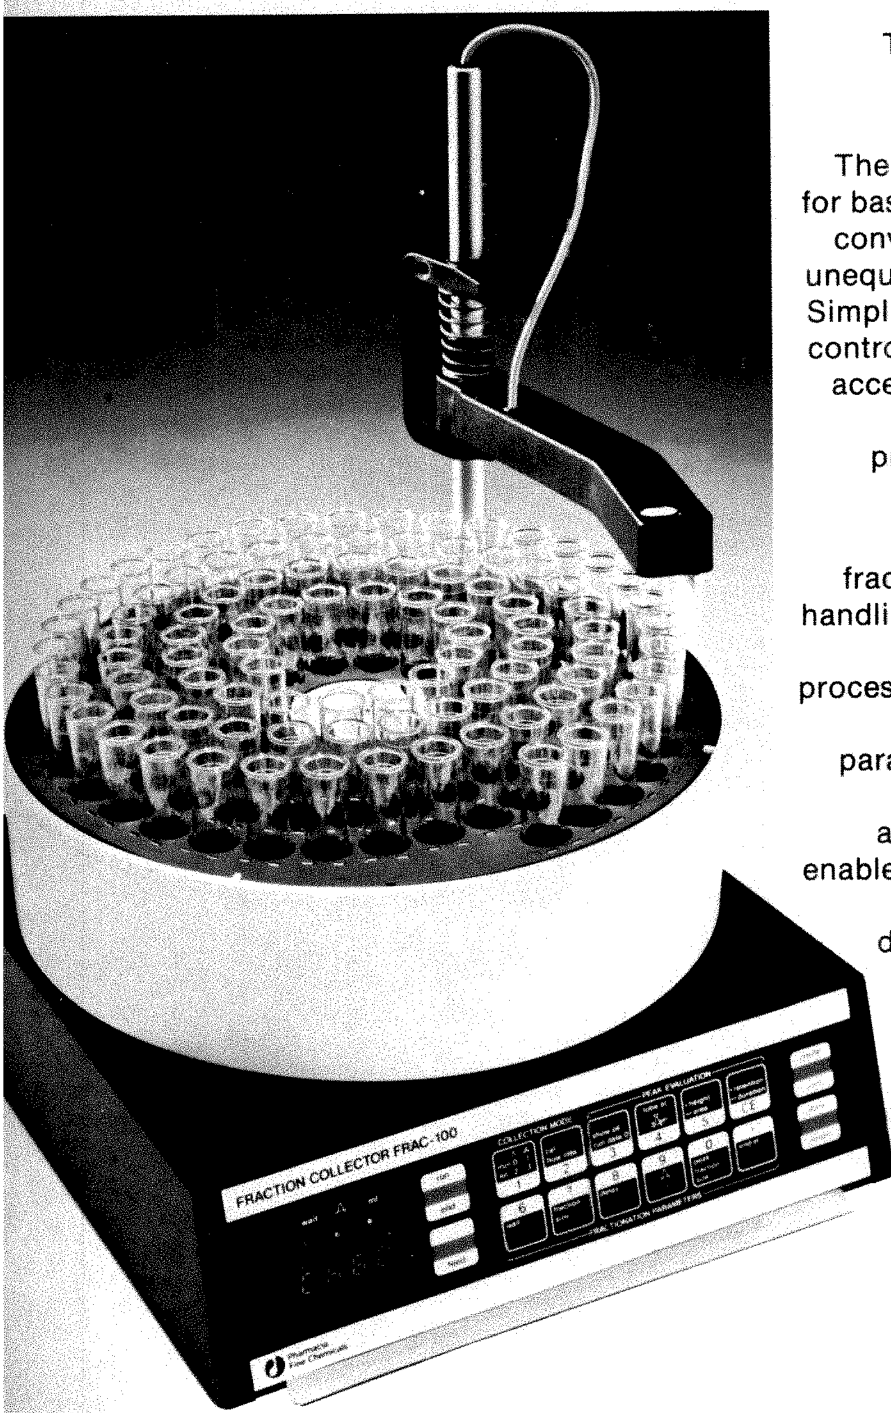
The FRAC-100 Fraction Collector



The FRAC-100 does what any other small fraction collector does - collects fractions, PLUS .....

The FRAC-100 will fulfill all your needs for basic fractionation requirements. As a conventional collector the FRAC-100 is unequaled in performance and reliability. Simplicity in design (3 moving parts) and control (flexible fractionation parameters accessed by a multifunction key board) accomplish fractionation routines previously attainable only with large, expensive instruments.

The FRAC-100, as a sophisticated fraction collector presents unique data handling and integration capabilities. The input of a 0-10mV detector signal is processed by the FRAC-100 to report as a digital display such separation parameters as peak height, peak width, peak retention and peak area. The addition of a PSV-100 solenoid valve enables selective fractionation of only the peak material as judged by a slope detector defined by a programmable threshold value.

If what you're looking for is a small, simple, inexpensive fraction collector - the FRAC-100 is your best choice!

If what you're looking for is a small sophisticated collector with power and abilities far beyond anything presently available - the FRAC-100 is your <u>only</u> choice!

How not to teach engineers

Changing the name of a research council will not help British engineering out of the rut. But what will?

British engineering education is once more in turmoil In spite of the appearance of the Finniston committee's report on engineering education just over two years ago, which went a long way to meeting previous discontents, and a more recent decision by the Science Research Council to add engineering to its formal title, the engineering professors from British universities, long known as a body of turbulent men, are still pressing for a separate engineering research council just for them The argument that inspires this movement has little substance and indeed is illogical if taken seriously What the engineering professors are doing is to combine elements from the Finniston report and their own practice which are consistent with each other but inconsistent with the needs of potential engineers, with the needs of British industry as they should be and indeed with the needs of education

The Science Research Council's decision to call itself the Science and Engineering Research Council seemed last year to be strictly cosmetic In reality, the Science Research Council had for many years been trying with conspicuous success to increase the proportion of the funds spent on engineering research in British universities The fact that over the years it has found this task very difficult is as much an indication of the receptiveness of the market — potential researchers in universities — to the availability of research funds as a sign that engineering is included in comparison with science and other fields of enquiry For the principle is that research is almost inevitably a less important part of British engineering education, at least as at present constituted, than of other scientific fields of enquiry (medicine perhaps excepted) For one thing (as the Finniston committee noted) many of those who enter engineering courses do so because they wish to join some part of the labour force at an early stage — wish to "get something done" Second, engineering research frequently entails use of large and expensive experimental rigs which, at least as British universities are at present organized, hard to come by Third, it is by no means clear whether research in a formal academic sense contributes to the creativity which the engineering professors, like the Finniston committee, consider to be the element in British engineering now most in need of being fostered In short, the case for regarding research as an essential part of engineering education rests only on the proper assumption that people who teach and do nothing else are probably poor teachers Yet, underpaid as they are, many British engineering academics prefer to spend what spare energy they have, not on the preparation of formal research reports, but on activities that may in the long run be just as useful to them as teachers — consulting for companies, working on real projects or perhaps even writing books that simplify scraps of information already known

So why is the cry that more funds should somehow be channelled into academic engineering research so insistent? The chief answer seems to be that the engineering professors and their followers have noted how, in other fields of science, people's prestige or even promotion depends on their formal completion of research projects of various kinds Finniston was persuaded of the importance of this model, suggesting that engineering would not acquire the status he rightly wished to give it until most engineering academics were able to brandish *curricula vitae* stuffed with research papers published in some formal body of literature The argument may be fair If this were indeed what most engineering academics could boast of, they would no doubt walk taller when mixing with their scientific colleagues in universities But it does not follow that the condition of engineering education would thereby be improved Indeed the Finniston report itself drew attention to the importance that engineering academics should be people who, first of all, were able to win the respect of their industrial rather than academic counterparts For, the argument goes, only then will their students respect them and listen to what they have to say

The same depressing conclusion is not equally applicable elsewhere, in many of the countries of Western Europe and the United States for example The reason for that difference, however, lies in one feature of the British engineering curriculum which needs more attention than it was given even by the Finniston committee Starting from its assumption about the motives persuading undergraduates to enter engineering courses in British universities, the Finniston committee argued that people wishing to work as engineers should be given plenty of opportunity to do so quickly In other words, the more a student was persuaded to acquire a good understanding of physical (and these days biological) science, the more likely he was to lose his sense that engineering is something different The result of that argument, accepted by the Finniston committee and most of those enthusiastic about its conclusions, is that even those engineering courses at British universities which have been "enriched" differ very little from the older courses to which have been grafted elements of the curriculum concerned with law, industrial relations and production engineering (whatever that may be) This implies that even if, as is likely, the next few years see a spread of these enriched courses throughout the British university system, engineers leaving the universities may still be ignorant of the rudiments of the sciences to which their skills apply Is this a recipe for providing the kinds of engineers likely to be at the forefront of industrial innovation? Or is it a device for making sure that even if the other obstacles to change in British industry were removed, engineers would still feel trapped by the past?

The Finniston report, rich as it was in comparisons between the economics of Britain and its industrial competitors, seems not fully to have heeded the implications of the curricular comparisons that it also included Elsewhere, especially in Western Europe, engineering education is indeed an intimate amalgam of sciences and its application To be sure courses are, by British standards, long — five rather than three or four years are commonplace The graduates from these more rigorous engineering schools appear to make a more direct contribution to the innovation of products and processes The Japanese example is perhaps even more striking — university engineers tend to be well trained in basic sciences and the companies which eventually employ them shoulder much of the task of helping them understand how their knowledge can be used Why should not the British educational system follow one or other of these paths? It

US contributors please note

From now on, authors in the United States and Canada should send their manuscripts either direct to London or to the Washington office, whose new address in *Nature,* 991 National Press Building, Washington, DC 20045, manuscripts should no longer be sent to *Nature*'s New York office

0028-0836/82/180001-02$01 00

would be wrong to blame the engineering professors, who appear willing to change, although they contribute to the suspicion growing between science and engineering in Britain Nor is the government to blame, for it seems fully aware that British engineering should be more innovative and more flexible The real difficulty is that for industry survival must now depend on making saleable products for the first time, and British industry does not fully understand what skilled engineers could accomplish

The Finniston report itself provided plenty of evidence to show that British engineers once at work have ahead of them a poor prospect for a career A few years after formal graduation, and once the two-year period required to become a chartered engineer is completed, the salaries of those still working as engineers for British companies appear to level off While the statistics are notoriously untrustworthy — many who began as engineers may quickly become salesmen or administrators — industrial companies appear to set little store by the work required of professional and experienced engineers But especially now, when the new technologies in microelectronics and telecommunications have thrown up almost an embarrassment of devices that might be manufactured and sold profitably, and when one of the most serious problems facing British companies and their competitors is to decide which of these might be made cheaply and sold profitably, there is a greater than ever need of people with a proper engineering education who might help chart a reliable course for the future What this in turn implies is that British industry must look for a system of higher education in engineering that will produce large numbers of qualified and creative people who will more often be employed in research and development than in the running of plants, production engineering or whatever and, if the engineering professors would reflect on that ideal state of affairs, they would surely recognize that then the status of engineers in Britain would truly be enhanced Contributing to the health of the economy would automatically win the respect that could not be acquired by a list of research papers an arm long It might then even be the case that engineering teachers, themselves transformed by industry's expectations of engineering qualifications, would more eagerly take up the funds that the Science and Engineering Research Council is apparently eager to seize back But another research council, exclusively concerned with engineering research would be at best a red herring

Economic research?

Can Congress realize its adage that investment in basic research will aid economic growth?

The US Congress is now wrestling with a problem common to all the industrial democracies how to get the most economic benefit out of the nation's investment in research and development Because the US economy is so decentralized, Congress is attacking the problem with the only central mechanism under its control, the federal research budget worked out each year between the current Administration and Congress Last December the US Congress, on a sweeping 90 to 0 vote, decided that one way to do this was to set aside one per cent of federal research and development funds (excluding those going to in-house research) for small independently-owned companies employing 500 people or less These firms have traditionally brought forth many more innovations than the giant US corporations that gobble up most of the federal industry research and development budget and spend most of the private money spent on industrial research in the United States

The "set-aside" is meant to do two things first to establish a federal policy that enhances the role of small businesses in research and development, second to generate more research results that can be turned into commercial activity on the open market The plan is modelled on a successful programme developed by the National Science Foundation that has enabled small firms to attract private capital, increase employment and, in a few cases, achieve great commercial success

Other countries are also trying to address this problem Great Britain has two smallish programmes, one that sets up "teaching companies", or long-term collaborations between universities and industry, and the CASE programme that works at the student level, placing individual students in companies in such a fashion that their industrial research earns them credit towards their degree Although having some direct federal programes in priority areas, West Germany relies primarily on tax incentives to stimulate industrial research and development Small German firms tend to contract with larger ones for the basic research they need to do before a project reaches the commercial stage All are concerned with the same thing how to transfer knowledge out of the basic research sector and into the increasingly competitive national and international marketplace

However, representatives of US universities have objected strongly to the bill, arguing that while the objectives are worthy, the mechanism of "set-asides" will shrink the share of the federal research budget that goes to the universities They would not care if Congress was in a spending mood and simply authorized more funds for small research and development firms But everyone in Washington is tight-fisted these days The Administration could not have supported the legislation, as it does now, if it proposed to add more money to the budget The legislation proposes to take the money from the existing budget, and so spokesmen for the universities have been crying, "Why us?", although the Senate version, which the House will probably also pass, limits the "raid" on basic research funds to one per cent of the basic research funds of any agency The objections from university spokesman are loud and clear However, there have been fewer objections from the contractors and applied researchers who now get the remainder of the federal research and development budget, some of whose funds will be used to make up the balance of the new programme

University scientists have reason to be concerned about protecting their share of the federal research and development pie from encroachments But the objections to this tiny set-aside — which is likely to be $300 million in all, of which a small part would come from basic research — have been strident even at a time when the workers at General Motors accepted voluntary wage and benefit cuts to help bail out that ailing enterprise If the most entrenched workmen's unions in the United States can make concessions to remedy the US economic troubles, cannot the better paid, supposedly more high-minded scientists?

In objecting to the legislation, spokesmen for universities and for basic research have been anxious to preserve their own turf at the expense of everyone else's Senator Warren Rudman, the prime mover behind the bill, is fond of quoting a prominent scientist at Massachusetts General Hospital stating he was not concerned about whether small businesses got more research and development, only about whether "one" of his investigators lost a grant because of it What is missing here is any perspective from the scientists that they are part of any larger effort Remember the old idea that the United States should invest in basic research for the sake of economic growth, productivity and the creation of jobs?

The new bills, therefore, put the US university science community squarely on the spot Thirty-seven years ago, Vannevar Bush and his colleagues persuaded the US government to sponsor basic research in the universities, and required that it have special, protected status, its own programmes and agencies, because, as Bush wrote, "Basic research leads to new knowledge It creates scientific capital It creates the fund from which the practical applications of knowledge must be drawn"

Small firms are also part of the "fund" from which practical applications are drawn, both those which do basic research and those which do not If the university spokesmen are truly concerned about national productivity, creating new inventions, and economic health — as they have said they were in selling their own budget requests to Congress in the past — they should support any measures that further that goal At least they should offer constructive alternatives But they do the image of science — and the US economy — no good by limiting their comment to paranoic fears that their particular sector will be hurt

National labs reach crossroads

US report looks abroad for ideas

Washington

The Energy Research Advisory Board (ERAB) of the US government has issued its preliminary advice on a critical study of the fate of the Department of Energy's (DoE) national laboratories This is a key study because the laboratories are also being looked at by the White House, which may not be favourably inclined towards them and will have much to say about their future

At stake is the role of nine facilities (see below), some of which do the most intensive high technology research in the world — on atomic weapons, fusion and lasers — gobbling up \$2,300 million, or half of DoE's annual research and development budget each year Apart from their atomic weapons work, they are entirely the creatures of DoE Starkly put, the choice is whether the laboratories should throw their doors open to become national centres, performing research for other federal departments, private industry, perhaps even other countries, or whether, as budgets decline, they should concentrate on a few things they do well and consolidate, with some of them closing down

The debate will be joined in the autumn when the ERAB panel makes a final report At that time, the White House Science Advisory Committee will be studying the fate of the DoE laboratories and those of the Department of Defense Mr George A Keyworth II, the President's science adviser and an alumnus of Los Alamos, has said that he thinks some of the laboratories should close down Last December, the Administration proposed that all DoE research be moved to the Department of Commerce, a suggestion that no one in Washington now takes seriously And James Edwards, Secretary of DoE, surprised ERAB recently when he told them that, in his view, the laboratories should remain in existence and throw their doors open to become national technical centres So the discussion, once joined, will be lively

The ERAB panel is headed by Ivan Bennett, dean and provost of New York University Medical Center DoE requested the study last September A preliminary report was sought this spring to feed into the White House's review Although the group has not decided its own view of the laboratories' fate, the preliminary report outlines the laboratories' strengths and future options

Some of the institutions, like Los Alamos, were founded as part of the weapons programme and retain important roles in weapons research Others, such as Ames Research Laboratory run by the University of Iowa for DoE, do basic research Oak Ridge has undergone a major transformation into a general applied research laboratory since its beginnings during the Manhattan project

The appendix to the ERAB panel's report deals with how major laboratories in other countries have adapted to changing times or to the stark fact of having fulfilled their mission The UK Atomic Energy Authority's laboratories at Harwell are discussed at some length Founded in 1946 to assist in developing civilian nuclear power, Harwell's task was nearly complete by the mid-1960s Then, the report notes, Harwell kept the same disciplines but took on new clients outside the government's agency The lesson of Harwell, it states, is that "once a large laboratory has been assembled, it can be useful to government in fields that extend far beyond its original mission and that such organizations can indeed change their mission without loss of vitality "

National laboratories covered in the ERAB report

Ames Laboratory
Argonne National Laboratory
Brookhaven National Laboratory
Los Alamos National Laboratory
Lawrence Berkeley Laboratory
Lawrence Livermore National Laboratory
Oak Ridge National Laboratory
Pacific Northwest Laboratory
Sandia Laboratories

Other examples from abroad are Amersham International, the UK government's source of radioisotopes which has been spun off as a company, and France, where government laboratories commonly create companies to perform specific work for industry The report notes the Dutch pattern of numerous small laboratories, which are two-thirds government-sponsored and one-third sponsored by industry

Sweden's Studsvik Energiteknik AB, the government's energy laboratory, had three years' warning that its government funding would be cut by 70 per cent The three years enabled the group to make a smooth transition to becoming predominantly sponsored by outside interests

The implication for the US national laboratories is that they can adapt and so probably should

The carefully worded list of options presented by ERAB includes "concentrating" the laboratories' efforts through vigorous management by the DoE, freeing them of legal constraints so they can work for other sponsors, transferring other federal tasks to them, making them more multi-faceted or narrowing their mission "to correspond with resources allotted", closing one or more laboratories, or mergers The suggestions are intriguing, but to implement any one of them will be a gargantuan task

Deborah Shapley

Disarray on chemicals control

Brussels

Fears are growing in environmental circles that the special programme on the control of potentially hazardous chemicals set up by the Paris-based Organization for Economic Cooperation and Development (OECD), is running into difficulties as a result of the Reagan Administration's pro-industry and protectionist policies The downgrading of the US Environmental Protection Agency (EPA) has coincided with a loose implementation of the toxic substances control act (TOSCA) Jacqueline Warren of the Natural Resources Defence Council, a leading environmental pressure group, has cited EPA figures on the premarketing notifications for new chemicals submitted since April 1979 showing that 66 per cent of submitted notices failed to include toxicity data, thus undermining progress to establish procedures to reduce the risk of new chemicals

Officials at OECD's headquarters are cagey, in view of the United States' negotiating weight, about admitting allegations that the enthusiasm evident under the Carter Administration for the OECD programme has waned A legislative gulf has certainly grown between the United States and the EEC, as a result of the way that TOSCA is being implemented and the changes within the EEC after the Sixth Amendment came into force last September This is likely to impair prospects for rapid agreement within OECD

Under the Sixth Amendment of the 1967 directive on dangerous substances companies must submit a stringent pre-marketing dossier on a new substance not only to national authorities but also to the European Commission and to the other member states Not surprisingly, EEC countries are now disappointed that disagreements within the OECD still loom large in two crucial areas which appear to have been resolved by the 6th Amendment In October this year a high level OECD meeting will be tackling the areas in

0028-0836/82/180003-02\$01 00

question — how to ensure satisfactory quality controls for the implementation of the "Good Laboratory Practices" scheme agreed on last year, and how the confidentiality of data is to be guaranteed

The Good Laboratory Practices scheme represents a commonly applied definition of the standards and procedures to be used in laboratories testing new chemicals Unfortunately mistrust has clouded the agreement High standards cost money and governments are not convinced that everyone is abiding by the rules as strictly as they ought to be, so the October meeting will examine proposals for methods to check that the practices are properly upheld

This will be another small step towards the programme's ultimate aim of guaranteeing that the marketing authorizations handed out nationally are acceptable elsewhere Only by using the Good Laboratory Practices scheme can a standard dossier of data on a new chemical substance, the minimum pre-marketing data, be accepted by other national authorities

The scheme involves, though, a free flow of allegedly valuable commercial information, and this is causing worries in the chemical industry that such information will not remain confidential. The issue is complicated by the fact that there are large differences among OECD countries in the laws relating to freedom of information Environmentalists are equally worried that poor access to information on toxicity considered confidential by industry will violate the principle of public participation in the assessment of the hazards of chemicals to which the public are exposed

The OECD's agreement on exactly what information is relevant to hazard assessment has disappointed both the industrial and environmentalist lobbies The various OECD working groups have come up with a document which defines what data should not be considered confidential and which specifically excludes information such as spectroscopic data which might reveal the chemical identity of a substance before a manufacturer wishes it to be generally known A final agreement has yet to be reached in sensitive areas such as pharmaceuticals The United States is held to be particularly responsible for back-tracking on this question as the list of non-confidential data continues to be reduced If too much remains confidential, hazard assessment made by industry or government will be harder to question, especially if there is consistency on marketing authorizations

So it seems there is still considerable work to be done within OECD before guidelines are agreed on what hazards can be considered acceptable, and this may prove to be the biggest stumbling block to further international cooperation in this field **Jasper Becker**

How Dr Melamed lost his degree

In 1976, new regulations came into force in the Soviet Union governing VAK, the "Higher Attestation Committee" responsible for conferring the degrees of Candidate (PhD) and Doctor (DSc/DLitt) The full text was not published at that time (a booklet was promised for "later") but the media placed considerable stress on the fact that the new regulations demanded scrutiny of the political attitude of the postulant for the degree

It now appears that this requirement can work retroactively During the past year, at least seven Jewish scholars have been deprived of their degrees, for having exhibited "anti-patriotic" attitudes in applying to emigrate to Israel A document — which claims to be a transcript of such a deprivation process — has just reached *Nature*, and is reproduced here in a slightly abridged form **Vera Rich**

From the stenographic transcript of the Scientific Council of the Faculty of Geology of Moscow State University, 20 January 1982.

Chairman (Professor Adonis G Gayanov) Members of the board already know the agenda for today's session *inter alia* the stripping of Vladimir Grigor"evich Melamed of his academic titles due to his anti-patriotic dealings, unworthy of a Soviet scientist

Melamed is not present, he is ill On 18 January, two days before this session, he notified me that he had a sickness certificate (*reads Dr Melamed's notification*)

I feel it is particularly necessary to point out the problem of his absence for the following reason According to paragraph 5 of the regulations of VAK on the conduct of sessions for the stripping of academic titles, the person from whom the title is to be stripped has to be present

(*After some discussion, — including pressure from the public gallery — it was decided to proceed in Melamed's absence*)

A G Lyubimov Allow me to read the material from the special committee of the board, set up to investigate the activities of V G Melamed, who expressed the desire to emigrate to the state of Israel

> Melamed has been working at Moscow State University for approximately thirty years Latterly he was in charge of one of the laboratories, and was dealing with pressure-modification of the permafrost process He distinguished himself by his energetic attitude and was therefore admitted to the Party In 1975, he received the degree of DSc, specializing in geophysics
>
> In November 1980, he submitted a request to emigrate to the state of Israel, which is known to be capitalistic and no friend of the Soviet Union In view of the increasing severity of the international situation and all that has been stated previously, we find that the decision of Melamed is an anti-patriotic act, unworthy of a Soviet scientist
>
> We are of the opinion that Article 104 of the VAK on the stripping of scientific titles can be applied to him Dated 18 December 1981 Signed by all members of the committee

Chairman Who wants to comment?

Professor Epinat"eva I have a question about Melamed's scientific profile Would you please specify what he has achieved in the scientific field?

Chairman This is not the question We are concerned with something else, not science We are not going to discuss the scientific work of Melamed, so this is not relevant

Professor Dmitriev Will the minutes of the decision of the committee be added to the documents that VAK receives from us?

Chairman Yes

Dmitriev Then I want to point out an error Melamed did not defend his doctoral thesis in 1976, as the committee says, but in 1977 And it is an ill-chosen expression to say, "and all that has been previously stated" From this one might conclude that he should be deprived of his degree, not only because of his wish to emigrate from the Soviet Union but also because he worked for Moscow State University for thirty years

Chairman Good, we shall correct this Any further comments? (*Silence*) Good I call on Arkadii Vasilevich Kalinin, member of the committee

Kalinin Today our board has a rather difficult task, which is, however, completely justified by VAK regulations As you all know, Article 104 of the VAK regulations deals with the stripping of academic degrees due to conduct unworthy of a Soviet scientist This includes offences such as anti-patriotism This leaves our board one choice, to decide whether or not Melamed's offence can be interpreted as anti-patriotic or not

According to the law, emigration is permitted for the sake of reunification of families Melamed informed the departments which grant exit visas that this was his intention However, no law prohibits public organizations from judging Melamed's activities

Academic titles in the Soviet Union are conferred not only on the grounds of scientific criteria We consider the function of an academic title to be more important than in the capitalist world It confers not only the right to a function, but a salary If Melamed remained a doctor, he would continue to do things to which he no longer has a right His titles should be taken away from him

Professor Nikitin I should like to add something in order to show two aspects of the anti-patriotism of Melamed First, he was a Party member for a number of years and also a propagandist When submitting his papers applying for an exit visa, he turned his back on all his early ideas

0028-0836/82/180004-02$01 00

Second, he is a qualified specialist, a scientist Now he is leaving in order to work on behalf of Israeli science, to work for our opponents, our enemies And this is even more than anti-patriotism

Chairman Thank you Does anyone else wish to speak? The case is probably completely clear and we can begin voting

J V Medvedkov Permit me to say something, not everything has been said I am especially qualified to speak Before I became involved in soil-sciences, I studied law

It is, as you know, not only a moral judgement or the opinion of colleagues if Melamed is stripped of his academic titles they give a right to a scientific function, a salary, the possibility of scientific work appropriate to his academic level, admission to libraries etc

A case like this is treated completely unambiguously by a special juridical act I mean the Final Act of the Helsinki Accords of 1975 I should like to quote from *Izvestiya,* 2 August 1975

> The submission of an application for reunification of family shall not lead to changes in the rights and duties of the person who made the request or of members of his family

Hence it is inadmissible that the board should seek to limit Melamed's rights because of his wish for reunion with members of his family in Israel

I have not heard any proof that Melamed's conduct constitutes an anti-patriotic offence

It is no accident that in such a complete work of reference as the *Soviet Encyclopaedic Dictionary* (Moscow, 1979) the term "anti-patriotic" does not occur One can use an expression which comes close to it, namely "anti-Sovietism" This term does occur in the *Soviet Encyclopaedic Dictionary* On pages 63–64 it says that anti-Sovietism is an attempt to defame and misrepresent everything that the Soviet Union has achieved in economic, political and cultural fields

When it is stated that Melamed's conduct is anti-patriotic, then he is apparently also accused of anti-Sovietism

By whom and where has it been proved that Melamed has done anything to misrepresent and run down those things which the Soviet Union has achieved?

His application to emigrate was submitted without any publicity It is an act which falls within existing laws and standards He did not give public announcements and did not publish books which misrepresent and run down all that the Soviet Union has achieved

I fear that in fact, the Soviet Union will be harmed by those people who have applied to the board with the demand that Melamed be punished

Chairman Any further comments?

Mrs F Melamed My husband is ill at the moment and I do not understand how it is possible for his case to be considered *in absentia* Today a matter is being discussed that is of vital importance to him His entire 30 years career in the service of Soviet science has been put in doubt Can one call such a career unpatriotic? Why do members of the board disregard the signature of the Soviet Union below the Helsinki Final Act?

Professor Epinat"eva It is one thing if a worker at a normal research institute or even the Academy of Sciences expresses the wish to emigrate, but it is totally different for people working at the university to do so The latter are dealing with young people, aren't they? The act that Melamed performed distorts the world view of our youth

S A Kats This concerns the shattering of an entire human life And you limit yourself to two short sentences If the matter had been dealt with by the court, the procedure would have been very different

Professor Kalinin I am against the fact that "anti-patriotism" and "anti-Sovietism" are equated When Herzen left Russia, it was an act that we call "anti-Tsarism" and not "anti-patriotism"

It was the last straw to say that Melamed would be anti-Soviet But can we call his action complimentary to the fatherland? He did not want to leave Moscow State University in order to make life easier for us So we do not have to make life easier for him I do not think that we are in violation of the Helsinki Accords

G O Marshuhuk I myself disapprove of Melamed's action, and I told him so But disapproving is one thing and accusing him of anti-patriotism, and punishing him severely by denying him the right to scientific work is something totally different

I S Irlin There is no doubt that Melamed behaved within the framework of the law

During the past six to seven years, some thirty thousand people left the Soviet Union to be reunited with their families Among them there were quite a number with doctoral or candidate's degrees But personally I do not know of any case where one was deprived of his scientific degree In my opinion the board wants to create a precedent

Professor V V Karus According to Article 104 of the VAK regulations, one needs three qualities to hold a scientific title qualification, patriotism and regard for ethical standards Patriotism is love for the fatherland which raised us But Melamed decided to leave the fatherland at a time of severe international tension and for a country that propagates a malicious hostility against the Soviet Union The right to work will not be taken from him, but why should he get an extra salary for working in a scientific field?

Chairman I request you to vote for the stripping of Melamed's degree of Candidate of Physico-Mathematical Sciences For the motion? Carried unanimously I hereby declare the meeting closed □

Agricultural biotechnology

Soon to start

Springtime has not induced germination of the British Technology Group's (BTG) plans for an agricultural genetics company but it is still expected to bloom this year One snag at present seems to be the degree of scepticism among those of the calibre to be potential scientific directors about the ability of any such company to be profitable within five years, as BTG would want

Although BTG considers the topic too sensitive to discuss, by all other accounts the plan is that the new company should have the same kind of special relationship with the UK Agricultural Research Council (ARC) as does Celltech with the Medical Research Council (MRC) Celltech was also set up by BTG (or, more precisely by the National Enterprise Board which has since fused with the National Research Development Corporation to form BTG) and operates in the field of biotechnology Its relationship with MRC allows Celltech first refusal on any discoveries within the realms of recombinant DNA and cell hybridization that emerge from the various units of MRC In return Celltech channels money back into MRC and has an obligation to help the council find other commercial outlets for discoveries in which it has no interest

ARC and many of its employers who work on subjects that will be of interest to the new company (some of whom are already consultants to BTG) tend to be enthusiastic about the prospect for several reasons

The first is the possibility of an easy and financially benefical way for ARC to channel its discoveries of commercial potential in the domain of plant breeding At present it has no such outlet New strains of plants developed by conventional techniques within ARC institutes have to be given to the National Seed Development Organisation which, although a profitable concern, donates its profits to the Treasury rather than directly to ARC

For discoveries in gene cloning and transfer, that have some potential for being used in the genetic improvement of plant

0028-0836/82/180005-02$01 00

strains, ARC has no ready outlet but individuals have sometimes had to contend with the rather persistent advances of some of the several American companies that have been set up in advance of any British counterpart A special relationship with a company, preferably British, would therefore suit ARC well

For its part, BTG is believed to have board approval for starting the company and to have a managing director in mind It has not however, yet found a scientific director and has met with some refusals already

One problem facing any potential scientific director is the need to ensure that the company is profitable within five years That was also the BTG stipulation for Celltech but the problem is greater in plant breeding because the genetic manipulation of plants by modern techniques is far less advanced than is that of bacteria, which Celltech use to make products of commercial value, such as rennin

Nevertheless the optimists believe that profits could be made within five years by concentrating initial efforts on the improvement of bacterial strains, particularly the nitrogen-fixing *Rhizobium,* which are used to inoculate crop plants and on the development of techniques of clonal and meristem propagation

Finance for the new company is being arranged by BTG which is almost certain to provide at least one third of the money from its own, governmental coffers The rest will be raised from private sources

Peter Newmark

University admissions

Still squeezed

Applications from home and European Community students for undergraduate courses at British universities are likely to be six per cent up this year on last, according to figures released by the Universities Central Council on Admissions (UCCA) (see table) But admissions to courses starting in October 1982 are expected to be down on admissions in October 1981

This is no surprise The government has implemented its policy of limiting university places just when the number of 18 year olds in Britain is increasing Hence, the previous policy of gearing university places to demand has been abandoned The Department of Education and Science, in recent evidence to the House of Commons Public Accounts Committee, has thrown light on how this policy may affect potential students The table below shows the department's estimate of the numbers of potential students that may be deprived of a university place in the academic years 1981–82 to 1983–84

Understandably, universities hope to make up the fees lost from home students by taking in more students from overseas But their aim has been made more difficult since the government removed the subsidy from overseas student fees The figures clearly show that full economic fees have deterred a high percentage of potential overseas applicants

The number of overseas admissions, however, is not necessarily a constant proportion of applications UCCA statistics suggest that the shortfall in acceptances of places from overseas students in October 1981 over October 1980 was only 19 per cent, compared with the 34 5 per cent shortfall in applications But statistics compiled by the University Grants

Annual percentage change in applications for undergraduate courses at UK universities

	1980 over 1979	*1981 over 1980*	*1982 over 1981*
Home students	+3 5	+4	+6*
Overseas students	−12	−34 5	−20*

*Estimates

Committee (UGC) suggested an even smaller shortfall in overseas admissions only two per cent in 1981 over 1980 This apparent discrepancy seems to be explained by the fact that UGC includes admissions for more non-degree undergraduate courses than does UCCA So it seems that overseas students are now opting for shorter, less costly courses

Last week, the House of Commons Public Accounts Committee published the report of its findings on the administration of university grants The committee seemed pleased with the move by the education department to reduce the amount of university income not subject to cash limits by transferring the grant paid to home students for their fees directly into the universities' purse The universities are praised for keeping their student intake on target last October (a 4 per cent shortfall over the previous year) — but the polytechnics, and other institutions of higher education, come in for a drubbing for increasing their intake by 18 2 per cent over the previous year The committee's report urges that the body now being set up to control higher education outside the university sector be developed quickly with full co-operation of UGC and laments the fact that steps to coordinate all aspects of higher education had not been taken before the cuts to the universities

The parliamentary committee also seemed satisfied by assurances that the universities are taking care not to offer new tenured appointments with no redundancy clause The Committee of Vice-Chancellors and Principals has been looking at more flexible forms of contract

Judy Redfearn

No. of home students, aged under 21, entering university (thousands)

	*1980–81**	*1981–82*	*1982–83*	*1983–84*
UGC targets	67 3	65 2	63 1	60 9
Target to maintain 1980–81 age participation rate†	67 3	68 5	70 4	69 5

* Actual intake

† Age participation rate is the percentage of 18–21 year olds in the population entering university, which was 7 5% in 1980–81

US research support

Question of size

Washington

In coming weeks, the US Congress will probably pass legislation that would give a major shot in the arm to small research and development firms in the United States, many of which suffer in the present economic climate, yet which are major sources of new technical inventions The legislation is not final, however, and is subject to considerable opposition voiced by spokesmen for the universities and government-sponsored basic research

The National Science Foundation (NSF) estimates that there are 13,000 small firms in the nation, defined as independently owned firms with 500 or fewer employees and performing research and development work Although numerous, accounting for 85 per cent of firms involved in such work, these small companies in fact spend only 4 per cent of all industry research and development dollars In contrast, giants such as McDonnell Douglas and IBM spend 87 per cent of US industry's investment research

Yet there is ample evidence that most innovations come from small firms One 1976 study showed that small firms produce 24 times as many innovations per research and development dollar as large ones, even though the small firms receive only 2 per cent of total federal support for industrial research

Small business found a champion last year in Warren Rudman a freshman republican senator from New Hampshire Rudman introduced a bill that would set aside one per cent of all federal research and development funds — which total some $40,000 million — for small firms They would compete for the money by applying to separate federal agencies for grants, awarded on a peer review basis, as seed money If the work was fruitful, some firms would qualify for follow-on funding In a third phase, the money would have to come from the private sector, or from other government sources if the government was interested in the company's work

The plan was modelled on the Small Business Innovation Research Program run by NSF, and a newer, similar programme run by the Department of Defense The NSF programme gave some $5 million in seed money to 42 small firms in 1977 By 1981, the 11 of them that qualified for follow-on funding had

0028-0836/82/180006-02$01 00

succeeded in raising $41 4 million in outside capital and equity Moreover, the programme apparently created jobs The 11 firms had employed 261 people in 1977, by 1982 they employed 616 people The most spectacular growth was in a genetic engineering firm, Collaborative Research of Lexington, Massachusetts, which received $25,000 in seed money in 1977 and by 1982 had raised $24 9 million from outside sources

The Rudman bill made a spectacular passage through the Senate in December Of the Senate's 100 members, 85 were co-sponsors of the bill, and it passed by a vote of 90 to 0 One modification exempted the $10,000 million in-house federal research and developement from the calculation A second modification was an amendment introduced by Senator Harrison Schmitt limiting the amount of funds to be set aside that could be taken from federal basic research budgets This amendment was an attempt to placate spokesmen for the basic research community and univerisities who attacked the bill as a raid on basic research funds They argued that development work in most federal agencies has powerful protectors, whereas basic research does not In the Department of Defense, for example, the contractors and armed services buying the MX missile, or Trident submarine, would keep their research and development funds from the amount set aside, so that the basic research funded by the Department of Defense would be unduly tithed

One fear being raised by university spokesmen is that the small firms' share of the federal research and development pie will grow, at the universities' expense The proposed one per cent sounds modest enough, but any amount would take some funds away from federal basic research at a time when such money is becoming scarce

Some university spokesmen argue that small firms do not do basic research of high enough quality to qualify for federal funds, and that a set-side programme will allow them to adhere to this lower standard They argue that such firms should compete with universities and other traditional research groups Several federal agencies prohibit for-profit firms from applying for research grants, although the National Institutes of Health has now lowered this barrier

In the coming weeks the House will have to decide which version of the legislation it will pass The variant most palatable to university spokesmen is that proposed by Don Fuqua, chairman of the House Science and Technology Committee This would leave oversight of the programme to the authorizing committees of Congress for each of the federal agencies involved, thus allowing them to devise individual set-aside programmes or exempt the agencies under their jurisdiction

The version most likely to pass, however, is a bill put forward by John J LaFalce, which is modelled on the original Rudman bill but is even friendlier to small business The LaFalce version would make the money set aside not one, but three per cent of all federal research and development, and does not exempt federal in-house research from the calculation The LaFalce version would make $1,200 million available to the small firms in the first year — contrasting with the more cautious Rudman bill, which phases in the programme, reaching the $300 million level in the third year But in view of the opposition to the set-asides that has surfaced elsewhere in the House, it seems likely that the LaFalce forces would be satisfied with a final version limiting the set-aside to one per cent, having a three-year phase in period, and a feature limiting the "raid" on basic research

Deborah Shapley

Call from arms

Washington

At its annual meeting in Washington the National Academy of Sciences (NAS) made one of its rare ventures into public policy pronouncements The assembled members adopted a resolution calling on the President and Congress and their counterparts in the Soviet Union "to intensify efforts to achieve an equitable and verifiable agreement" limiting strategic arms, and to "reduce significantly the number of nuclear weapons and delivery systems" The resolution further urged them to reduce the risk of accidental war, to inhibit proliferation of nuclear weapons, and to "continue and observe" all arms control agreements including Salt II, signed by the United States and the Soviet Union in 1979 but not ratified by Senate Finally NAS urges the avoidance of "military doctrines that treat nuclear explosives as ordinary weapons of war"

The NAS resolution makes no mention of the "nuclear freeze" urged by other groups around the country It was passed almost unanimously, with a few abstentions and one dissenting vote Proposer for the resolution was Marvin Goldberger, president of California Institute of Technology and chairman of the academy's Committee on International Security and Arms Control The resolution was sent to the President via his science adviser, George A Keyworth II

Deborah Shapley

Polish Academy of Sciences

Slow progress

Poland's new legislation on the Academy of Sciences will ensure parity of funding for the institutes of the academy and the research institutes of the production ministries, according to Warsaw radio A main concern of Polish scientists has been the lack of separate budgets for the various institutes funded on the principle of dividing research into "problems" funded nationally The new bill, which is under discussion by the Council of Ministers (Cabinet), thus seeks to redress one of the major grievances of the academy scientists expressed at last September's National Congress of Solidarity in Gdansk It therefore forms part of a current tacit policy on the part of the ruling Military Council for National Salvation (WRON) to grant various "social" demands from the Solidarity programme while keeping open the question of the future of the independent trade union movement

Much, however, remains uncertain, and nothing has been announced so far about one of the most contentious issues — the status of the Secretary of the academy At present, the incumbent of this post holds quasi-ministerial rank, and is responsible in the first instance to the prime minister, not to his fellow academicians During "renewal", as part of the nationwide drive towards "self-governance", there were strenuous moves (headed by the academy lobby within Solidarity) to change this anomalous state of affairs and ensure greater autonomy for the academy, thus ending the long-standing friction between the members and scientific employees of the academy on the one hand, and the academy bureaucrats on the other

There has also been no news since the military council took power of many other proposed reforms, despite their apparent innocuousness For example, it was proposed that the academy should decide, on purely academic grounds, whether or not its members should be able to travel abroad At present, non-scientific criteria still play a major role in such decisions The emergency regulations on foreign travel for scientists stress that the would-be traveller must be given a thorough political vetting

Not surprisingly, this can pose problems for academy scientists A case in point is that of Artur Swiergiel, a young physiologist who, since last October, has been researching at the Babraham Institute of Animal Physiology in Cambridge

Mr Swiergiel had a six-month scholarship under an agreement between the British Council and the Polish Academy of Sciences Last November, realizing that he would need extra time for his experiments, Mr Swiergiel applied for an extension On 31 March, he received a telegram from Professor Maciej Zurkowski, director of the academy's Institute of Animal Breeding and Genetics, confirming the extension Three weeks later, a second telegram arrived, stating that Professor Zurkowski had been informed by "the academy" that the extension had been refused No explanation was given — but Mr Swiergiel had formerly served on the Warsaw regional executive of Solidarity

Muscular dystrophy research

Positive move

Not content with the paradoxical increase in public donations to charities in times of recession, the Muscular Dystrophy Group of Great Britain (MDG) is aiming to raise an additional income of £1 5 million from industry over the next four years And to coordinate the use of this money, earmarked for supporting clinical trials and work on the X-chromosome with that of their regular income, MDG have created the full-time post of research development director and filled it with an eminent scientist

At the age of 59, Professor Arthur J Buller takes on the new job In his career Professor Buller has moved across the spectrum of bodies supporting UK medical research, serving as a member of the Medical Research Council (MRC) from 1975 to 1981, becoming dean of the Faculty of Medicine at Bristol University in 1976 and moving to the government's Department of Health and Social Security as Chief Scientist in 1978 Now he feels less optimistic about public sector support for research and views the drain on university funds and the cutback in government support for research as a serious threat to the dual support system Medical charities can, he feels, ameliorate this situation

MDG works on an annual budget of £1 5–2 million raised through 450 voluntary bodies (the Muscular Dystrophy Association of the United States has a budget in the region of $16 million) In 1981 a total of £1,321,719 was made available for research — 45 specific projects have been approved for the academic year which began in October 1981 The biggest handout will go to the group's own research laboratory in Newcastle (£189,254) Two London hospitals will receive over £100,000 for work investigating tissue culture in dystrophic muscle and in the development and differentiation of single muscle cells

The additional money gathered by the fund-raising committee will be diverted to what the group describes as "significant new research developments" It is hoped that £1 million will go to work on the X-chromosome The techniques of recombinant DNA and gene cloning are already being applied to the X and other chromosomes with the dual aims of developing reliable methods of prenatal diagnosis and discovering the underlying genetic defect of several incurable diseases Such work is already funded by the MRC and the Cystic Fibrosis Trust but MDG want to make certain that efforts are specifically directed to Duchenne muscular dystrophy, a disease linked to an unknown defect of the X-chromosome

The other £0 5 million that MDG hope to raise from industry will be spent on clinical trials The assessment of these is likely to be helped by the availability in a London hospital of a £200,000 nuclear magnetic resonance machine This was purchased with the assistance of MDG and will enable muscle metabolism to be studied without taking tissue samples

MDG is a working example of how medical charities can give invaluable support to research when public sources are running dry It may also prove that charity can keep new research initiatives at home — additional funds help stem the brain drain

Jane Wynn

Musical chairs at the CEA

The French Commissariat a l'Energie Atomique (CEA) is to be reorganized, little more than a decade after the reforms of Andre Giraud set the CEA on its feet again

In Giraud's time, the problem was that the CEA had lost a major battle over the choice of power reactor for a French nuclear programme CEA wanted the indigenous French gas-cooled system, whereas Electricité de France backed the American pressurized water reactor (PWR) Electricite de France won, and the broken CEA had to be given new confidence Giraud achieved that, and also helped set up France's nuclear industry, now so successful, behind the PWR

Why the need to reform again? In part, CEA has outgrown the Giraud structure It now controls many subsidiary companies whose management needs to be rationalized But, more importantly, the new broom of the socialist government is to sweep clean The catchwords are decentralization and regionalism "Some reform of the CEA would have had to take place anyway" a CEA spokesman said last week "but it's going to go further with the new government than it would have done with Giscard d'Estaing"

M Michel Pecqueur, CEA's administrator-general, is to announce details of the reforms this week, with the hope — if the trade unions agree — that the budget for next year should be determined under the new structure That means things must move fast, for the budget process begins in June

One key issue will be the role of the seven *délégués*, who control the key sectors of CEA (nuclear applications, reprocessing, research and so on) Some say that these Paris-based posts carry too much power, and there must be some devolution to the units that the *délégués* control — among them the fundamental research laboratories at Fontenay-aux-Roses However, one of the délégues last week expected their roles to remain much the same after the reform The names of the posts might be changed, but the duties would not Indeed, it is claimed that the reforms will not be revolutionary No doubt that is CEA's intention

Robert Walgate

Ecology in the Sinai

Time of change

The final hand-over of the Sinai last week brought to an end an era of strict conservation and ecological surveying. Although there had been proposals, at the time of the Camp David talks, that the Sinai should become an "International Ecological Park for Peace", these have failed to materialize Moreover, according to Israeli ecologists, Egyptian plans to develop the Sinai could lead to the repetition of Israeli ecological mistakes committed with the best intentions by the early settlers

Under the Israelis, three major ecological centres had been established a bird migration monitoring station at El Arish on the Mediterranean, a field studies school near the Santa Caterina Monastery, and the Ras Muhammed underwater observatory None of these is still in operation, although a special agreement was signed ensuring the continuation of the Santa Caterina school The unique coral habitat at Rad Muhammed has been virtually destroyed by soldiers fishing with hand-grenades

Under Israeli control, ecological protection in the Sinai reached an almost ludicrous level, with tourists forbidden to pick up seaweed or coral from the beach for fear they might then drop it in the desert and upset the ecological balance

The Egyptians have ambitions plans for developing the Sinai, but Israeli ecologists know all too well the ecological hazards of the pioneering spirit — citing drainage of the Huleh swamps in North Galilee, and Ben Gurion's plans for intensive development of the Negev

Whether or not in cooperation with Israel, the Egyptians are matching Israeli developments They are particularly interested in developing solar ponds as energy sources, and Israeli plans to replenish the Dead Sea from the Mediterranean One Egyptian plan envisages an artificial "Dead Sea" in the Quattana depression, south-west of El Alamein As this lies below sea level, the canal bringing in Mediterranean water could be used to generate power, while the resulting salt lake could, as in Israel, be concentrated by evaporation to form the basis of a chemical industry

The emotional and political overtones of the return of the Sinai to Egypt make it unlikely that the Egyptians would seek Israeli advice on how best to develop the area However, the Israeli ecologists, who have worked long hours during the past few months to make their Sinai studies as complete as possible, express themselves willing, to make their data available to the Egyptians.

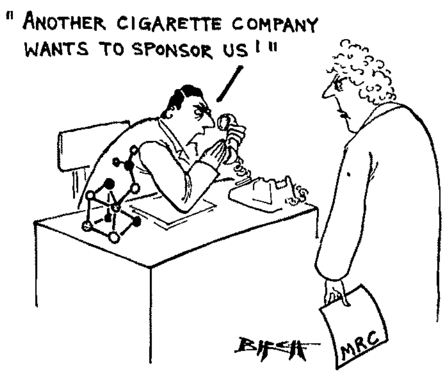
MRC research unit

Job vacancy

The immediate future of the British Medical Research Council's (MRC) Pneumoconiosis Unit in South Wales seems assured, although life there remains unsettled Early last year, the unit had been the subject of a regular review by the MRC which had recommended staff cuts and greater emphasis on research supported by industrial contracts The fears of staff that the MRC was preparing to wind down the unit for final closure in 1987 when the director was due to retire, were heightened when the director, Dr Peter Elmes, left his post last January Those fears were allayed, however, when the MRC announced that it would appoint a new director — advertisements will be placed shortly In the meantime a four-person committee is in charge of the unit's daily administration

Dr Elmes's departure, however, highlights a problem for a handful of MRC units whose work is largely vocational Those units must win some of their money from contracts placed by the Health and Safety Executive, to whom the MRC still hands over some of its budget under the Rothschild customer/contractor principle Frustrations can arise when the contracts are for routine toxicological studies which divert staff from fundamental research for which the units are primarily intended



The MRC has used the problem to argue for an adequate budget to maintain fundamental research But it has also urged the units to win more contracts from industry as well as the Health and Safety Executive to help it out of its fiscal difficulties The more general problem, of course, is that routine toxicological studies on occupational hazards must be done and there are few suitable independent laboratories outside the MRC

The MRC's plans for the Pneumoconiosis Unit have begun to take shape over the past two or three years Hence there has been a shift in emphais from clinical to *in vitro* research and the unit's staff has been reduced Since the MRC's review early last year, the unit has received regular visits from a committee to advise on its work and research commissioned by industry has increased Dr Elmes, however, was not happy about the changes He mentions delays to research work caused by lengthy negotiations with industrial customers, both at the outset of a piece of research and during its progress, and industry's reluctance to publish results quickly

An illustration of some of the difficulties is provided by the case of kaolin workers in Cornwall The MRC, according to Dr Elmes, had been unwilling to support studies into the causes of an excess of lung disease in the workers on the grounds that they did not constitute fundamental research Industry and the Health and Safety Executive, which did come up with the money, awarded funds piecemeal for individual studies as the project progressed, thereby causing delay Publication of the final results, which apparently suggest a link between kaolin exposure and lung disease has been delayed because of industry's desire to reduce the risk before it is widely known

The MRC believes that many of these problems can be avoided if the terms under which research is conducted are made clear to industry at the outset Hence, the council would like the Pneumoconiosis Unit to continue its efforts to win more industrial contracts But the precise balance between applied and fundamental research, it says, remains to be seen One important factor in determining the unit's structure will be the views of the new director **Judy Redfearn**

US science education

Nearing a crisis

Washington

Mr George A Keyworth II, the President's science adviser, termed the "next few years" as "critical in science education in the United States" But he has extinguished any hopes that the Administration will do anything about it until the next presidential term

In a speech to the National Science Teachers Association (a group whose ability to carry out its job has been impaired by Administration cuts of all funds for pre-college science programmes run by the National Science Foundation (NSF)), Keyworth repeated the unfortunate truths many US leaders have learned of late about how poorly, and how little, science and mathematics are taught in US schools

For example, these subjects consume only seven per cent of elementary school teaching time, and even less time at the secondary level The ability of students in science and mathematics has deteriorated steadily, and most people leaving school and going into non-technical professions have little idea of what science and technology are about The public, he noted, spends $100,000 million annually to run US public elementary and secondary schools, while it spends around $6,000 million a year playing video games

Keyworth absolved the federal government of any role in solving the problem, except to produce graduate students in science "The alarm being raised about reductions in federal support for science education is misplaced We ought to be alarmed that those organizations and people spending the really big amounts of money seem to assign low priority to science education

"Our most important job is to work together to convince our local communities, school boards and universities that science is as basic as history, that students who must study English in the twelfth grade must also study maths But the federal government cannot and will not make this happen We parents, teachers and citizens must take up this challenge directly "

Rebutting this argument is F James Rutherford, who designed some of the high school science programme set up as a response to the Soviet Union's Sputnik, and who testified a week after Keyworth's speech to the opposite effect. He said that US elementary and secondary education is so decentralized and so locally controlled that no one is spending "really big amounts of money" There is no central focus for change or curriculum development except at the federal level, said Rutherford, who is now chief education officer of the American Association for the Advancement of Science

Keyworth had argued that the post-Sputnik science education effort simply did not take root and that geography and demography worked against it Rutherford says the decline was a direct result of earlier cuts in the NSF programme for science education (which once consumed half of NSF's entire budget) The Reagan Administration, for two years, has run down the remaining $80 million of that money so that only $15 million will be left in 1983 and this is allocated to graduate student fellowships

Rutherford notes that the timing of the Administration's initiatives precludes anything further happening during Reagan's current term as president The Secretary of Education, Terrel H Bell, has established a National Commission on Excellence in Education, due to report in October 1983, when the government's 1984 budget will be virtually complete John Slaughter, director of NSF, has said that his most important task as NSF director will be to set up another commission, on pre-college education in maths, science and technology, to report in late 1983 Thus these studies would have no impact, Rutherford notes, before the 1985 budget at the earliest, after the next election

So while Keyworth calls the problem critical, he does not propose to do anything about it, except to have the teachers lobby their communities, and weep

CORRESPONDENCE

Sequence libraries

SIR — Thank you for your article "Europe leads on sequences" (*Nature* 15 April, p 596) on our efforts to establish a nucleotide sequence library I welcome the attention given to the problems of data collection — a general discussion of these matters is both timely and important

I do feel, however, that a few points require clarification First, credit for the library at the European Molecular Biology Laboratory must also be given Kurt Stueber (of the Genetics Institute, Cologne), from whose collection we started, and who continues to work closely with us Similarly, any discussion of nucleic acid sequence data collections in Europe must mention Professor Richard Grantham's group at Centre d'Evolution Moleculaire (Lyon), who have run a large data bank for many years

Although a central data library has yet to be established in the United States (later this year according to NIH), several groups there have maintained large and excellent data bases for some time The largest of these are the collections of Dr Walter Goad and his group at Los Alamos Scientific Laboratory, and Dr Margaret Dayhoff and her group at the National Biomedical Research Foundation (Georgetown)

This is not a case of "too many data banks" The different approaches taken have each generated their share of good ideas, and if the present cooperative atmosphere can be maintained, a really excellent international resource combining the best ideas can result

GREG HAMM

European Molecular Biology Laboratory, Heidelberg, FRG

"Useless" research?

SIR — *Nature*'s leading articles show a persistent concern for the well-being of British universities, lately concentrating on research support and on the dual support system, at the expense of more important matters

We are all concerned to protect research but I believe you seriously underestimate the resilience of the British research effort and its supporters The latter are strong, vocal advocates of their cause and I know of no good reason why we should be alarmed at this moment Much of the fundamental research in question is expensive and in no way urgent It will survive a little slowing down and a little less international competition

Of much greater concern is the industrial-economic basis of the country and the contribution to that basis which needs to be made by universities and, of course, by other agencies of higher education In this context you mention (without, however, developing) the need for educational diversity It is an essential requirement of any successful organization that it posses the highest degree of diversity compatible with its integrity The model for a successful university system should be the usual model of any evolving system, namely a dynamic steady state stabilized in this case by the inevitable boundary conditions of budgets, standards and student numbers It is essential that, within the system, there be both lateral and longitudinal flexibility in subject content and student effort Such a pattern leads inevitably to the co-existence of broad degrees and specialized degrees, of vocational and non-vocational options, of universities and polytechnics, and of low level and high level exit qualifications There needs to be a marked change in the emphasis of university teaching towards the Design-and-Make Society and I would remind you of the Royal Society of Arts initiative in support of Education for Capability

There is nothing radically wrong with British universities that a little loosening up will not cure The present financial crisis, for example, will be coped with readily if all those over 60 or, if necessary, over 55 will simply make way for the young and for any subsequent changes in subject emphasis deemed necessary Making way does not imply "walking the plank", but rather continuing one's vocation in teaching, research or both in retirement or semi-retirement Some mortgaging of our financial future might still be necessary but not for long. Not every university can be saved an ugly confrontation in this way but the system as a whole could be Since I am in favour of the present number of universities, a little more even spreading of the costs and the cuts would be entirely in order Any suggestion that this would deprive us of necessary excellence is nonsense

In winning back a little of the country's confidence in us, it would be as well not to go on supposing that our present arrangements are the best of all possibilities A glance at France, Germany and the United States would convince many that this is not so

The single honours degree is not the be-all-end-all For its own good, the dominating influence of Oxbridge and its concentration on scholarly excellence and other platonic virtues will have to be challenged by other equally exacting paths of excellence, paths of university study which also lead to competence and usefulness If it is true that the annual toast of the Cambridge Philosophical Society is or was "Here's to our researches, may they always be useless!", is it surprising that our industries falter? This simplified analysis is no doubt open to criticism, but I shall be content if it stimulates discussion of ways forward rather than of defences of the *status quo*

GRAHAM HILLS

University of Strathclyde Vice-Chancellor, University of Strathclyde, Glasgow, UK

Research accountant

SIR — In an otherwise admirable article on current affairs and research at the Imperial Cancer Research Fund in *Nature* of 15 April 1982 (p 595), Robert Walgate is misleading in his interpretation of the accounts

The income for the year ended 30 September 1981 is correctly stated to be £17 million, but £12 8 million (75 per cent) was spent on running the laboratories and extramural units, and £803,389 (4 7 per cent) on appeals, whilst a further £2 7 million (15 8 per cent) was spent on supporting the Liverpool cyclotron and trials with interferon In addition we earmarked a sum of £2 5 million towards the cost of replacing the research laboratories that we shall lose when the Burtonhole Lane, Mill Hill premises revert to the MRC in 1986

A B L CLARKE

Imperial Cancer Research Fund, London WC2, UK

Not all cranks

SIR — In his review of Gardner's *Science Good, Bad and Bogus* (*Nature* 28 January, p.351) Sir Peter Medawar asks "was it not Cuvier who named a fossil ichthyosaur as *Homo diluvii testis* — man-witness-of-the-flood?"

No, it was not And to make matters worse it was actually the good baron who showed the beast for what it was a Miocene salamander Later in his review, Medawar states "Not all scientific nonsense is written by cranks though quite a lot of it is the work of scientists who asseverate upon difficult subjects of which they have no deep understanding" Perhaps together with Medawar's "electrician-eugenicists" and "astronomer-microbiologists" we should include the immunologist-palaeontologist? Perhaps this is too harsh for I have no intention to Shock (*ley*) — it is just that Medawar has given little quarter to the many, doubtless deserving, persons who have come under his fire in the past and I only wish to see him play his own game according to Hoyle

ANDREW FORESTER

Institute for Environmental Studies, University of Toronto, Canada

April Fool!

SIR — In your April Fool's Day issue, the article on pages 392–393 ends with the statement, "Long life is a fishy business indeed" There is more than long life that is "fishy" here You have been caught in a pseudonym web again, although this time indirectly The authors of the article from *Acta Gerontol (Prag)* are kidding somebody, as "Dlouhy-Zivot" means long life in Czech, and "Ryba" means fish Anyway, hyphenated names in Czech are rare

FRANK A PITELKA

University of California, Berkeley, USA

Creative energy

SIR — As a priest with a keen interest in astronomy and cosmology I have long pondered over the apparent contradiction to the second law of thermodynamics that is present in the standard big bang theory I therefore read the paper "A model for the cosmic creation of nuclear energy"[1] with much interest

Having attempted to exorcize the notion of a literal interpretation to the opening chapters of *Genesis*, I was amused to read in the above article, 'We find that the main creation of nuclear energy started around 10 s after the big bang, and most of the exergy was created during the first few minutes, 85 per cent during the first hour, and that the process was essentially completed during the first 24 h " Perhaps we also wish to add, "And there was evening and there was morning, one day "!

"The first day of creation, who can act rationally on such a day!" — Alexander Solzhenitsyn

Institutional biosafety committees and public participation: assessing an experiment

Diana B. Dutton* & John L. Hochheimer†

The most innovative aspect of institutional biosafety committees, responsible in the United States for local oversight of recombinant DNA research, is mandatory participation from outside the institution. A survey of Californian committees and selected national data reveals wide variability in committee structure and procedures. Public participation, although constrained in various ways, has been generally constructive.

THE regulation of recombinant DNA research has evolved at a pace almost as dizzying as that of the research itself. Only seven years ago, the scientific community voluntarily halted certain experiments while potential hazards were investigated. In 1976, the National Institutes of Health (NIH) issued regulatory guidelines mandating specific methods of physical and biological containment, and prohibiting high-risk experiments. Since then, regulatory controls have been steadily relaxed in light of evidence that risks may be less than initially feared. But some experiments are still considered potentially hazardous, and disagreement persists about whether the research poses long-term or low level risks[1-3].

Another major trend has been regulatory decentralization. In 1978, revised guidelines shifted primary authority for enforcement from NIH to locally-appointed institutional biosafety committees in order to simplify administrative procedures and to encourage local responsibility, although NIH continued to monitor committee decisions[4].

Effects of NIH guidelines

Since 1978, the authority of biosafety committees has expanded to the point where virtually no federal oversight remains. Greater discretion has also been delegated to individual researchers, less than 15 per cent of permitted experiments now require prior approval from the biosafety committee. Retrospective review enables the committees to monitor safety standards without impeding most experiments. A recent report by the Congressional Office of Technology Assessment calls the guidelines "a comprehensive, flexible, and non-burdensome way of dealing with the physical risks associated with recombinant DNA research while permitting the work to go forward"[1].

The 1978 guidelines also instituted significant changes in public participation in decision-making. NIH's Recombinant DNA Advisory Committee was broadened to include more individuals from fields outside the biomedical sciences, each biosafety committee was required to include at least two members not affiliated with the institution (often called "public" members) to represent community interests. Further, biosafety committees were required to make the minutes of their meetings available to the public upon request and were "encouraged" to hold public meetings whenever possible.

These provisions were adopted in response to charges by public interest groups and others that decision-making had been dominated by scientists and technical experts[5,6]. They evoked sharply divergent reactions. Many scientists were openly sceptical about the public's involvement in complex technical issues[7,8]. Some warned — recalling Lysenkoism — that it could lead to political repression[9]. Others saw a greater danger in the widening rift between science and society, and looked to increased public involvement in science to heal this rift[10]. The 1978 guidelines clearly struck a compromise between the basic changes proposed by critics[11] and the pleas of scientists to "quietly dismantle the whole hateful (regulatory) artifice" (ref 7). Yet, these provisions did offer the possibility of a direct public voice in decisions at the local level and, in this sense, launched an experiment in public participation in science policy.

This study assesses the success of that experiment based on a survey of biosafety committees in California and national data. We focus especially on public participation because this is the most innovative aspect of the regulatory system, as well as the most controversial. The findings suggest that lay members have played a constructive role on biosafety committees — although constrained in various ways — and that involvement has been generally worthwhile.

The time is ripe for such an assessment. In November, the Recombinant DNA Advisory Committee considered making all the NIH guidelines voluntary rather than mandatory, but instead left them mandatory while again reducing their scope and placing still more responsibility for monitoring on biosafety committees. (This recommendation was recently adopted by NIH.) Despite this expanding role, biosafety committees have never been systematically evaluated. Previous plans announced by NIH for a two-year national study met strenuous opposition from biosafety committee chairpersons[12] and have not been pursued.

The regulation of recombinant DNA research symbolizes, to many, the way that society will deal with scientific and technological innovations involving potential risks. For such issues, as Court of Appeals Judge David Bazelon has noted, the only measure of confidence possible may be in the process by which decisions are made[13]. Thus, extraordinary effort has gone into developing a regulatory framework for recombinant DNA research that could provide sound, legitimate decisions responsive to local concerns, the Office of Technology report calls this framework "a possible model for societal decision-making on technological risks". The evidence presented in this paper points to certain strengths and weaknesses, but should not substitute for a more thorough investigation.

Survey methods

Data on Californian biosafety committees were obtained from surveys of chairpersons and nonaffiliated committee members. Questionnaires were sent to each chairperson of the twenty Californian committees registered in June 1980 with the Office of Recombinant DNA Activities of NIH. Nineteen committees responded, including twelve in academic institutions, five in non-profit research institutes and two in private corporations. Questionnaires were also sent to all of the 48 nonaffiliated committee members asking about committee performance and their own roles, forty-five questionnaires were returned, a response rate of 94 per cent. Due to these small sample sizes, few differences are statistically significant. Those that are significant are noted.

National data are based on a transcript of the plenary session of a meeting of about 200 biosafety committee chairpersons and other representatives, held in November 1980[12], and on a brief survey completed by

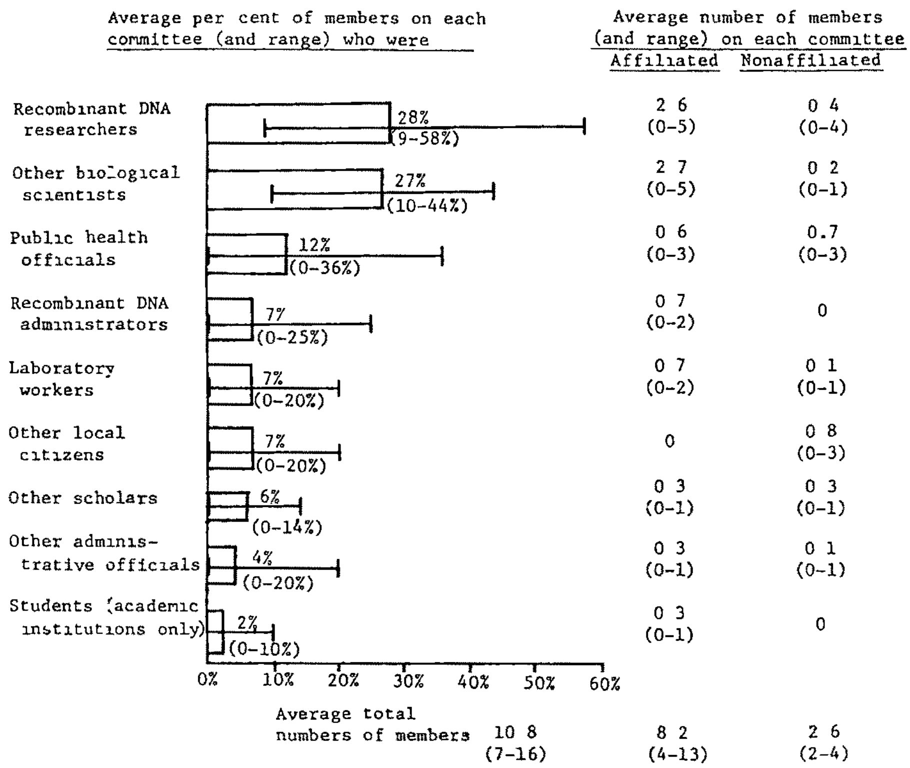

Fig 1 Membership of California biosafety committees.

98 of the 100 participants in the meeting's health surveillance workshop (survey results provided by S Barban, Office of Recombinant DNA Activities, NIH)

Survey findings

Since biosafety committees have had considerable discretion in interpreting guideline requirements, we describe first some general patterns of operation before discussing results on public participation

Most striking is the great diversity in almost every aspect of committee activities from the frequency and content of meetings to the performance of mandated functions For example, five of the Californian committees met once every three months during 1979, while several did not meet at all and one met fifteen times Most of these meetings were convened as the need arose, in fact, eight of the nineteen committees reported no regularly scheduled meetings About a third of the committees conducted some business by telephone or letter, several functioning this way almost entirely Some committees delegated substantial authority to chairpersons, others relied heavily on subcommittees Some committees were concerned only with recombinant DNA while others considered other potential biohazards

The number of research proposals reviewed also varied greatly Several California committees did not review any research proposals in 1979, while one reviewed 68 In both the Californian and national samples, about 60 per cent of all biosafety committees reviewed ten or fewer proposals Overall, committees spent about 30 minutes per proposal in meetings, but averages ranged from less than 10 minutes in one committee to more than an hour and a half in another In general, smaller committees reviewed fewer proposals and spent more time on each of them Some committees spent most of their time reviewing proposals while others concentrated largely on policy issues and other business In California, committees at private corporations devoted the least time to policy and committee business (20 per cent), while those in academic institutions devoted the most time to such matters (57 per cent)

The guidelines require that institutions ensure "appropriate training" for biosafety committee members, principal investigators and laboratory staff, conduct "appropriate" health surveillance of recombinant DNA research personnel; and adopt emergency plans for accidental spills[14]. But since specific criteria are not provided, committees have interpreted these responsibilities quite differently Nationally, the majority of committees offer no formal training courses Training for committee members in California varied from none to a combination of university courses, manuals and laboratory tours In the national sample, 89 per cent of the committees delegated responsibility for training laboratory staff to principal investigators, although several also assigned partial responsibility to the biological safety officer or to the biosafety committee

Plans for emergency spills also differed considerably Some Californian committees tailored plans specifically to recombinant DNA research, others relied on standard safety procedures In the national survey, 13 per cent of the respondents reported that their biosafety committees had no emergency plans for serious accidents or contamination, and 51 per cent reported no such plans for work-related illnesses Although serious accidents in recombinant DNA laboratories were thought to be rare, more than a third of the respondents said that their committees would probably not know if any had occurred About a third also said that laboratory staff were not told they were at increased risk of infection if pregnant or taking certain drugs Overall, 15 per cent of the respondents reported that their committees did not do a "good job" in protecting the health and safety of laboratory personnel

The majority of institutions had no special health surveillance for recombinant DNA laboratories In California, 13 of the 19 committees reported no such surveillance, for reasons ranging from "lack of evidence of medical hazards" to the statement that "routine monitoring procedures are adequate" Likewise, fewer than half of the committees in the national survey had "established medical programmes" Most industrial biosafety committees reported that employees were given standard comprehensive medical examinations modified only slightly for recombinant DNA laboratory personnel. Participants differed as to what form local surveillance should take (routine physical examinations and serological sampling were generally not seen as useful), but they did agree that the present uncoordinated approach would not allow detection of low level health effects.

Approval of research projects

The Californian biosafety committees approved 96 per cent of research proposals reviewed in 1979, 73 per cent of them without modification Only 4 per cent of all proposals were rejected, and the majority of committees (11 of 19) rejected none of the proposals considered

There was again variation among committees One, however, required modification of every proposal reviewed, while four approved all proposals without change Rejection rates varied within a narrower range (0–10 per cent) The two corporate committees approved the largest proportion of proposals as submitted, compared with those in academic and research institutions (86 per cent versus 76 and 61 per cent), required the fewest modifications (14 versus 19 and 36 per cent), and had the lowest rejection rates (0 versus 5 and 3 per cent)

High approval rates could mean that only high quality proposals were submitted, that proposals had already been modified through informal consultation, or that the committee's review was not

sufficiently critical. From the data to hand we cannot say which interpretation is most valid, although informal consultation appears to be common Most local decisions were eventually confirmed by NIH, since 1978 the Office of Recombinant DNA Activities has rejected only an estimated 5 per cent of proposals approved by biosafety committees (statement of W Gartland, Office of Recombinant DNA Activities, NIH, at 25 September 1980 meeting of the Recombinant DNA Advisory Committee)

Once proposals are approved, a number of committees apparently take no further formal responsibility for enforcing the guidelines At the national meeting, about a third of the committees represented in one workshop did not monitor laboratory procedures after initial protocol approval. Yet, as the workshop leader pointed out, problems are more likely after equipment has been operating for a while Because continuous monitoring is important, the guidelines include periodic review of experiments among the committees' mandated functions[15] Evidently this requirement has been widely ignored.

Composition of the committees

The guidelines leave the choice of committee members to the institution, but require each committee to include at least two non-affiliated "public" members, and to have a "biological safety officer" if research requiring P3 or P4 containment is being conducted[16] In California and elsewhere, most members are appointed by the administration In Cambridge and Amherst, Massachusetts, the city governments are also involved in selection, but such external involvement is unusual Most committees comply with the membership requirements, although the national survey revealed several institutions that had P3 facilities and no biological safety officer

The Californian committees ranged in size from 7 to 16 members, averaging 11, and all had the required number of nonaffiliated members Figure 1 shows the average composition of these committees, and reveals wide variation For example, recombinant DNA researchers comprised anywhere from 9 to 58 per cent of each committee, and there was comparable variability for most membership categories The "typical" committee consisted of 55 per cent recombinant DNA and other biological scientists, with five to ten per cent of the membership in each of the other seven categories Scientists were in the majority on most committees; only two contained fewer than 50 per cent scientists and one had more than 90 per cent Six of the 19 committees were composed entirely of men, and all were chaired by men Otherwise, there were few consistent patterns.

The guidelines state that the non-affiliated members "shall represent the interest of the surrounding community with respect to health and protection of the environment", and they list as suitable examples "officials of State or local public health or environmental protection agencies, members of other local government bodies, or persons active in medical, occupational health, or environmental concerns in the community"[17] Many of the Californian committees followed these suggestions. the two largest categories of nonaffiliated members were public health or other government officials (33 per cent) and local citizens (31 per cent)

The third major category reflects a rather different response 25 per cent of all nonaffiliated members were recombinant DNA or other biological scientists working at different institutions In two committees, the non-affiliated members consisted entirely of outside scientists. Although most such scientists were well qualified technically, their qualifications for representing community interests on public health or environmental issues were generally not evident from their *curricula vitae*

A major premise underlying the proposals to broaden participation in biosafety committees was that local citizens and other non-scientists would raise different issues from scientists, offering contrasting perspectives Data from the Californian survey support this premise. Predictably, lay nonaffiliated members had more trouble understanding discussions than did scientists (66 versus 43 per cent), and tended to rate their own contributions as less valuable Several lay members reported that their suggestions were given little weight. One commented that "the committee served mainly as a rubber stamp The tasks require specialized expertise "

On the other hand, lack of technical understanding could sometimes be advantageous. As one lay member said, it "requires the committee to think at a less hurried pace about potential problems . to think through problems from a somewhat different perspective", and to seek "information that a trained person might have assumed was implicit" One said simply, "I am the gadfly "

Scientists and non-scientists also had different views about community influence Lay nonaffiliated members were a good deal more sceptical than nonaffiliated scientists about direct community input to committee proceedings. Yet the nonaffiliated members, apparently because they viewed themselves as representatives of the community, were almost twice as likely as the scientists to say that committee decisions "always" took account of community views (38 versus 20 per cent)

Value of public participation

Committee representatives at the national meeting disagreed about the value of lay members Some thought that such members contributed little. Others claimed that community members played an important role — that they helped to avoid potential conflicts of interest and "caused the committee to operate in a more tidy fashion" Several stressed the useful political function of public members in providing a sense of open communication with the community and in defusing potential animosity

Do the benefits of public participation come at the cost of increased inefficiency or incompetent review? The Californian survery provides no evidence of such a tradeoff. Committees with local citizens reviewed almost twice as many research proposals in 1979 as those with no citizen members (20 4 versus 10 9 proposals), at the same time spending a somewhat larger fraction of meetings policy issues (36 versus 26 per cent) and covering more such issues (2 8 versus 2.5 per cent). Furthermore, although committees with citizen members spent less meeting time per proposal (27 versus 37 minutes), their review does not seem to have been more superficial than that of other committees, as they had a slightly higher rate of proposals rejected (6 versus 1 per cent) and of modifications requested (24 versus 21 per cent). These differences were independent of committee size, even though committees with citizen members tended to be larger, and larger committees tended to have lower approval rates Within both smaller and larger committees (Table 1), those with citizen members had lower approval rates as well as higher rates of modification and rejection.

With lay members in the clear minority on most committees, it is perhaps surprising to find even small differences. These findings are consistent with psychological research indicating that lay people tend to define technical issues more broadly than experts and to be more

Table 1 Comparison of rates of approval of research proposals for institutional biosafety committees with and without citizen members, by committee size

	Committee size			
	7–10 members		11–16 members	
Research proposal Approval rates	No local citizens	1–3 local citizens	No local citizens	1–3 local citizens
Per cent approved as is	70	63	98	81
Per cent approved with minor modification	29	35	2	7
Per cent rejected	1	3	0	11
Number of biosafety committees	5	7	3	4

cautious in assessing possible risks[18] And they bear out James Watson's warning that "public members may take regulation seriously, unlike the molecular biologists"[7]

Public access

Community representation can also occur by direct participation in committee meetings Thus, the guidelines "encourage" open meetings whenever possible[19]. Many commentators had urged stronger measures — mandatory open meetings that were publicized and held at convenient times — fearing that a voluntary provision would have little impact

Such fears were justified The Californian survey as well as the national meeting indicate that most committees have done little to encourage public participation; many have actively discouraged it Almost half (42 per cent) of the Californian committees held no open meetings Of the eleven committees that did have "public" meetings, only five held them on a regular schedule, in all cases on a weekday during working hours More significantly, these meetings were apparently not announced When queried about different forms of publicity, not one committee reported any announcement of meetings on bulletin boards, in campus or local newspapers or in other public media At the national meeting, most chairpersons also reported that their committees did not publicize meetings widely It is hardly surprising that public attendance has been minimal About half of the Californian committees holding "public" meetings reported that no one attended while others had typical audiences of one or two

As in 1978, many still dispute the value of open meetings Almost half of the committee chairmen in California felt that open meetings were not desirable Objections raised included the use of meetings as a "political" forum, possible violations of confidentiality, inhibition of frank discussions by committee members and fear that a lay audience ignorant of technical issues would impede the committee's operation

In committees that had open meetings, however, almost all the chairmen thought they were desirable, for reasons ranging from preventing public misconceptions to informing committee members about community views The performance of these committees compared favourably with those with closed meetings with regard to number of proposals reviewed and policy issues discussed (Table 2) And, like committees with public members, those with open meetings spent slightly less meeting time per proposal, yet were somewhat more critical in their judgements, rejecting more proposals as well as requiring more modifications These differences were independent of both committee size and citizen representation They suggest that open meetings do not make committees measurably less efficient and may, in fact, lead to a more critical review of proposals

Effects of open meetings

If there are differences between open and closed meetings, they probably have less to do with specific issues raised by audience members than with subtle changes in atmosphere Most people attending committee meetings asked general questions about research procedures or policies such as earthquake standards or laboratory safety Yet comments from nonaffiliated members suggest that open meetings may nonetheless have had an effect on the committee As one member noted, "community members are the only 'outsiders' at the meeting", adding, "Without them, who are the watchdogs?"

Assuming that open meetings facilitate direct communication with the community, one would expect committees with open meetings to receive more views from the community and to be more responsive Table 2 shows just the opposite pattern Nonaffiliated members on committees with open meetings more often said that the community had no input and that committee decisions did not always adequately account for community views One explanation may be that, as one member put it, open meetings "sensitize academic members to community concerns", leading to greater awareness of the ways in which the committee was not responding to the concerns they heard Alternatively, members of committees with open meetings may simply have had higher expectations concerning community influence Despite scepticism about the amount of community participation, however, almost all nonaffiliated members rated it as somewhat or very helpful

Minutes of meetings provide another source of public information about committee proceedings The guidelines require that such minutes and related documents be made available upon request[20] Here again, this requirement has had a negligible impact, only one of the Californian committees reported receiving requests for minutes Militating against such requests was the fact that the meetings were unannounced, and the minutes were typically stored in an administrative office not readily accessible

There is a potential conflict between public accountability and the privacy necessary to protect trade secrets, as the guidelines acknowledge So far, such conflicts have arisen mainly in proprietary institutions At the national meeting, corporate committees reported that meetings were not open to the general public Outside members, many paid by the companies, had to guarantee confidentiality, further limiting public accountability In California, only the two corporate committees reported restricting the agendas of meetings because of proprietary concerns, although four other committees took special precautions to protect potentially patentable results before releasing minutes

Are biosafety committees worthwhile?

Most chairpersons at the national meeting seemed to think that the time and effort spent by biosafety committees were greatly out of proportion to the risks of recombinant DNA research and therefore that the committees were largely unnecessary Opinions expressed in the Californian survey were strikingly different More than 80 per cent of the chairmen thought the guideline requirements concerning biosafety committees were "about right", while 91 per cent of the nonaffiliated members agreed that "biosafety committees as they presently function are worthwhile" This difference in views may be due not only to changes in perceptions of risk between 1979 and 1980 but also to the different sources of data — individual questionnaires versus the group process that produces a consensus

Comments in the California survey, as in the national meeting, highlighted functions

Table 2 Selected comparisons of biosafety committees with open and closed meetings

	Committees that have No open meetings	Committees that have 50-100% open meetings
Average number of research proposals reviewed in 1979	14 1	18 0
Average meeting time spent per proposal (minutes)	56	51
Proposal approval rates		
approved as is	79%	70%
approved with modification	20%	24%
rejected	1%	6%
Average number of policy and procedural issues discussed that were listed by chair	1 6	3 5
Per cent of nonaffiliated members who said community had no input into committee proceedings	38%	58%
Per cent of nonaffiliated members who said committee decisions did not always account adequately for community views*	47	78
Number of biosafety committees	8	11
Total number of nonaffiliated members	18	27

of biosafety committees Many nonaffiliated members believed that the committees had an important role in promoting safety, for instance, one commented that they "force researchers to meet strict standards, as enforced by the campus environmental health officer Several hazardous projects have either been aborted or redesigned because of our action" Others thought that biosafety committees provided a useful forum for internal review of controversial issues and also "a sense of security to the public agency and to the scientific community — no secrets, open communication"

Discussion

In combining technical evaluation of scientific issues with provisions for accommodating social values and limiting conflicts of interest, institutional biosafety committees represent a significant policy innovation The experience of the Californian committees — which appear to be typical of committees elsewhere — suggests three general conclusions about their performance

First, the considerable diversity of biosafety committees appears to reflect not only varying local circumstances but also variable effectiveness Furthermore, the varying approaches (if any) to surveillance prevent development of a standardized system that might be more capable of establishing safety or detecting hazards

Compliance has been variable even on specific requirements of the guidelines Not all institutions conducting P3 research have appointed biosafety officers, and many do not monitor experiments after initial approval Continuous monitoring is also hindered by infrequent committee meetings The Office of Technology Assessment reports that biosafety committees "usually meet monthly", but only one of the 19 California committees met that often in 1979, and the frequency of meetings has undoubtedly declined since then Stanford's committee, which met four times during 1979, now meets only once a year unless special problems arise (interview with D Perkins, chairman of the Stanford Biosafety Committee by M London)

The low rates of rejection of research proposals also raise questions about effectiveness While these low rates may result from high quality proposals, they may also be due in some cases to inadequate review by the committee Previous studies of similar institutional committees monitoring human subjects research, suggested that their low rate of rejection of proposed experiments was at least partly due to poor performance

A second conclusion that may be drawn is that, given the highly decentralized nature of the biosafety committee system, clear minimum standards for essential elements of the system would be helpful One of the key experimental variables in these committees has been public participation, yet the guidelines define this variable only very generally through the requirement for nonaffiliated members The stated intent is that such members shall represent the surrounding community with respect to health and the environment, and the regulations stipulate that institutions are expected "to adhere to the purpose of the guidelines as well as to their specifics"[21] But precisely *how* community interests are to be represented is left notably ambiguous, inviting disparate interpretations Thus, a quarter of all nonaffiliated members were biological scientists from other institutions, many engaged in recombinant DNA work and with no evident qualifications for representing community interests

More specific provisions concerning public representation, such as those recently adopted by the Food and Drug Administration for human subjects committees[22], could have avoided this ambiguity Provisions had been proposed in 1978 that committees include a certain proportion of non-scientists or reflect the demographic composition of the community, to ensure direct community involvement (following the examples in the guidelines) rather than representation by outside scientists[11]. But NIH rejected these proposals on the grounds that the biosafety committee "is in large part an expert committee whose essential function is to evaluate research protocols in respect to containment levels, using the explicit instructions of the guidelines Rigid quotas are not necessary"[4] With such ambivalence about the role of public members, it is not surprising that the regulations remained ambiguous

It would also have been useful to define what constitutes "appropriate" training for biosafety committee members Insufficient technical instruction compounded the frequent difficulty that many nonscientists had in understanding discussions, and a number stressed the need for more systematic training on basic research techniques and terminology

The role of the public

Minimum standards for critical factors such as technical support and provisions for community representation need not restrict local experimentation in meeting or exceeding these baselines Such standards are vital in a decentralized regulatory system where effectiveness depends largely on local structures and procedures Without mechanisms for assuring accountability to community interests, public participation in biosafety committees has not been fully tested

Yet it is clear that some committees did make a genuine effort to involve local citizens and were at least partially successful The results of these experiences suggest a third conclusion which, although tentative, is perhaps the most important given a chance, public participation seemed to work fairly well Most community representatives took their role seriously and contributed to effective committee performance by broadening discussion and encouraging more critical scrutiny of research proposals Public meetings, even with limited attendance also appeared to give committees a better understanding of community concerns without impeding committee operation Many members believed that the committees were an important channel for public communication about an issue that remains sensitive, and that public involvement caused no evident harm to the research or to science

Even if federal regulations are eliminated, the controversy over how to regulate recombinant DNA research is not likely to disappear It has recently emerged anew in communities where genetic engineering companies have been set up. Because NIH regulations do not cover commercially-sponsored research, several towns and states have recently passed or drafted ordinances extending the present guidelines to industrial research and adding other requirements[18] Thus, biosafety committees or their equivalent may well continue to be a key element in local regulation As a workable mechanism for direct public participation, these committees have established a significant precedent in the decision process concerning science and technology

We thank Drs William Gartland, Stanley Barban and Elizabeth Milewski of the Office of Recombinant DNA Research Activities, NIH, for making records available, Nancy Pfund and Ralph Silber for helping design and conduct the California survey, and Natalie Fisher, Valerie Herman and Kathy McFadden for technical assistance Funding was provided under a grant from the NSF's EVIST Program and the National Endowment for the Humanities

NEWS AND VIEWS

New frequency standards from ultra-narrow Raman resonances?

from Peter Knight

THE high-resolution study of atomic and molecular resonances over the past decade has led to the establishment of an atomic time standard based on the very stable atomic beam microwave transition between the hyperfine ground states of the caesium atom. Laser excitation of atomic or molecular transitions offers potential improvements in this 'standards' field but has been dogged by linewidth problems The lasers jitter in frequency and the optical transitions investigated have been broadened by motion, collisions or by spontaneous decay, so that the gain in frequency over the microwave transition is offset by the increase in linewidth Much effort is being expended to produce more stable lasers and to generate narrower spectral lines, in part because of a general spectroscopic interest and in part to find new laser-driven atomic clocks that could supplement or even supplant the Cs clock This could meet new demands for ultra-precise time intervals A recent experiment reports a new ultra-high-resolution laser spectroscopic excitation which not only eliminates laser jitter problems but also almost all line-broadening mechanisms, including that of a finite lifetime, and leads to a spectral line whose centre is stable to great precision

Ezekiel and his colleagues at MIT and the Rome Air Development Center have measured an optical atomic resonance of width 650 Hz (Thomas *et al. Phys Rev Lett.* **48**, 867; 1982). This width is four orders of magnitude less than the inherent natural width of one of the states involved and almost certainly less than the linewidths of the phase-jittering lasers used to excite the transition This remarkable example of a 'subnatural' linewidth has major implications for frequency and atomic clock standards Already, the preliminary data are claimed to compare well with the short-term stability of a conventional Cs atomic beam clock Ezekiel's

Peter Knight is in the Optics Section, The Blackett Laboratory, Imperial College, London SW7 2BZ

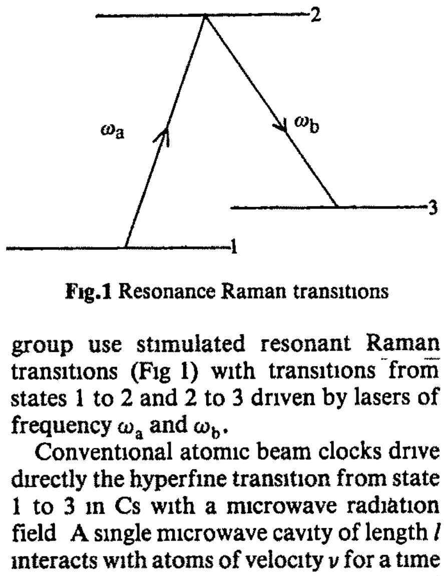

Fig.1 Resonance Raman transitions

group use stimulated resonant Raman transitions (Fig 1) with transitions from states 1 to 2 and 2 to 3 driven by lasers of frequency ω_a and ω_b.

Conventional atomic beam clocks drive directly the hyperfine transition from state 1 to 3 in Cs with a microwave radiation field A single microwave cavity of length l interacts with atoms of velocity v for a time $t \sim l/v$ as they fly through in a beam, and will excite a resonance at frequency $\omega \sim \omega_{31}$ ($\equiv(E_3-E_1)/\hbar$) of width of order $\Delta\omega = t^{-1} \sim v/l$ by simple Fourier arguments States 1 and 3 are both ground states and are not broadened by any other influence (there is no Doppler broadening in the microwave–beam interaction, there are no collisions in the dilute beam and no natural broadening of the line) To decrease this transit-time width $\Delta\omega$ and increase the resolution $\Delta\omega/\omega_{31}$ suggests increasing l In fact, two separate microwave cavities separated by a distance $L \gg l$ and fed in phase are used The atom has a probability amplitude a_1 of being excited in the first cavity and a_2 in the second The transition probability $P = |a_1 + a_2|^2$ has a two-slit interference pattern due to the quantum interference between different routes from indistinguishable initial and indistinguishable final states The interference lineshape is called a Ramsey resonance and has a width $\sim (v/L) \ll (v/l)$, making possible ultra-high-resolution spectroscopy

An optical transition between the ground state 1 and excited state 2 is not often limited by this transit-time broadening Instead the linewidth is produced by grossly larger influences The Doppler motion-induced spread in frequencies amounts to several GHz, which can be circumvented either using the new non-linear laser spectroscopic tricks, or by exciting a well collimated atomic beam perpendicularly with a well collimated tunable laser beam Providing the atomic beam is not too dense, collisional widths can also be eliminated The excited atom still interacts with its environment· it couples to the vacuum-quantized radiation field and consequently decays spontaneously with a lifetime typically of order 10^7 Hz This width seems immutable, and the spectral structure in the natural width forever unresolvable However this is not the case there are several ways in which atomic coherence can be exploited to generate subnatural linewidths, and I have reviewed these elsewhere (*Comments atom molec Phys.* **10**, 241; 1981) Nevertheless, we would not expect more than an order-of-magnitude improvement from even the most accomplished subnatural spectroscopist, simply because the penalty paid for the decrease in linewidth is exponential loss in signal strength

Ezekiel *et al* have used stimulated resonance Raman transitions from state 1 to 3 via state 2, by the absorption of a photon of frequency ω_a from one laser field and the stimulated emission of a photon of frequency ω_b into another laser field, such that $(\omega_a - \omega_b) \approx \omega_{31}$ A peculiarity of such transitions is that the Raman interference line has a width governed by the sum of the widths of states 1 and 3 only, with no real contribution from 2 Proof of this requires extensive analysis of the dynamics of the laser excitation and is true only for Raman difference frequencies $(\omega_a - \omega_b)$ close to ω_{31}; otherwise 2 will strongly contribute to the transition dynamics If the frequency ω_a is chosen to be exactly resonant with the ω_{21} transition frequency and ω_b is scanned through the ω_{23} resonance frequency and the decay fluorescence from state 2 measured, a Raman lineshape is generated in the fluorescence intensity versus ω_b Its overall shape is a Lorentzian of natural

0028-0836/82/180016-02$01 00

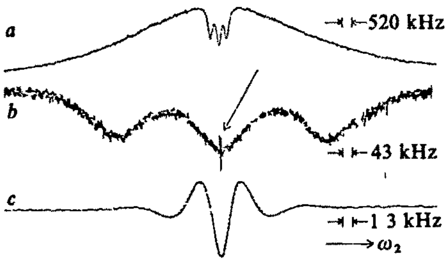

Fig. 2 Raman and Raman–Ramsey fringes observed by Ezekiel *et al* in sodium (from *Phys Rev Lett* **48**, 867, 1982) The arrow points to the fringes See the text for details

width (usually 10^7 Hz), but when $(\omega_a - \omega_b) \approx \omega_{31}$ (that is, at the 'two-photon' resonance frequency) a narrow non-absorbing 'hole' (G Orriols *Nuovo Cim* **B53**, 1, 1979) is burnt into the lineshape At this hole frequency, the atom is entirely transparent. Physically the Raman (or two-photon) hole is due to atomic coherence The atom is optically pumped by the two lasers into a coherent superposition of ground states 1 and 3 in which dipole moment induced on the 1–2 transition exactly cancels the 2–3 induced dipole This vanishing total dipole moment leads to zero net absorption and consequently no decay fluorescence The dipole moments only cancel close to Raman resonance elsewhere population can be excited into 2 and contributes a fluorescent, naturally broadened line

Ezekiel *et al* chose to study resonance Raman transitions in a sodium atomic beam in which state 1 is the $3^2S_{1/2}$ $(F=1)$ hyperfine ground state, 3 is the $3^2S_{1/2}$ $(F=2)$ hyperfine state and state 2 is the $3^2P_{1/2}$ $(F=2)$ hyperfine sublevel, of lifetime 16 ns The atoms are excited by co-propagating laser fields, and Raman dips are observed on a 10^7 Hz-wide fluorescent background when $\omega_a = \omega_{21}$ and ω_b is scanned through ω_{23} Three Raman dips are observed corresponding to Raman transitions between different magnetic sublevels in states 1 and 3, separated by the 300 mG Zeeman field applied to the atoms Each has a width governed principally by the transit time $t \backsimeq l/v$ in the region simultaneously irradiated by the two laser beams The two laser fields need to be correlated in their phase fluctuations or the two-photon, or Raman coherence will be washed out Ezekiel's group eliminate this phase fluctuation problem by deriving one frequency, ω_b, by acousto-optic modulation from a stabilized laser of frequency ω_a, such that phase-jitter in the two beams is precisely correlated Since Raman coherence depends in part on the phase difference between the light fields, the correlated jitter leads to a non-fluctuating Raman phase factor and to a Raman dip which can be, in principle, narrower than the laser bandwidth

As the Raman, or non-absorbing, dip is uninfluenced by the upper state decay lifetime τ, a Ramsey double-excitation technique can be used with a long delay $T \gg \tau$ without loss in signal but generating ultra-narrow lines similar to those in the Cs atomic clock The two correlated frequencies ω_a and ω_b are mixed and used to excite the sodium atomic beam in two regions separated by a distance L Figure 2 shows the sequence of lines observed for $L \backsimeq 15$ cm In Fig 2*a*, three Raman dips are observed on a 10^7 Hz-wide naturally broadened fluorescence line as ω_b is scanned though ω_{23} excited in a single interaction region A Raman width of 50 KHz is attainable Figure 2*b* shows the expanded scan of the Raman dips, now excited by two interaction regions separated by 15 cm, with central fringes corresponding to Ramsey interferences on the central Raman line (Ramsey fringes on the other dips are washed out by stray magnetic fields) Figure 2*c* shows the further expanded scan of these central Ramsey fringes Increasing the interaction separation L to 30 cm produces fringes of width 650 Hz (HWHM)

If these Ramsey–Raman techniques were applied to the Cs hyperfine Raman transition, a short-term stability $\Delta\omega/\omega \backsimeq 2\ 5 \times 10^{-11}$ seems possible over 1 s, which approaches the stability of a 30 cm interaction–separation Cs atomic clock The laser technique can be improved by decreasing laser-induced Stark shifts, optical pumping signal enhancement, laser-cooling of atoms to increase flight times and perhaps by applying it to ions in electromagnetic traps The new technique has arrived just as metrologists all over the world are seriously investigating new possibilities to replace the ageing Cs microwave atomic clock, and will be scrutinized carefully as a potential time-keeper of great stability □

Enhancing elements for activation of eukaryotic promoters

from Moshe Yaniv

TINKERING with recombinant DNA systems for the expression of genes in eukaryotic cells has recently thrown up a new class of regulatory sequences These are the 'enhancers', short viral sequences that can stimulate, by up to two orders of magnitude, the transcription of coding sequences from their own promoters Even more remarkably, they do so whatever, within reason, their position or orientation with respect to the coding sequences.

Enhancers were first discovered as sequences near the early genes of simian virus 40 (SV40) and polyoma that are required for virus viability[1-4] Approximately 30 base pairs (bp) upstream of these genes is found the TATA sequence typical of eukaryotic genes transcribed by RNA polymerase II and which appears to determine the specific site of initiation of transcription In SV40, between 113 and 257 bp upstream of the RNA start point is a directly repeated 72 bp sequence Removal of one 72 bp sequence has little effect, however, if part of the second sequence is removed the genome is rendered non-viable because at least one of the repeats is required for transcription of SV40 early genes

It is now clear that viral enhancers can also exert their effects on cloned nuclear genes Schaffner's group has shown that the SV40 72 bp repeat can increase the expression of a cloned rabbit β-globin gene in HeLa cells by 200-fold The globin gene was introduced into the HeLa cells by the calcium phosphate co-precipitation technique and its expression was measured after 2–3 days, before the integration of this DNA into the cellular genome The SV40 72 bp repeat has to be covalently joined to the gene (that is, it functions in *cis*), but surprisingly it works even if it is several kilobases upstream or downstream from the transcription initiation site, and its orientation with respect to the gene is unimportant[5] Similarly, Chambon's group has shown that the activity of the chicken conalbumin or adenovirus major late promoters can be stimulated by the SV40 enhancer[6]

These observations clarify and extend earlier suggestions that viral sequences may affect the activity of eukaryotic genes Capecchi's finding that the transformation of TK⁻ (a thymidine kinase mutant) mouse cells by plasmids carrying herpes virus *tk* gene is more efficient when the plasmid also carries the SV40 genome was probably mistakenly interpreted in terms of more efficient integration[7] The stimulation of expression of rabbit β-globin gene in HeLa cells by a 244 bp DNA fragment from polyoma virus[8], of human β-globin and in certain cases of the herpes *tk* gene by the SV40 72 bp element[4,9], and of the chloramphenicol acetylase gene linked to chicken α-collagen promoter by SV40 sequences [10] are probably other demonstrations of enhancers in action

Enhancers do not seem to be limited to papovaviruses 72 bp directly repeated sequences are also found in the long terminal repeats that flank integrated retroviruses (for example Moloney sarcoma virus) Although these sequences have no obvious sequence homology with

Moshe Yaniv is at the Institut Pasteur, 28 rue du Dr Roux, 75724 Paris Cedex 15

0028-0835/82/180017-02$01 00

those of SV40 they can replace them to produce viable hybrid molecules[11]

The presence of enhancers in retroviruses may explain some recent intriguing findings that appeared to be inconsistent with the promoter insertion model of viral carcinogenesis[12] According to this model, integrated retroviruses can provide active promoter sequences that increase the expression of cellular genes. By integrating upstream of the cellular homologues of viral oncogenes, and consequently increasing their expression, retroviruses lacking their own oncogene are thought to be able to transform cells However, Payne *et al.* have shown recently that in bursal lymphoma cells, avian leukosis proviruses can be integrated upstream or downstream and in either transcription orientation relative to the cellular *myc* gene (*c-myc*) — the cellular homologue of the putative transforming gene (*v-myc*) of myelocytomastosis virus Clearly these findings are inconsistent with a simple promoter insertion model, however they fit nicely with the known properties of enhancers

An interesting possibility is that enhancer sequences may have a role in regulating cell differentiation Polyoma viruses are normally unable to grow in early embryonal mouse cells, or in differentiated derivatives of these cells Mutants of polyoma with the capacity to replicate in embryonal cells were found to have sequence rearrangements[13-16] in the region of the virus shown to contain enhancing sequences, although not of the 72 bp repeat type[8] These results suggest that enhancers may be involved in tissue- or cell type-specific control of gene expression

The mechanism of action of enhancers is unknown but several possibilities may be envisaged Prominent amongst these are that enhancers may act as chromatin organizers, RNA polymerase entry points, sites of attachment to the nuclear matrix or regulators of local DNA superhelicity Of course these possibilities need not be independent or mutually exclusive Some evidence that enhancers may regulate chromatin structure comes from their presence in regions of papovavirus genomes not packaged into nucleosomes in cells[17-19] This may lead to changes in the structure of chromatin propagated on both sides of the enhancer and thus permit efficient transcription of neighbouring genes Alternatively the nucleosome-free region may act as a high-affinity site for binding RNA polymerase[20]

How enhancers really work, and whether they have a role in the normal control of cellular gene expression, are clearly exciting problems likely to be the subject of much future research Already it seems that genomic DNA contains sequences homologous to viral enhancers[21], and what may be an enhancer has been found upstream of the sea urchin H2A gene[22] □

The great galactic centre mystery

from Guenter R Riegler

WHEN γ-ray astronomers discovered last year that the positron–electron annihilation radiation from the galactic centre region varied on a time scale of six months[1], it became necessary to reconcile possible explanations for the phenomenon with data from the radio and IR bands This provided the impetus for a recent workshop* that examined the central parsec of the galactic centre using data from all available spectral ranges

Images of the central few parsec of the Galaxy can be readily obtained through two experimental 'windows' bremsstrahlung emissions of ionized gas near 6 cm wavelength, and thermal emission of heated dust near 10 μm Both maps show a non-uniform brightness distribution[10] and their similarity implies that the ionized gas and the heated dust are distributed along an arc-like structure

Observations of the galactic centre at radio wavelengths show a non-thermal compact radio source surrounded by ionized gas moving at high velocities The compact source varies on time scales as short as one hour[2], but we are not yet able to form a consistent picture of the actual source size Neither ordinary pulsars nor binary stellar radio sources match the spectral index and luminosity of the compact radio source

Maps of line emission of atomic hydrogen, ionized hydrogen and molecular gas (primarily ammonia and formaldehyde) show a complex distribution at all scale sizes from a few parsec to a few kiloparsec The large, non-circular motion of a large portion of the gas may suggest it is being expelled from the centre, while the large velocity dispersion in the central parsec suggests a massive collapsed object New searches for H_2O masers in the galactic centre, reported at the workshop by Güsten (Max-Plank-Institut fur Radioastronomie, Bonn), imply that star formation is not the source of the high thermal flux in the galactic centre region

IR observations[3] show that ionized gas in the central few parsec of the galactic centre is concentrated in at least 14 small clouds An ionizing radiation of $\sim 10^{50}$ photons per s is required but its origin is debatable, sources might be distributed among, or in, each discrete IR source, or a central source of radiation might ionize all clouds

Aitken and co-workers (University College London) found that peaks in the interstellar grain temperature coincided with the positions of IR sources (as deduced from peaks in 10 5 and 12 5 μm continuum radiation), and argue that this implies that internal sources of luminosity power the discrete sources With colour temperatures derived from maps at 5, 10 and 56 μm, Rieke and Lebofsky (University of Arizona) argue that each IR source is heated by a cluster of stars of spectral type earlier than I. Gatley (UK Infra-Red Telescope) showed that most of the central parsec is transparent at UV wavelengths, so that heat sources need not be embedded in the IR-emitting dust clouds The ionizing radiation may therefore be produced by a distributed source which is merely centrally concentrated about the position of IRS 16 (commonly accepted as the IR counterpart of the non-thermal compact radio source in Sgr A West)

The main argument for the existence of a central massive object at the galactic centre comes from a study of the dynamics of ionized gas clouds Lacy[3] found that the motions of the gas clouds are best fit with a mass distribution which includes a central mass in addition to a distributed mass, each of $\sim 3 \times 10^6$ solar masses ($M_\odot$) The central mass could be a star cluster, for example, a highly evolved OB association as favoured by Lacy

The conjecture that there might be a black hole of mass 1–5 x 10^6 $M_\odot$ at the galactic centre was made more than a decade ago by Lynden-Bell and Rees[4] Arguments for and against its existence were given by several speakers at the workshop Lacy (Caltech) pointed out that a model of spherical accretion of ordinary

*A workshop on the galactic centre was held on 7–8 January 1982 at the California Institute of Technology The proceedings will be available from the American Institute of Physics, New York, in June 1982

Guenter R Riegler is in the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109

0028-0836/82/180018-02$01 00

interstellar gas towards a massive black hole would be inconsistent with the observed Sgr A IR spectrum and the required ionizing flux The accretion rate which is required to power all activity in the galactic centre region, $\sim 10^{-5}$ $M_{\odot}$ yr^{-1}, may also be augmented by debris from stellar disruptions or from nearby collisions involving giants Some authors, particularly Ozernoi and his collaborators[5], have argued against the massive black hole hypothesis on the grounds that the rate of star capture would be incompatible with observations Rees (University of Cambridge) reviewed these arguments and showed that it is nevertheless possible to construct models in which the luminous flare from each stellar remnant's impact with the black hole would not lead to excessive average luminosities

Charge-coupled device images of the galactic centre at an effective wavelength of 0 9 μm came from three groups and all showed a pair of faint, very red sources within a few arc seconds of IRS 16 and the compact non-thermal radio source The sources are not as highly reddened as had been expected and it was suggested that line emission from doubly ionized sulphur may contribute to the observed photon flux within the bandpass of the CCD/filter combinations

The positron–electron annihilation line at 511 keV has been observed by at least five experimental groups over the last decade and is, in fact, the only non-solar γ-ray line that has been confirmed by multiple measurements The line emission[6] implied an annihilation rate of 10^{43} per s, and a luminosity of 10^{37} erg s^{-1}, compared with an observed luminosity at IR wavelengths of 10^{40} erg s^{-1} (the bolometric luminosity of the source of ionizing radiation in the galactic centre must be still higher by roughly an order of magnitude[3]) Furthermore, the luminosity of the annihilation radiation exceeds the radio luminosity (1 35–31 cm) of the non-thermal source[7], and is a few hundred times more intense than the X-ray luminosity, measured by the Einstein Observatory from the central few parsecs of the Galaxy[8]

The first satellite measurements of the 511 keV line from the galactic centre in 1979–80 showed that the emission had decreased by a factor of roughly three over a time span of six months[1] Recent experiments by Leventhal (Bell Laboratories) and Paciesas (Goddard Space Flight Center) did not observe a positive signal for line emission from the galactic centre, consistent with the assumed further decrease in intensity Jacobson (Jet Propulsion Laboratory) pointed out that the available data are statistically consistent with a model consisting of an extended, constant-intensity source and a point-like, variable source of 511 keV line emission

If the variable positron emission comes from a point source at the galactic centre, then some inferences can be made about the positron source as well as the positron annihilation region As pointed out by Ramaty (Goddard Space Flight Center) and Lingenfelter (University of California, San Diego), the width of the 511 keV line and its temporal variation[1,6] require that the annihilation region have a temperature, density, degree of ionization and size which are consistent with the peculiar warm clouds[3] and the other compact IR sources[7] observed in the central parsec of the Galaxy

The nature of the positron source is also strongly constrained by the observed line emission variation multiple, extended sources such as pulsars, supernovae, black holes, or cosmic-ray interactions with the interstellar medium are excluded Blandford (Caltech) suggested that the positrons might be produced by an electromagnetic cascade process in the magnetosphere of a $\sim 10^6$ $M_{\odot}$ black hole In this model, high-energy ($\gg m_e c^2$) photons and electrons interact with much cooler ambient photons and gas Lingenfelter and Ramaty point out that interactions in which the photon, electron and ion energies are all comparable, and of the order of $\sim m_e c^2$, are much more efficient for electron–positron pair production The necessary energy could be provided either in the vicinity of a very compact source, like a black hole of $< 10^2$ $M_{\odot}$ (to agree with arguments by Ozernoy that the tidal disruption of stars would otherwise be inconsistent with stellar luminosity in the vicinity of the galactic centre) or by interactions of high-energy beamed photons with one another

Oort (Leiden Observatory) described the galactic gas motion of scale sizes of ~ 1 pc, ~ 300 pc and 1–3 kpc The non-circular motions and the tilted distributions of the molecular clouds in the two larger-size regimes have been ascribed to either eruptive activity from the nucleus, or large-scale streamings in a non-axisymmetric potential field, but a unified model is apparently not yet available Recent studies by Lake (Bell Laboratories) of orbits in three-axial ellipsoids have shown the existence of 'anomalous' orbits in tilted planes which may explain at least part of the observed features on the 1–3 kpc size scale The molecular clouds within 300 pc are, however, more likely to originate from an eruption in the nucleus of the Galaxy □

Are Sahelian droughts predictable?

from S I Rasool

WHILE the controversy over whether the Earth as a whole is cooling down or warming up continues to rage unabated, there are a few large-scale climatic phenomena with major economic and social repercussions that are becoming amenable to analysis One is the Sahel drought problem Others include the circumstances which lead to the onset of the Indian monsoon and the impact of Pacific sea-surface temperature anomalies on North American climate and the upwelling of cold water off South America, with its important effects on fisheries and global climate Unlike these latter phenomena, however, the Sahel drought has not been the object of coordinated measurements and intensive research The lack of activity is all the more conspicuous in light of the enormous increase in the amount of climatic data acquired over Sahel in the last ten years

Landsats 1, 2 and 3 have now provided about ten years of uninterrupted observations over Sahel which can be used to estimate temporal changes in the surface cover and in the albedo The man-made increase of albedo, impeding convection, has been put forward as the principal factor triggering the drought The energy balance over Sahel and its variation at different times in 1978 and 1979 has also been successfully measured with Meteosat I Meteosat II has now become operational and will continue to provide information on cloud cover, and on ground albedo, surface temperatures and atmospheric water vapour over Africa and the Atlantic NOAA meteorological satellites are also giving daily coverage of meteorological parameters over most of the Earth But how can one get the people with this vast quantity of data talking to those who need the data?

COSPAR (International Committee on Space Research) is keen to see how observations from space can help resolve some of the fundamental issues in the earth sciences and decided to sponsor a workshop on the Sahel climate problem The OECD's Club du Sahel, which is interested in the economic development of

the Sahelian countries, hosted the workshop and it was held in Paris in January

The Sahel drought of 1969–73 was not considered to be unique as there have been other long periods of severe drought, notably in the 1910s and 1940s Detailed analysis of data from some 1,200 stations in Africa (S Nicholson, Clark University) suggests that the Sahel drought is related to rainfall anomalies on a continental scale, extending from southern Africa to just north of the Sahara desert, which characteristically persist for as long as 10 to 15 years at a time Among possible explanations for recurrent long-term climate anomalies are the displacement of the Inter-Tropical Convergence Zone (for yet to be discovered reasons) and changes in global east to west air circulation patterns caused, in part, by changing conditions over distant oceans (Indian, Atlantic and Pacific) leading to lack of moisture over the Sahel at the beginning of the rainy season

The persistence of drought may in part be caused by biogeophysical feedback mechanisms involving long-term changes in the heat balance of the Sahel, partly driven by changes in surface properties (such as albedo and soil moisture) Modelling studies (P Rowntree, British Meteorological Office) indicate that soil moisture in the Sahel may have a significant effect on the circulation of the atmosphere and on rainfall over West Africa Analysis of Landsat data (M F Courel, IBM Scientific Center, Paris) indicates an increase in surface cover and a decrease in surface albedo over northern Senegal in the past eight years

The amount of dust blown from the Sahara Desert over the Atlantic Ocean is enormous, ranging from 100 to 400 million tons a year, and making up as much as one-half of all the dust in the Earth's atmosphere The dust may change the energy balance of the ocean–atmosphere system over the Atlantic considerably (T Carlson, Pennsylvania State University) and affect the climate of the Sahel and possibly of the whole world, although the precise magnitude of the phenomenon is not yet known

Scientists from COSPAR at the meeting recommended that intensive analysis be made of surface and radiosonde data from the Sahel and Central Africa for the past 15 years Such data are available but have not yet been completely assembled and analysed Coordinated and intercalibrated analysis of satellite data from pre-drought, maximal drought and post-drought periods would give a better understanding of the mechanisms behind the onset of the drought, and its persistence in 1969–73 Over the past 10 to 15 years, satellites have furnished a large body of observations of the Sahel, neighbouring regions of Africa and the Atlantic from which information on cloud cover, dust, surface temperature, surface albedo, heat balance and soil moisture could be extracted The COSPAR scientists also suggested that a field experiment in the Sahel, within a 200×200 km area, be carried out to measure the vertical and horizontal fluxes of moisture and heat Such a field experiment, within the grid of a standard general circulation model, could be designed based on existing ground and satellite networks and would provide a critical test for the general circulation model.

The scientists attending the meeting urged COSPAR, in cooperation with the World Climate Program and the Club du Sahel of the OECD, to create an *ad hoc* working group to speed up implementation of these recommendations All the necessary ingredients seem to be there an enigmatic problem of extreme economic and social importance, the existence of large amounts of unanalysed data both from ground and space, and good scientists apparently available to start working on the problem Get the right data to the right people and we may actually begin to see what causes the droughts in Sahel □

Meteoritics: evidence for chemical fractionation in the early Solar System

from Robert Hutchison

CHONDRITES, the most numerous of meteorites, are stony types which have not been melted since they formed some 4 55 Gyr ago They are complex and contain not only minerals that formed at high temperatures, but also volatiles that seem unlikely to have condensed from a gas of solar composition unless the temperature was below 700K The siting of these volatiles has a bearing on theories of the formation of the ordinary chondrites which, in turn, place important constraints on theories of planetary formation There are three main theories, explained below, of which the first two have the most supporters

(1) When the various materials accreted, different proportions of volatile-rich fraction were included Different parts of chondritic parent-bodies were subsequently heated and metamorphosed to different degrees, but without loss of volatiles An unequilibrated chondrite, such as Tieschitz, thus contained, on formation, a higher proportion of 'Holy Smoke' (ultrafine-grained, volatile-rich matrix) than a metamorphosed member of the same chemical group, such as Allegan[1]

(2) Each chemical group of the ordinary chondrites had, on accretion, a uniform composition Heating and metamorphism occurred in conditions where volatiles were lost, the loss being greatest in the types subjected to the highest temperature[2]

(3) A theory favoured by a minority, including myself and some of my co-workers, is that ordinary chondrites accreted when hot (1,070± 100K) Volatiles were most readily introduced into the material nearest the surface, which cooled most rapidly[3–5] No post-accretionary heat source is required

It is clear that the first and third hypotheses lead to a theory of heterogeneous accretion of planetary bodies, while the second favours homogeneous accretion Choice of the most plausible theory is obviously crucial to our understanding of the origin of the Earth and makes identification and separation of the volatile-rich fraction in chondrites of particular significance

It is not surprising, then, that over the past two decades there have been many mineralogical and chemical investigations of chondrites aimed at deciphering their thermal and chemical histories in the hope that part of the story of planetary formation may be pieced together

Somewhat contradictory conclusions were reached in three of the most recent contributions to this field Rambaldi *et al*[6] argued that in ordinary chondrites, the volatiles tend to be concentrated in 'Holy Smoke', some of which may even be identifiable in chondrite types which equilibrated at high temperature In contrast, Ashworth[7,8] identified ultrafine-grained, 'non-clastic' matrix as a minor component in a few highly unequilibrated ordinary chondrites only Finally, Christophe-Michel-Lévy[9] suggested that equilibrated ordinary chondrites accreted over a range of temperatures extending up to 1,270K, whereas an unequilibrated H-group chondrite accreted below 620K, only in this last case was fine, volatile-rich dust incorporated

Part of the problem of these conflicting interpretations lies in the strengths and weaknesses of the different techniques used Rambaldi *et al*[6] took samples of six ordinary chondrites and used freeze–thaw and/or gentle disaggregation followed by sieving to produce various-size fractions down to 0 08 μm Instrumental neutron activation analysis was used to determine up to 24 elements in each size-fraction and further, as yet unpublished, information, has been derived from the electron microprobe and the scanning electron microscope (SEM)

Ashworth used the high-voltage electron

Robert Hutchison is Curator of the Meteorite Collection at the British Museum (Natural History), Cromwell Road, London SW7 5BD

0028-0836/82/180020-02$01 00

microscope on ion beam-thinned samples to identify minerals and examine textures at the submicrometre level, but detailed work is of necessity limited to very small areas Christophe-Michel-Lévy's SEM approach looked at textures and minerals, with semi-quantitative chemical information on the latter, in essentially untreated fragments of meteorite Each of the three approaches provides useful information which cannot be obtained using the other techniques, the chemical data of Rambaldi *et al.* cannot yet be had from single, sub-micrometre-sized grains

Rambaldi *et al* [6] found that the finest size-fraction of each meteorite — that richest in 'Holy Smoke' — was generally richest in moderately volatile and volatile elements such as K, Zn and Sb, these fractions tended also to be enriched in refractory elements such as W and the rare earths This is true of the H5, equilibrated chondrite, Allegan, but, except for Zn, Ag and W, not true of the unequilibrated, H3 Tieschitz And here lies the problem Although the distribution of the 24 elements between the size-fractions may be explained in general terms, difficulties arise with individual meteorites

For example, Co, Ni and Fe are enriched in the finest fraction of Tieschitz relative to the two coarser fractions Rambaldi *et al* [6] suggest that this may be due to the presence of a Ni-rich magnetite However, Christophe-Michel-Levy[9] found the finest-grained matrix to be mainly iron-rich olivine, and Ashworth[8] states that this 'dark matrix' has "troilitic and metal-rich varieties" Neither author found magnetite in Tieschitz It may be concluded, therefore, that Rambaldi *et al* 's finest size-fraction probably contains a mixture rich in olivine, metal and troilite, but with other phases too A further observation of Christophe-Michel-Lévy[9] helps clarify the reason why the rare earths La and Sm are depleted in the finest size-fraction of Tieschitz She noted that in this meteorite, phosphate is associated with Fe–Ni metal, occurring largely as inclusions within metal grains Phosphate has also been found as tiny crystals in cracks in metal where it probably formed from P, expelled from metal, by reaction with O and Ca from neighbouring 'dark matrix' (A W R Bevan and R Hutchison, unpublished) Phosphates concentrate rare earths, and, although the crystals are fine-grained, most (and most rare earths) probably would have been retained in metal during the gentle disaggregation carried out by Rambaldi *et al* [6]

So what of 'Holy Smoke'? Search for a carrier of volatiles in the ordinary chondrites essentially began in 1973. In that year, Anders' group discovered that some whole meteorite samples of the brecciated H-group chondrite, Supuhee, are enriched in Tl and Bi relative to CI chondrite[10] For several reasons CI chondrites are taken to be our best available sample of unfractionated condensable Solar System material Enrichment of the volatile metals Tl and Bi in bulk Supuhee was therefore interpreted as indicative that a fraction must exist which is enriched in these metals by some hundreds of times relative to CI This is because Supuhee is composed mainly of high-temperature minerals and so the volatile-rich fraction — termed 'mysterite' — cannot occupy more than a few per cent by volume Anders' group concluded that 'mysterite' represents a rare substrate on which Tl and Bi condensed at a late stage in the cooling of a solar nebula

'Mysterite' or 'Holy Smoke' must, however, be widely distributed among ordinary chondrites. Tieschitz, for example, contains more Bi and as much In and Tl as CI[10] Dodd[11] and others have shown that this stone contains only 8 per cent by volume of material with a grain size less than 100 μm, and it has already been stated[8,9] that in this fraction most grains are of high-temperature minerals If water and carbon, with other volatiles, are concentrated in the remainder of the fine-grained matrix, then this can constitute no more than about one per cent of the whole meteorite by volume It is the search for, and characterization of, this type of material that now looms large in meteorite research[12] □

The aging of the brain

from Patrick Rabbitt

CONFRONTING an immanent future in which one-fifth of the population of the developed countries will be aged over 65, delegates to a conference* on the aging brain need not lack large general questions to attack It is a comment on the present underfinanced and fragmentary state of research on aging that most papers were disjunctive presentations by research teams primarily known for their expertise in other areas None of these teams can yet afford to commit all their resources to the systematic study of the aging central nervous system (CNS) For this reason there could be little discussion between groups interested in psychology and behaviour, in neuroanatomy and physiology, in neuroendocrinology, in neurochemistry and pharmacology or in animal models of aging

Several important general problems of the aging CNS were illustrated, rather than illuminated, by the context in which they were raised D J Reis (New York) and his colleagues neatly pointed out the increasing variability in performance which occurs among aging animals This can be due to different rates of cell loss, both between different animals and between different areas of the same brain Alternatively, rates of loss may be constant across different brains and brain areas, but this loss may start from different initial levels of neuronal density Or, of course, variability in performance may be due to interactions between both these factors Reiss and his group found differences in local brain weight in the caudate nucleus and the olfactory tuberule in BALB and CBA mouse strains These differences correlated with differences in behaviours thought to be mediated by dopaminergic neurone systems in open fields and in habituation to exploration of objects in dark slots in a test box The strains also show different responses to amphetamine This raises the fascinating possibility that specific differences in particular parts of the brain related to the presence or absence of single genes, or groups of genes, provide a direct link between genes, brain anatomy, neurochemistry and behaviour The implications for relative cell loss with aging seem secondary to this important news

For functioning human beings the most intriguing question about the aging of the brain is whether, individually or universally, we suffer a steadily accelerating loss of ability after some brief peak in our early twenties or whether, more happily, we can look forward to a long plateau of optimal function followed by a mercifully sudden 'terminal drop' in performance just before death which makes it irrelevant whether we have our wits about us or not L F Jarvik (University of California, Los Angeles), who has studied a particular group of people, including some monozygotic twins, since the late 1940s, is one of the few investigators in the world who has data bearing on this question She discussed

*The 10th Aharon Katzir-Katchalsky Conference on 'The Aging of the Brain' was held in Mantua, Italy on 26–29 March 1982

psychometric data on 35 of these people as their average age rose from 64 to 73 years and found, overall, no significant decline and, indeed, an apparent improvement on some sub-tests as age increased From 73 to 84 years the picture was less encouraging and, when group mean scores were considered, all test scores declined

This does not yet answer the question since group mean scores might decline because particular individuals within the group might become ill and approach death just before testing, and the proportion of people showing such terminal changes in performance and contributing to mean scores would be certain to increase as the group aged Jarvik's analyses of her data bore out this possibility Individual subjects showed little or no decline in performance through the seventies and into the eighties Moreover, abrupt declines in performance in individuals were good statistical predictors of impending death Equally interestingly, elderly peoples' self-rating of their own health status was also a good predictor of their actual future survival — as good as, but (perhaps disappointingly!) no better than, their physicians' predictions

All longitudinal studies are certain to be criticized because at the time when they yield their richest data the focus of scientific interest is bound to have changed One cannot, alas, time travel 20 or 30 years to include cases or use tests which become crucial as the state of the art advances However, investment in really adequate longitudinal studies need only be very modest Such studies are expensive to initiate, but very cheap to run once they are begun Jarvik's study illustrates, but does not resolve, the great simple questions about changes in human efficiency with advancing age If we want to know more about our own personal futures, and about the futures of the societies we have to plan, no single investment can yield so much useful information for so modest an outlay □

Engineering organic molecular layers

from C W Pitt and I A Shanks

Scientists and engineers are taking a renewed interest in thin films of organic materials deposited, molecular layer by molecular layer, by an unconventional process attributed to Irving Langmuir and Kathleen Blodgett and dating from the 1930s Such films can exhibit a remarkable perfection of structure over large areas and as the successive monomolecular layers may be of the same or different materials, a kind of 'molecular engineering' is made possible

Long hydrocarbon chain molecules, with a hydrophilic group at one end and a hydrophobic group at the other, can be made to form a continuous film by spreading them on a water surface The nature of the groups at the ends of the molecules ensures that one tip of the molecule is immersed in the water while the other remains in the air A movable barrier which penetrates the water surface may be used to compress the film into a condensed layer exactly one molecule thick in which the oriented molecules are held together by van der Waals' forces The film may then be transferred from the water surface on to a solid substrate by dipping the substrate through the surface and then withdrawing it whilst continuing to compress the film Repeating this process allows a multilayer film to be progressively built up

The Langmuir-Blodgett (L-B) technique undoubtedly emerged at a time long before the technology to exploit its unique capabilities was available A recent three day symposium* made it clear that the situation has now very much changed Recent work has highlighted materials that have attributes which can be readily exploited when they are deposited as L-B layers Many of these material systems have been developed as modified molecular structures tailored specifically for this deposition technique.

Typical of the molecular structures reported were the diacetylenes — a monomer/polymer system incorporating a conjugated triple bond which may be induced to cross-link using an electron beam or by UV or visible radiation Diacetylene films are being investigated as gate region insulators in indium phosphide field effect transistors and as layers in optical waveguiding devices Double bond molecules, such as ω-ticosenic acid, have been deposited as very thin electron beam resists capable of defining lines less than 600Å wide, while even the simple fatty acids have found application, in very pure form, in modifying the surface properties of semiconductors used in Schottky barrier diodes and photodiodes

A radically new approach to modelling biological membranes is also offered by the L-B technique The fluid bilayer of lipid molecules may be simulated by a simpler structure fabricated from reconstituted purified natural membrane components and laid down by the L-B process Protein complexes, such as bacteriorhodopsin, can be immobilized in such layers, simulating the natural system Possible applications of these biocomposite films include filtering solutions with chemically selective elements incorporated in the L-B layer Entirely synthetic membranes, such as polypeptide layers, have also been fabricated, although applications are less apparent at this stage

A technique for retaining the interesting properties of non-amphiphilic molecules, while enabling L-B deposition, is clearly emerging, that of attaching a hydrocarbon chain and a polar group to an aromatic ring-type molecule Tetraphenylporphyrins, anthracene, perylene and pyrene were all reported as molecules which have been treated in this manner Applications include tunnelling layers and electro-fluorescent display panels

In addition to using these films in device applications they are also of interest as investigative tools in the understanding of a wide range of other phenomena Examples are the use of manganese stearate monolayers to explore existing theories of two-dimensional magnetism and of monolayers of fatty acids and their salts to probe the mechanisms of the sliding friction between surfaces The similarity between L-B multilayers and liquid crystals has also been noted and papers were given on the deposition and properties of *n*-pentyl cyanoterphenyl and other liquid crystalline materials □

*A three day symposium of forty invited scientists and engineers was organized by the Rank Prize Funds to explore the science and optoelectronic applications of Langmuir- Blodgett layers The participants included both junior researchers in the field and eight invited speakers from Europe, the US and the UK

REVIEW ARTICLE

Human body clocks and the timing of sleep

Arthur T. Winfree
Department of Biological Science, Purdue University, and Institute of Natural Philosophy, West Lafayette, Indiana 47906, USA

The alternation of sleep and wakefulness in humans exhibits surprising regularities during long-term isolation from the usual time-of-day cues. The inferred domination of our consciousness and physiological states by internal clocks may soon have practical implications for medicine and psychiatry.

WE ALL fall asleep from time to time and no one seems to know why[1-4] While obliged to adhere to a daily schedule of work and rest, light and darkness, most people go to sleep and wake again once a day at predictable times The regularity of this schedule is imposed ultimately by the rotation of the whole Earth, but it turns out that rhythmicity persists even in the absence of any imposed schedule[5-11] There are some intriguing regularities about the timing of sleep onset and the subsequent wake-up in these conditions of so-called 'temporal isolation' They reveal the presence of an internal clock with natural period just a little longer than the Earth's rotation period Aschoff and co-workers were the first to recognize the influence of this clock on the timing of sleep and in the daily rise and fall of body temperature[5 6 11 12,13] There may even be two timers one is a circadian clock with spontaneous period 24–25 h dominating the rhythms of body temperature, plasma cortisol and rapid eye movement sleep, the other seems to have a longer period governing the ebb and flow of sleep and associated physiological rhythms such as growth hormone secretion[14-20]

Prolonged temporal isolation

Inferences about the number and variety of timers affecting our sleep habits are drawn from data similar to those of Fig 1 Here we see the times of sleep (black) and waking (white) of an individual living without external time reference for 4 months in a cave[21 22] Figure 1 replots the original data in the TV-raster format now conventional the time axis is broken up into consecutive equal intervals (in this case, of 24 3 h) stacked from top to bottom The whole picture is then duplicated to the right to emphasize the continuity of time from the right edge of each 24 3-h interval to the left edge of the next

The black bars would be stacked in a vertical column if sleep and waking recurred at exact 24 3-h intervals They do not The intervals intermittently grow longer, shearing the stack of black bars to the right as it descends The raster plot in Fig 1 conspicuously depicts a slow but relentless change of organization in the timing of sleepiness Czeisler[23] was the first to notice this in a diversity of such records It appears that briefer records can often be assigned a place in a similar progression sleep onsets tend to recur at longer and longer intervals, while still preferentially occurring near the temperature minima (recurring at 25-h intervals) Near the bottom of Fig 1, sleep and waking alternate about once in every two cycles of 24 3 h. This phenomenon has been observed in humans at least since the cave experiments of Chouvet *et al*[21,22] Isolated subjects, emerging from a month's studious or meditative confinement, exhibit understandable perplexity, even disbelief, that the time has passed twice as fast as they reckoned. During these 2 1 intervals, one subject on average slept 19 h at a stretch and stayed awake 31 hours before retiring again, never aware that his days were abnormally long Such individuals typically eat somwhat more at three meals between rising and retiring, but not enough more to prevent weight loss (E D Weitzman, personal communication) Needless to say, this was at first alarming to observers outside, responsible for the subjects' well-being (ref 11, p 59)

Whatever the reason for this gradual drift, it seems to have little effect on another regularity independently noted several years ago by Zulley[24-28] and Czeisler[23] Figure 2 shows the durations of many sleeps in three independent experiments in conditions of temporal isolation Sleep duration, plotted vertically, is arranged horizontally according to the timing of sleep onset relative to the temperature rhythm In Fig 2*a*, sleep onset is measured from the previous temperature minimum In Fig 2*b* it is measured from a regression line through a long series of temperature minima found to recur on average every 24 9 h In Fig 2*c*, using the data of Fig 1, it is measured from a regression line at a 24 33-h period, indirectly inferred to parallel the temperature rhythm In all cases sleep durations are shorter for sleeps undertaken later—but only up to a point sleeps undertaken too late after the temperature minimum abruptly become long again

Our usual 8-h sleeps fall near the middle of this ramp There is some question about whether the smooth curve one might draw through the descending cloud of dots also rises to connect the cloud's lower end to its upper end this gap may be a discontinuity typical of rhythmically modulated threshold mechanisms[29] There being few sleeps of middling duration (if any) that begin near this critical time, a gap devoid of wake-ups appears in the raster plot (shaded in Fig 1) There is no corresponding gap devoid of sleep onsets, nor do sleep durations fall into any clear pattern when plotted against sleep onset time, nor can sleep onset time be anticipated with precision comparable to the anticipation of wake-up timing implicit in Fig 2 Sleep onset and wake onset seem to be governed by different principles

Mathematical allegories

A variety of mathematical models have been postulated to describe the regularities noted above[11 13 18 29-34] For the present they remain more nearly computational metaphors than testable deductions from physiological hypothesis However, the more sophisticated among them (see, for example, refs 18, 30) may soon prove useful in disentangling the relative contributions of various possible cues to entrainment of human body clocks Without such cues, and without their somehow perturb-

0028-0836/82/180023—05$01 00

ing the mechanisms of our internal clocks, we could not keep our habits synchronous with the day/night cycle. Such cues may include mere knowledge of time of day[8,9 13 35], light/dark transitions (ref 36 p 20, and refs 32, 37–40), compulsory sleep itself[11,33 36 37 40–44], food and stimulants[44–48], or even a young man's delight to receive illicit daily letters from a young woman lab assistant while the professor was out of town (ref 11 p 36, and R Wever, personal communication)

The supra-chiasmatic nuclei

The physiological sources of circadian timing seem to lurk somewhere in the central nervous system[49–54] Control of sleepiness/activity timing in mammals probably resides in a pair of tiny structures called the suprachiasmatic nuclei (SCN) in the hypothalamus, astride the crossing of the optic nerves[55–59] Only last year was an anatomical locus presented as the SCN in man[60] Single cells in this region respond to visible light in rough proportion to the log of light intensity striking the eyes[61–64] (The primary visual areas, in contrast, respond mainly to spatial and temporal gradients of light intensity) This absolute intensity information is conveyed along the retinohypothalamic tracts, identified in a wide variety of mammals (including primates but not yet in man) They start in the left and right retinal ganglion cells and ramify (with mixing) in the left and right SCN[65] Stimulation of this pathway by light or by electrical impulses does alter the firing of SCN neurones[61–63,66] The aggregate firing of SCN cells increases and decreases 10-fold with circadian period in ostensibly constant conditions (ref 67 and S T Inouye and H Kawamura, personal communication) In rats the metabolic rate of SCN tissue, assayed by 2-deoxyglucose uptake also continues rhythmically in constant conditions[68–70] An island of SCN isolated from its neural surroundings in the rat still shows a persistent circadian rhythm of neural activity, while similar rhythmicity no longer occurs elsewhere in the brain[67] It follows that if there is no biochemical or thermal rhythm impinging on the neurally excommunicated SCN, then the SCN in this species is indeed a self-contained oscillator

Combining observations on rats and monkeys, we might conclude that sleep/wake timing is indeed governed by at least two independently competent clocks But no one yet knows whether both function in any one species, nor in particular, whether they do in man

Artificial light: too dim to cue human body clocks?

Our internal clocks normally remain quite predictably synchronized to the 24-h period of environmental cues (and therefore also to each other) The question of what constitutes a compelling cue is obviously of vital importance and is the subject of vigorous experimental investigations The anwers differ significantly from one species to the next Bright light may be a universal cue, its synchronizing role has been doubted only in the case of man

Activity in the SCN suppresses release of melatonin from the pineal gland, so does visible light, presumably acting through the SCN A melatonin secretion rhythm seems to free-run in synchrony with core temperature (A J Lewy *et al*,

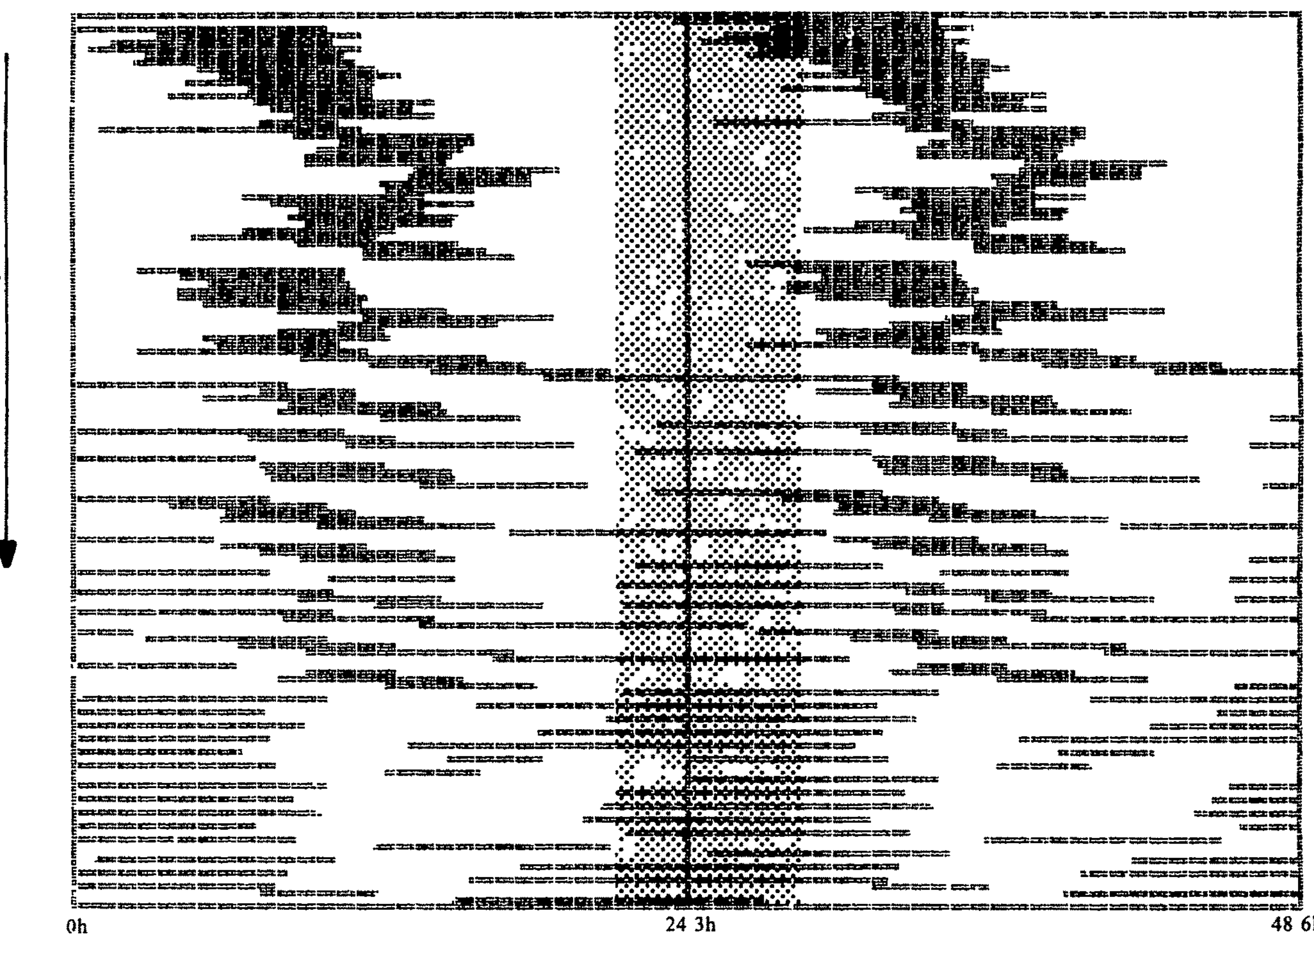

Fig. 1 Data[21,22] of digitized and reassembled double-plotted raster format following Czeisler[23] Sleep time is indicated by a black line from left to right, with successive 24 3-h intervals stacked from top to bottom This diagram is really a cylinder of 24 3-h girth along which alternating intervals of sleep and waking are plotted along a helically wound time axis It is slit open and laid flat for the publisher's convenience, the whole picture is replicated to the right, shifted up a line, to exhibit its continuity across the arbitrary slit line Notice the shaded range of phase in the 24 3-h cycle when spontaneous wake-up seldom occurs There is no corresponding range devoid of sleep onsets

in preparation) The immediate and immediately reversible effect of light on melatonin release thus provides one assay (as yet uncalibrated) for the impact of light on the sleepiness/activity timer

Quantification of this impact has been sorely needed since the discovery[13] that in certain conditions light may be a less effective synchronizer than social stimuli (in man)[11 36,37] Perlow *et al*[71] showed that room light inhibits melatonin secretion in primates Do the several studies showing lack of comparable impact in humans reveal a basic neuro-anatomical or physiological change unique to humans? Richter[72] presents these speculative matters from a rather different viewpoint, that people override their internal clocks with the aid of artificial light, supposing that artificial light is as good as sunlight for these purposes

Lewy *et al*[73 74] provide a first quantitative estimate of the impact of light in man by monitoring plasma melatonin during exposure to light of various intensities The results suggest instead that humans are not altogether insensitive but rather only much less sensitive to dim light than are the primates and nocturnal rodents examined to date In particular, intensities (about 500 lux) comparable to those of indoor artificial illuminants used in experiments throughout the past decade have little or no effect on melatonin secretion The light/dark alternations used in those experiments may have been dark/dark so far as the sleepiness timer is concerned

Intensities of about 2,500 lux (more like outdoor sunlight) are effective in man If similar exposures are needed to phase-shift the circadian rhythm, it could clarify much of the debate over man's entrainment more by social stimuli than by the light/dark cycles that cue every other organism It also suggests an understanding of Klein and Wegmann's observation[75] that the symptoms of 6 hours' jet lag persist longer in transatlantic passengers who retire to their hotel rooms to sleep it off, than in others imposed upon to go outdoors[73]

Therapy for mood and sleep disorders

In some individuals melatonin secretion is suppressed by dim light Lewy *et al*[73] report suppression by as little as 500 lux incandescent light in four subjects who are peculiarly susceptible to manic-depressive alternations This observation enhances interest in recent conjecture[74 76–80] that fluctuations of mood, including manic-depressive alternations, may be caused by abnormal mutual phasing of circadian rhythms Wehr *et al*[78] have found that by deliberately advancing the sleep/wake rhythm by 6 h relative to the temperature rhythm, they could sometimes abort depressive episodes in one patient More recently in another patient, Lewy *et al*[81] precociously terminated recurrent winter-time depression by artificially lengthening the photoperiod

Phase relations between sleep and core temperature can also be quite different in individuals who for some reason are not normally responsive to the usual synchronizing cues[82] Among sightless individuals, those who do entrain show diverse phase angles relative to the civil and solar day[83 84] Some sightless individuals, some recluses and older people living indoors with little social contact, and perhaps individuals with stronger circadian clocks, sometimes retire and rise later and later every day like the tides Eventually, pursuing their solitary interests by night and sleeping by day, 180 degrees out of phase with surrounding society, they drift still later into synchrony again after another 2 weeks or so[85–88] (see Fig 3 for an example)

All subjects fail to synchronize to scheduling at too short or too long a period relative to their own internal clocks. Wever[89] has exposed subjects in his temporal isolation facility to gradually lengthening (or shortening) days As their activity cycles shift with respect to the light/dark cycle and their temperature cycles shift with respect to their activity cycles, they gradually become 'early birds' or 'night owls' This becomes noticeable subjectively only when their usual timing of waking or retiring transgresses a boundary of daylight However, when the driving period becomes too extreme (beyond 22 or 27 h), both internal and external synchronization fail: neither core temperature fluctuations nor sleep/wake alternations follow the light/dark cycle, nor do they remain entrained to each other Curiously, the subject remains unaware of any change

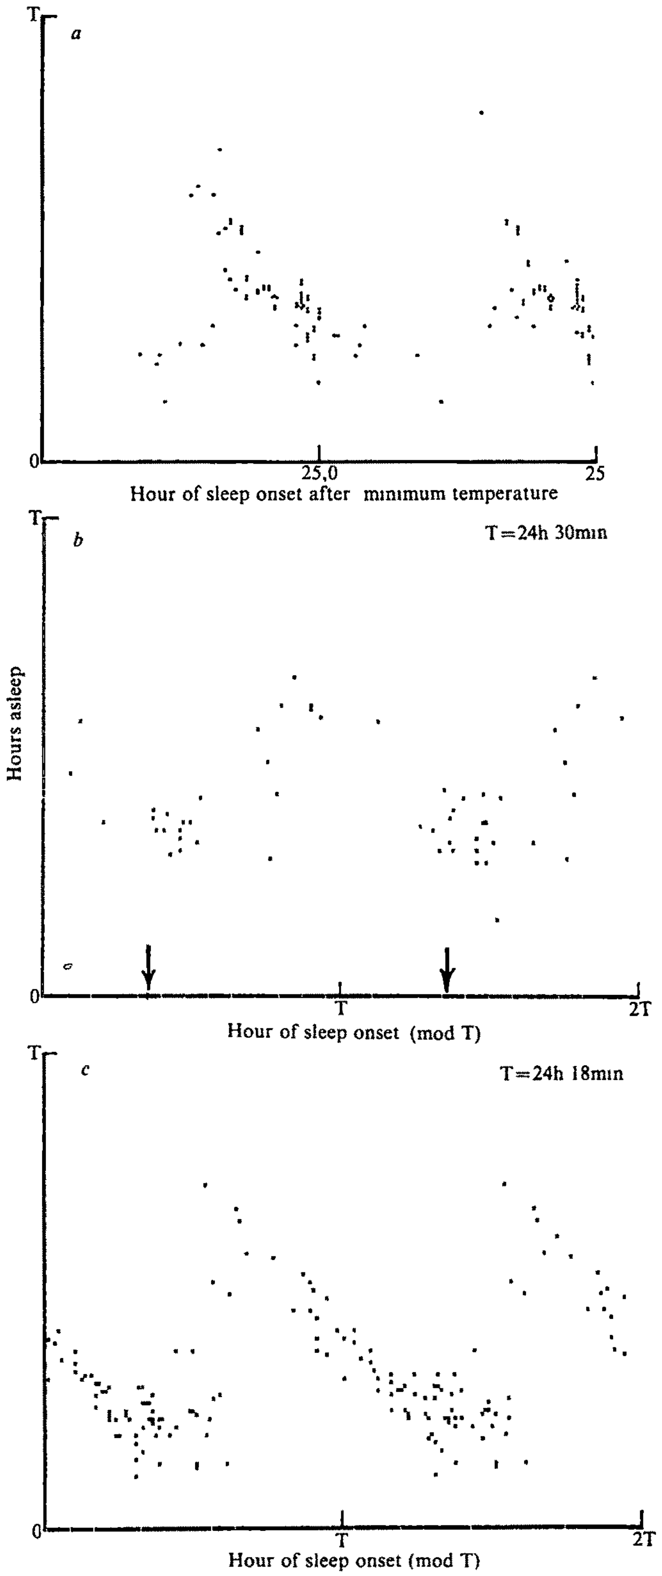

Fig. 2 *a*, Human sleep durations plotted against circadian phase (from ref 27) as described in the text *b*, As in *a*, with PRO1 data from ref 23, as described in text, the arrows mark approximate temperature minima *c*, As in *a* and *b* but data from refs 21, 22, subject J C digitized and reprocessed following Czeisler[23] The blank line inserted after 7 weeks represents transition to continuous dim light for the final 80 days Note that the vertical and horizontal scales are not identical here

within himself he just thinks that the room lights are being operated capriciously[11,36 89]

Some kinds of insomnia, previously dismissed as personal idiosyncrasy, seem to reflect treatable aberrations of the circadian clock and/or the sleep/wake system A simple manoeuvre is reported[90–92] to cure the 'delayed sleep phase syndrome', estimated to afflict hundreds of thousands of people Some people's sleep/wake rhythm, subject to rhythmic driving both by the internal temperature oscillator and by an external civil day, adopts an inconvenient phase relative to the civil day In the cases that come to clinical attention, both sleep and waking are tenaciously delayed about 6 h relative to what is usual for most people This makes it virtually impossible for them to hold any job that requires alertness in the morning However, by delaying three more hours each day for 6 days, one eventually arrives at the desired schedule and it remains stable long after termination of the phase-shifting therapy (Fig 4) However, the problem recurs after working late, travelling too far westward too abruptly, or otherwise losing yet 6 hours more Then another 18-h delay must be arranged[90 91] It would appear that such individuals can travel abroad only by remaining on a home-base schedule during a brief excursion, or, if they must synchronize to the civil day abroad, by circumnavigating and crossing the International Dateline westward

Daylight savings, jet-lag and shift work

A small phase shift of this sort has been imposed on hundreds of millions of people twice annually since the implementation of Benjamin Franklin's plan for daylight-saving time The possible consequences were never considered and are not fully known Monk and Aplin[93] recently found that the time of retiring adjusts immediately but that the time of awakening (or

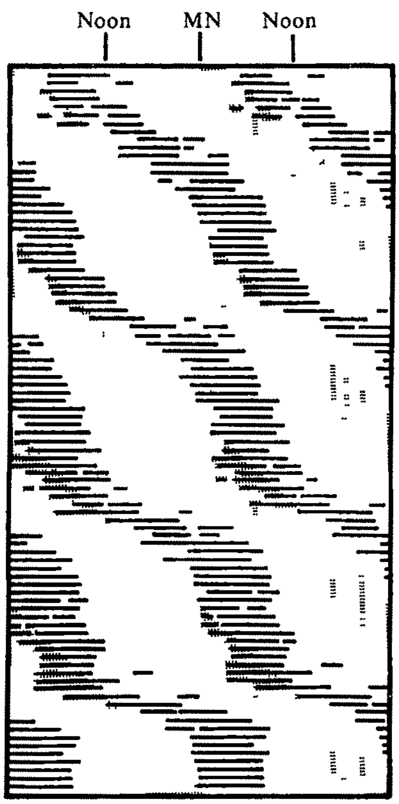

Fig. 3 In the same format as Fig 1 but with 24 0-h girth, a recording of more orderly alternations of sleep and waking in a non-blind individual who, nevertheless, does not synchronize to the 24-h world His own period waxes and wanes (the slope of the sleep-onset border varies) as his phase relation to the 24-h world changes (from ref 88) Note again the shaded zone of no-waking in this man's internal period, roughly corresponding to his temperature minimum

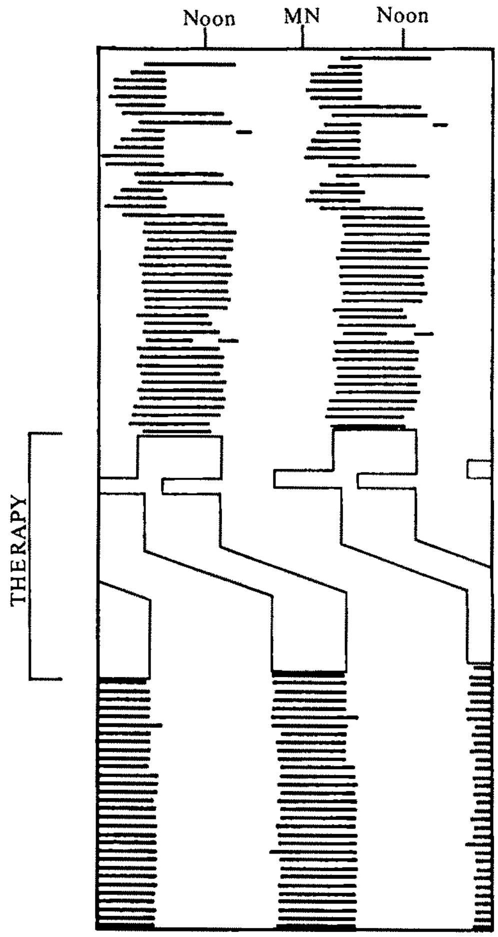

Fig. 4 The format is as in Fig 3 Sleep is indicated by a black bar in each of 110 stacked days During therapy, sleep was confined within the zigzag channel It retains the new timing with respect to the civil day (Adapted from ref 91)

duration of sleep, see Fig 2) needed a week to adjust fully The advancing (springtime) shift was somewhat more difficult than the delaying (autumnal) shift, as might be expected *a priori* for a species whose internal clock already has a somewhat longer period than the natural day Much the same happens when we travel either east or west Travel by air compresses the phase shift into a single day After transmeridian flights, about one person in four reports some indisposition associated with resynchronization[94] The abundant literature of jet-lag seems internally contradictory in many respects, and therefore suggests that individuals vary enormously in their reactions to diverse rescheduling stimuli Recent reviews[94–98] agree that internal phase relations remain abnormal for up to a week Nearly all flight experiments indicate substantially quicker adjustment after westward (delaying) flights across as many as nine time zones, than after comparable eastward (advancing) flights The latter also result in a depression of temperature-rhythm amplitude for several days Duration of flight, whether outbound or homebound, the time of departure and change in wake duration do not matter for the subsequent course of resynchronization

Both in laboratory isolation units and outside, the diverse physiological and psychological rhythms readjust at their diverse individual rates—even with some advancing and some delaying, most commonly when crossing 9 to 12 time zones[41 94] In free-running conditions of temporal isolation, subjects do not preceive the jet-lag-like dissociation of their own internal rhythms Wever[11 99] reports that subjects even feel better during the prolonged dissociation he calls internal desynchronization These observations conflict with universal expectation that

derangement of internal timing should cause discomfort or damage I know of no unequivocal demonstration that this internal dissociation in itself causes trouble apart from the inconvenience of trying to sleep, eat or think quickly at times when either local society or one's own body is not ready for it This latter discomfort is experienced by individuals who are out of synchrony with society but still internally synchronized This can be important shift workers include air-traffic controllers, nuclear submarine and power-plant operators, emergency-room doctors and intensive-care unit nurses Greater error rates have been measured during shift work[94,100,101] Individuals whose temperature exhibits larger daily excursions tend to take longer to adjust to each shift[41,99,102] This suggests itself as a selection criterion for individuals required to cope with frequent changes of scheduling

What is the best procedure for hastening adaptation to a new schedule (assuming this is a good thing to do)? Advice seems unreliable but the best guess may be just to maximize the contrast between our circumstances day and night with respect to light/dark, meals and social factors that provide synchronizing cues My personal impression, based on no more than conversation with other travellers during about fifty Atlantic crossings, is that for some people direct sunlight helps a lot

The timing of sleep and wakefulness is only one facet of the intricate patterning of temporal contrasts that pervade human physiology The medical profession is beginning to find ways to incorporate recent understanding of the predictable ups and downs of metabolism, the large excursions of hormone titre, drug susceptibility and plasma ion balance that previously limited the effectiveness and safety of routine procedures[103,104]

I am indebted for financial support during this survey to the NSF, the Institute for Natural Philosophy and the USAF School of Aerospace Medicine, and for hospitality to George Oster and the University of California at Berkeley during sabbatical leave from Purdue University I thank the many workers here cited who freely shared with me their time and unpublished data

An explanation of $^{13}C/^{12}C$ variations in tree rings

R. J. Francey

Variations in the $^{13}C/^{12}C$ ratio in trees are examined in the light of a simple expression relating the relative isotope composition of plant material, δ_p^{13} to δ_a^{13}, the atmospheric isotope value, c_a, the atmospheric CO_2 concentration and c_i, the internal concentration of CO_2 in leaves The expression gives good agreement with δ_p^{13} measurements where independent information on c_i exists, such as seasonal growth, growth low in the canopy and in conditions of low humidity. The expression provides possible explanations for two previously unexplained phenomena the absence of anticipated changes due to fossil fuel-induced changes in δ_a^{13}, and regional differences in δ_p^{13} trends

THE isotopic composition of carbon stored in the growth rings of trees may represent a record of $^{13}C/^{12}C$ variations in atmospheric CO_2, or of physiological responses to environmental changes, or a combination of both. In the first category, several authors[1–4] have attributed a decrease in $^{13}C/^{12}C$ in tree rings over the period 1850–1950 to an increasing component of ^{13}C-depleted CO_2, released into the atmosphere by increasing fossil fuel combustion, and/or by deforestation and expanding agriculture. In the second category, others[5–9] have sought an explanation of $^{13}C/^{12}C$ variations in tree rings through correlations with temperature Here there is normally an assumption of constant $^{13}C/^{12}C$ in the atmosphere, and a common, temperature-sensitive metabolic process within plants is implied In the third category, Mazany *et al*[10] assumed $^{13}C/^{12}C$ in air to be influenced by respiration from surrounding vegetation, which in turn responds to environmental factors such as temperature and water availability As in the first category Mazany *et al.* assumed constant fractionation in the carbon flow from the atmosphere to the biosphere

We investigate here the applicability to tree-ring studies of a new, quantitative expression[11], relating the carbon isotope ratio in those plants having the most common C_3 mechanism of photosynthetic carbon fixation to the physiological properties of a leaf When applied to tree-ring sequences corresponding to the period of industrialization, the fractionation expression carries implications concerning the response of trees to increasing levels of CO_2 in the atmosphere

Carbon discrimination in plants

An expression[11] for δ_p^{13} of the photosynthate in a C_3 plant is approximated in the form

$$\delta_p^{13} \simeq \delta_a^{13} - a - (b-a)c_i/c_a \qquad (1)$$

where δ_a^{13} is the fractional difference between $^{13}C/^{12}C$ in air surrounding the leaf and that in a reference material, c_a and c_i are the CO_2 concentrations in the external atmosphere and leaf intercellular spaces, respectively Furthermore,

$$c_i = c_a - A/g \qquad (2)$$

where A is the rate of CO_2 assimilation by the plant and g is the conductance of the boundary layer and stomatal pores to the diffusion of CO_2 The diffusivity of $^{13}CO_2$ in air is 4 4‰ less than that of $^{12}CO_2$, and this is the value of the constant a The value of b is determined by the isotopic discrimination of the ribulose-1, 5-bisphosphate carboxylase enzyme, thought to be the main source of fractionation in C_3 plants[12], with magnitude ~30‰ (ref 13)

In the derivation of equation (1) the CO_2 concentration drop from the intercellular spaces to the chloroplasts is assumed to be small, and intrinsic fractionation in photo- and dark-respiration steps is assumed negligible In its application to tree rings, the fractionation associated with translocation, and with the conversion of the photosynthate to other chemical factions such as cellulose or lignin, is assumed to be relatively small and not influenced by environmental factors In the application of equation (1) in this article we assume that b is constant

Qualitatively, this model is quite similar to those of Park and Epstein[12], Troughton[14] and Grinstead[15] Progress towards a quantitative model has also been made independently[13 16] but the ease of application of equation (1), is a significant advantage in interpreting carbon isotope behaviour in plants It is supported by the range of δ_p^{13} values observed in C_3 plants and by a correlation between δ_p^{13} and c_i/c_a in these species[17] Further support is drawn from measurements of δ_p^{13} and c_i/c_a following water stress[18] and of the temperature[19 20] and humidity[21] dependences of δ_p^{13} in growth chamber experiments

Paraphrasing[19], factors which reduce CO_2 assimilation rate through effects primarily on the mesophyll capacity for photosynthesis (for example, very low light intensities, and deficiencies of certain mineral nutrients) will increase c_i/c_a and reduce δ_p^{13}, factors which reduce CO_2 assimilation rates primarily through reduction of supply of CO_2 through the stomata (for example, large vapour pressure deficits) will decrease c_i and increase δ_p^{13} Note that in some situations a change in an external parameter may affect both A and g in equation (2) with no marked effect on c_i/c_a and thus δ_p^{13} (ref. 19)

Discussion

The possible relevance of equation (1) is explored with reference to observations of a number of reported phenomena Note that because relative rather than absolute δ^{13} values are discussed, the term δ_p^{13} is used at different times in reference to different material (such as cellulose, whole wood, and leaves) We discuss (1) the seasonal variation in δ_p^{13}, (2) the 'juvenile' effect in δ_p^{13}, (3) correlations between δ_p^{13} and regional ring width, temperature and precipitation, (4) variations of δ_p^{13} within a tree, (5) the absence of a fossil fuel-induced depletion of ^{13}C in Tasmanian trees, (6) regional differences in long-term δ_p^{13} trends

0028-0836/82/180028—04$01 00

Seasonal variations in δ_p^{13}

Lowden and Dyck measured a 2–5‰ decrease in δ_p^{13} values in both maple leaves and grass collected from an exposed site in Quebec during May to September The seasonal (and diurnal) variation in δ_a^{13} in the free atmosphere obeys a simple atmosphere biosphere mixing relationship[23–25] With typical ≥ 10 p p m v concentration decreases from May to September at high northern latitudes, this implies a δ_a^{13} increase of ~0 5‰, far smaller and in an opposite sense to the seasonal change in δ_p^{13} Lowden and Dyck hypothesize that the δ_p^{13} changes might be a direct consequence of changing photosynthesis to photorespiration ratios

Equation (1) is a quantitative description of such processes Whilst no information has been located on the seasonal variation of c_i in trees, there is ample evidence in measurements on crop plants of c_i increasing with age from peak photosynthetic rate to near senescence[26–30] Typical increases are 20–50 p p m v , which in equation (1) for typical values of c_a, δ_a and b, imply δ_p^{13} decreases of 2–4‰, in close agreement with the values of Lowden and Dyck in both leaves and grass

During initial leaf development A will be low and c_i high, that is over the full growth season we might expect a rapid decrease in c_i, a levelling off, followed by the slow increase to senescence[30] If this occurs in *Pinus radiata*, then measurements of 1–2‰ changes in δ_p^{13} within a ring of a New Zealand specimen[31] can be readily explained by equation (1) These indicate increasing δ_p^{13} early in the growth season (1/6th of a ring width), with high or slowly decreasing δ_p^{13} over the middle (4/6ths of a ring), and a very low δ_p^{13} in the late wood (1/6th of a ring) The effect is measured in both cellulose and lignin, confirming a mechanism early in the sequence of CO_2 assimilation The trend of the δ_p^{13} change with respect to season is confirmed by measurements on early and late wood from Australian *Athrotaxis selaginoides*[32] (At these latitudes c_a and δ_a^{13} in the free atmosphere are practically constant throughout the growth season[33 34]). In both cases the magnitude of the δ_p^{13} change of 1–2‰ is perhaps too large to be explained by temperature dependent fractionation process, or by local modification of δ_a^{13}, but quite compatible with observed seasonal changes in c_i

The juvenile effect in δ_p^{13}

Steadily increasing δ_p^{13} values with time, often observed in the innermost rings of a tree[4,15 35 36], have been attributed[4 37] to reassimilation of respired CO_2 which is retained within the plant canopy But this explanation has been questioned for trees which grew in relative isolation, and an age-related physiological factor suggested[15 35]

A step increase in δ_p^{13} accompanying a step increase in ring width[38] during early growth years, together with no δ_p^{13} increase in a well-exposed island tree[38], argue against an intrinsic age-related effect, and are qualitatively compatible with a 'canopy-effect'

The close proportionality between δ_a^{13} and c_a values observed in forest environments by Keeling[24 25] can be used to predict c_a levels some 40 p p m v above ambient, which must be maintained on average during photosynthesizing periods, to produce the typical 2‰ magnitude of the 'juvenile effect' Studies in a coniferous forest[39] (and O T Denmead, unpublished) and in a tropical rain forest[40] show that during daytime CO_2 in air is generally depleted by <4 p p m v through most of the stand, higher concentrations only occur close to the forest floor Even in dense forests δ_a^{13} is similar to that in background air[24 25] Periods of maximum photosynthesis generally coincide with periods of maximum instability and convective mixing in the atmospheric surface layer, whereas the value of 40 p p m v above ambient represents night-time conditions of extreme stability and dark-respiration in the Keeling data, and far exceeds any daytime value Normal selection of trees for δ_p^{13} analysis minimizes those situations of extreme atmospheric stagnation which might favour significant ^{12}C cyclic enrichment in trees[37]

While soil respiration may contribute to low δ_p^{13} low in the canopy through δ_a^{13} in equation (1), changes in c_i/c_a offer an alternative, or at least a contributory, explanation At low irradiances rate of assimilation, A, and to a lesser extent, stomatal conductance, g, are reduced The net result is that c_i increases[41]. In the extreme, as the irradiance drops near that level at which the photosynthetic rate is zero, c_i approaches c_a, the concentration of CO_2 outside the leaf On these grounds we expect low δ_p^{13} values at low irradiances.

Measurements on wheat plants grown in well-ventilated controlled chambers under shade cloth (in 220 $\mu E\ m^{-2}s^{-1}$) when compared with similar plants grown in light levels of 640 $\mu E\ m^{-2}s^{-1}$ show a 2‰ reduction of δ_p^{13} (ref 20), strongly suggesting that low light levels do produce δ_p^{13} changes of the sign and magnitude of the observed juvenile effect

Shading is unlikely to produce an explanation for juvenile ^{13}C depletion in isolated trees However, there are other external factors which affect the mesophyll capacity for photosynthesis and which could well vary during early tree development, for example, certain nutrient deficiencies, so that equation (1) provides a promising starting point for further research

δ_p^{13} and ring width, temperature and precipitation

The seasonal variation interpretation, plus interpretation of δ_p^{13} versus temperature results from growth chamber measurements[19,20], associate more positive δ_p^{13} with faster assimilation rate, A Correlations of δ_p^{13} with ring width by Mazany *et al*[10] and Tans and Mook[42] associate more positive δ_p^{13} with narrow rings and thus presumably slower assimilation rates

The general response of trees in arid areas is for ring widths to be wide in wet, cool years and to be narrow in warm, dry years, extreme water stress can cause stomatal closure and reduced CO_2 uptake as shown by Fritts[43] Low humidity has been shown[44] to reduce g and c_i, so that in conditions of high temperature and low precipitation we could expect narrower rings, lower c_i and, by application of equation (1), higher δ_p^{13}, as seen by Winter and colleagues[18 21] Measurements on juniper leaves and twigs from a wide area of arid Arizona, in which more negative δ_p^{13} are associated with lower growth temperatures and higher precipitation[45], are compatible with this

A similar argument can be applied to the Mazany *et al*[10] trees from the same area, however, they demonstrate a striking improvement in the δ_p^{13} versus ring-width index correlation when a regional rather than individual ring width index is used This seems to be their major reason for favouring an explanation in terms of regional modification of the atmosphere by respired CO_2 (that is, good conditions are reflected in vigorous regional growth, more respiration and an atmosphere with depleted δ_a^{13}) The rapidity with which CO_2 mixes in the atmosphere, particularly during photosynthesizing hours and in sparsely vegetated areas[24 25 46 47] would seem to invalidate an explanation involving significant regional modification of c_a, δ_a^{13} values In the context of equation (1), the higher correlation with regional indices requires that changes in average c_i are primarily determined by contemporary regional conditions whereas many factors are known to determine individual ring widths The fact that δ_p^{13} in the Dutch trees correlates inversely with ring width and directly with temperature and inversely with precipitation[42], as inferred for the Arizona trees, is suggestive that similar influences are at work

A recent summary of δ_p^{13} versus temperature coefficients indicates considerable complexity[48] In general, the δ_p^{13} response in tree rings to environmental parameters such as temperature and precipitation might be expected to be complex if δ_p^{13} is determined from equation (1) For example, growth chamber measurements on tree seedlings show how both positive and negative δ_p^{13} versus temperature coefficients might be obtained, depending on whether the change is below or above the temperature corresponding to peak photosynthetic

activity[19,20], and the optimum temperature is different for different species Thus there may be both a species and a range dependence Added to this will be quite non-linear influences resulting from stress, the most obvious being stomatal response to extreme hot dry conditions This places great emphasis on site and species selection if δ_p^{13} in trees is to be used for environmental reconstructions

Variations in δ_p^{13} within a tree

Several authors have drawn attention to variations of δ_p^{13} around the circumference of a ring[4,10,38,42] of magnitude 1–4‰ Again it is difficult to explain the magnitude of this effect in terms of local modification of δ_a^{13}—previous measurements of δ_a^{13} versus c_a (refs 24, 25) require large CO_2 gradients of 20–80 p p m v to be maintained across a tree for the major portion of the growth periods It is especially difficult as these trees have generally been selected from positions of relative isolation

For the same reason large differences due to a cyclic enrichment process[37] are difficult to envisage The main evidence presented by Keeling for the cyclic enrichment process, effectively a comparison of maximum daytime δ_a^{13} values with maximum night-time c_a values at various forest sites, can be explained by the seasonal variation in the large-scale atmospheric δ_a^{13} values

Variations in stomatal conductance, g, for example due to differences in structure and shading in leaves[49], or variations in leaf assimilation rate, A, due to shading[20], appear to offer a more realistic explanation through equations (1) and (2) For example, even though Wong *et al*[50] show that c_i is approximately constant in *Eucalyptus pauciflora* over a range of irradiances above 250 $\mu E\, m^{-2} s^{-1}$, the small changes observed are sufficient to imply δ_p^{13} changes of ~1‰

No fossil-fuel depletion of ^{13}C in Tasmanian trees

Cellulose from eight Tasmanian trees[38] exhibits a practically constant δ_p^{13} with time over the period 1750–1970 This is in contrast to the predicted decrease of 0 7–0 8‰ (refs 42, 51) There is even greater contrast if an additional large amount of CO_2 has been released as a result of forest clearing and agricultural practices[31] It does not reflect direct observation of a δ_a^{13} change in the atmosphere[52] It also contrasts with a summary of most reported Northern Hemisphere δ_p^{13} measurements[53]

The eight Tasmanian trees represent two species, and a wide range of environments (small island to extremely exposed mountain ridge) but with all sites sharing desirable features in the context of monitoring global atmospheric CO_2 The areas are remote from large-scale industry and experience persistent winds off the southern ocean, enhancing mixing The seasonal variation in CO_2 is small and temperatures are stabilized by the surrounding (particularly upwind) oceans The very high and persistent rainfall (typically in excess of 2,000 mm yr^{-1}) implies minimum water stress with its corresponding effects on fractionation In a forest situation the selected species typically have most of their foliage at or above canopy level

The absence of a δ_p^{13} trend which reflects the anticipated δ_a^{13} trend in any one of the eight trees, requires an effect operating on a regional scale (≥100 km) of similar magnitude but opposite sign to the fossil fuel signature in the atmosphere Equation (1) provides a possible solution without recourse to complete coincidence While the δ_a^{13} decrease due to fossil fuel release is associated with an increase in c_a, the effect of increasing c_a in the equation, all else being constant, is to increase δ_p^{13}

Physiological data on c_i/c_a in trees is scarce, and over the 50–100 year time scale, is non-existent The strength of the present argument rests with the feasibility of the mechanism, when no alternative explanations exist Even those physiological experiments which suggest constancy of c_i/c_a in some plants over short time scales[19], are of an accuracy which do not exclude the small changes necessary to reconcile the Tasmanian δ_p^{13} measurements with the anticipated δ_a^{13} changes due to fossil fuel combustion

For example, combination of the predicted δ_a^{13} curve[42,51] with the Tasmanian mean curve plus equation (1) implies

$$[c_i/c_a]_{1970} \simeq 0\ 9[c_i/c_a]_{1870}$$

and thus

$$[c_i]_{1970} \simeq [c_i]_{1870}$$

In other words the trees have, to a first approximation, maintained a constant c_i This conclusion does not depend on the value of b, and depends only weakly on the δ_p^{13} value used The simplistic application of equations (1) and (2) implies either reduced stomatal conductance, g, or increased assimilation rate A over the 100 years of increasing CO_2 levels In view of the abundant water availability, the latter is favoured

There are many complexities in the real situation which must be better understood before the model for fractionation and the tree records can be used with confidence in this fashion However, we have illustrated a possible sensitive means of probing physiological behaviour over long time scales

Regional differences in long-term δ_p^{13} trends

A composite δ_p^{13} curve from 26 European and North American trees shows a decrease of almost 2‰ from 1850 to 1975, which includes a slight increase between 1940 and 1960 (refs 4, 53) Several Northern Hemisphere individual trees[2,3] have been reported with similar δ_p^{13} decreases up to around 1940–50, all in marked contrast to the practically constant δ_p^{13} in the Tasmanian trees from 1850 to 1970

Considerable caution is required in attributing these differences in δ_p^{13} to environmental differences on a hemispheric scale For example, the mean of four Dutch trees[42] decreases between 1860 and 1940 by no more than 0 5‰, with an increase of almost 0 4‰ from 1940 to 1970, overall these are not significantly different (in view of the scatter between individual trees) from the Tasmanian trees But the one other reported Southern Hemisphere tree-ring result[1] is very different from the Tasmanian results with a steady 1–1 5‰ decrease from 1890 to 1960

The predicted change in global δ_a^{13} due to fossil fuel combustion of around 0 7–0 8‰ (refs 42, 51) from 1750 to 1970 is equally incompatible with the 2‰ change of Freyer[4] as it is with the flat Tasmanian record In both cases the differences from the predicted curve are too large to be explained by measurement error A large additional release of CO_2 around 1860 associated with an 'agricultural explosion' has been postulated to explain the larger δ_p^{13} trends[4,31]

Use of an 0 032‰ p p m v^{-1} biosphere–atmosphere mixing relationship observed[54] between 1956 and 1978 as an upper limit to that applicable over the past 200 yr can be used to predict 1750 levels of atmospheric CO_2 considerably lower than the 270–290 p p m v typically employed in global carbon budgeting models (G I Pearman and I Enting, personal communication) More realistic mixing over the 200-yr time scale comes from such models[42,52], which include realistic air–sea fractionation factors, and these suggest a relative insensitivity of δ_a^{13} to biospheric release Thus it is not obvious that the postulated explanation for the large δ_p^{13} trends is valid

The maximum latitudinal difference in δ_a^{13} that can be maintained over decades is expected to be small For example, the current difference in annual average CO_2 concentration of 3–4 p p m v from pole to pole[31], if assumed due to fossil fuel combustion, represents a 0 1–0 2‰ difference in δ_a^{13} Keeling *et al*[54] measured a difference between North America and South Pole of <0 1‰ in 1978, although results of Kroopnick *et al*[55] in 1970, when corrected for seasonal effects indicate a 0 5‰ difference over a similar latitude range A recent two-dimensional and seasonal model of global carbon exchange

(refs 33, 56–58 and P. Hyson, personal communication), estimate a total change, 1850–1970, of ~0.2‰ between 50°N and 50°S. Thus even if the Freyer[4] results do reflect a global δ_a^{13} change, the conflict with the Tasmanian δ_p^{13} trends is about twice that discussed above. It is true that both cannot represent large scale δ_a^{13} changes.

It is equally unrealistic to suggest that regional or sub-canopy modification of δ_a^{13} could explain the differences. This is because of the small magnitude of daytime δ_a^{13} differences from background air in even quite dense forests[24,25], and the wide variation in ages, exposures, and species, of trees showing common trends[38]. The only possibility of reconciling all observations, seem to be in systematic variations in the fractionation of atmospheric CO_2 as it is assimilated by trees.

Drawing on examples and discussion above, possible examples of environmental influences on the fractionation process in trees which operate locally, but on decadal to century time scales, include: (1) shading in developing forests, where individuals have significant subcanopy foliage; (2) nutrient depletion; (3) changes in assimilation rate resulting from regional temperature trends, or from interactions with changing atmospheric pollutant levels; (4) changes in stomatal behaviour resulting from trends in atmospheric pollutants or humidity.

For tree-ring sequences over the past 50–100 yr it can be argued that δ_a^{13} is known to greater accuracy than c_i/c_a; using the fractionation expression, measurements of δ_p^{13} may become useful in plant ecophysiology.

We thank Dr G. I. Pearman, Mr P. Hyson and Dr Ian Enting (CSIRO, Division of Atmospheric Physics) for computational work with respect to the carbon budgeting models. Professor C. B. Osmond and Dr Ian Cowan and Dr Roger Gifford offered valuable comments.

Function of a tRNA gene promoter depends on nucleosome position

Stephanie Wittig & Burghardt Wittig

Institut für Molekularbiologie und Biochemie, Freie Universität Berlin, Arnimallee 22, 1000 Berlin 33, FRG

We have used an in vitro *procedure to direct nucleosomes to different sites on a chicken embryo tRNA gene. The results show that transcription of the tRNA gene depends on nucleosome position and in a functional promoter structure, the constant gene sequence TTCGA coincides with the nucleosome middle axis.*

EVIDENCE is accumulating that the chromatin structure of expressed genes differs in several respects from non-expressed genes[1–14]. As genes are associated with nucleosomes regardless of their functional state[14], the recognition of nucleosomes that have become specifically altered requires a higher level of programming such as exposure of a recognition DNA base sequence. The particular location of such a sequence within the nucleosome could serve as the structure that is recognized. Such a nonrandom association of nucleosomes with respect to DNA base sequence is generally called 'phasing' although this term covers several different phenomena (for review see ref. 15). The limits of long-range phasing of regularly spaced nucleosomes and of sequence-specific nucleosome positioning have been discussed critically by Kornberg[16]. It is possible that base-specific DNA binding proteins serve as a phase trigger for regularly spaced nucleosomes. In the assays normally performed, such nucleosomes would display a nonrandom association with the DNA base sequence, unless due to inherent

0028–0836/82/180031—08$01.00

inaccuracies of nucleosome spacing, the effect was not apparent within a short distance from the phase trigger[16]. Recently, we have found such a short-range phasing of nucleosomes for several chicken embryonic tRNA genes[17]. The tRNA structural gene sequence always begins ~20 base pairs (bp) inside the nucleosome core, and the phased association probably does not extend farther than about five nucleosomes. In one fragment of nucleosomal DNA investigated, in which a second tRNA gene is present in the same orientation as, but does not fit into the nucleosome phasing of the first, the phase seems to be re-adjusted for the second gene. A strikingly similar picture was obtained by investigators who performed a computer simulation of the above—they found that a sequence-specific DNA binding protein triggers the phase for regularly spaced nucleosomes positioned essentially at random[16].

Our own view that the histones of the nucleosome cannot account for the phase relationship between tRNA genes and nucleosomes was supported in the early stages of the investigations described here. Phasing could not be restored in nucleosome assembly experiments using cloned chicken embryo $tRNA_2^{Lys}$ genes regardless of whether isolated histones[18], histone octamers[19] or nucleosome monomers served as the histone source[20]. Even when the cloned DNA was incubated before the addition of histones plus crude protein extracts to allow binding of sequence-specific proteins, the assembled nucleosomes were not phased. These results led us to hypothesize that the observed phase relationship between tRNA genes and nucleosomes may be established during replication, when DNA is newly packed into the repeating nucleosome structure. Sequence-specific DNA binding proteins involved in the replication process[21] and/or stretches of single-stranded DNA (ssDNA)[22,23] may be the phase-triggering structures. The *in vitro* system used here, which is described only briefly (details will be published elsewhere[24]) allows a site-directed assembly of nucleosomes. Using this system we investigated whether a particular location of a regulatory gene sequence within the nucleosome structure was suitable for programming the expression of that gene.

The DNA base sequences essential for promotion of tRNA gene transcription have been recently identified[25]. As in the case of genes encoding 5S RNA[26,27] these sequences are also located within the structural gene. They are split into two regions, one consisting of nucleotides constantly found in the dihydrouridine stem of mature tRNA, the other encoding the conserved loop sequence TTCGA of the tRNA pseudouridine stem. The latter sequence, which is the region of symmetry for a complementary palindrome[28], is localized *in vivo* near the middle axis of the nucleosome in chicken embryo tRNA genes.

The site-directed nucleosome assembly system

The assembly extract used was a crude nuclear preparation of chicken embryos[29], consisting of two components, a soluble nucleoprotein fraction and a histone source. The former fraction was prepared by incubating nuclei at elevated temperatures in an alkaline buffer, followed by sonication at high salt concentration. The procedure was identical to that used for the initial

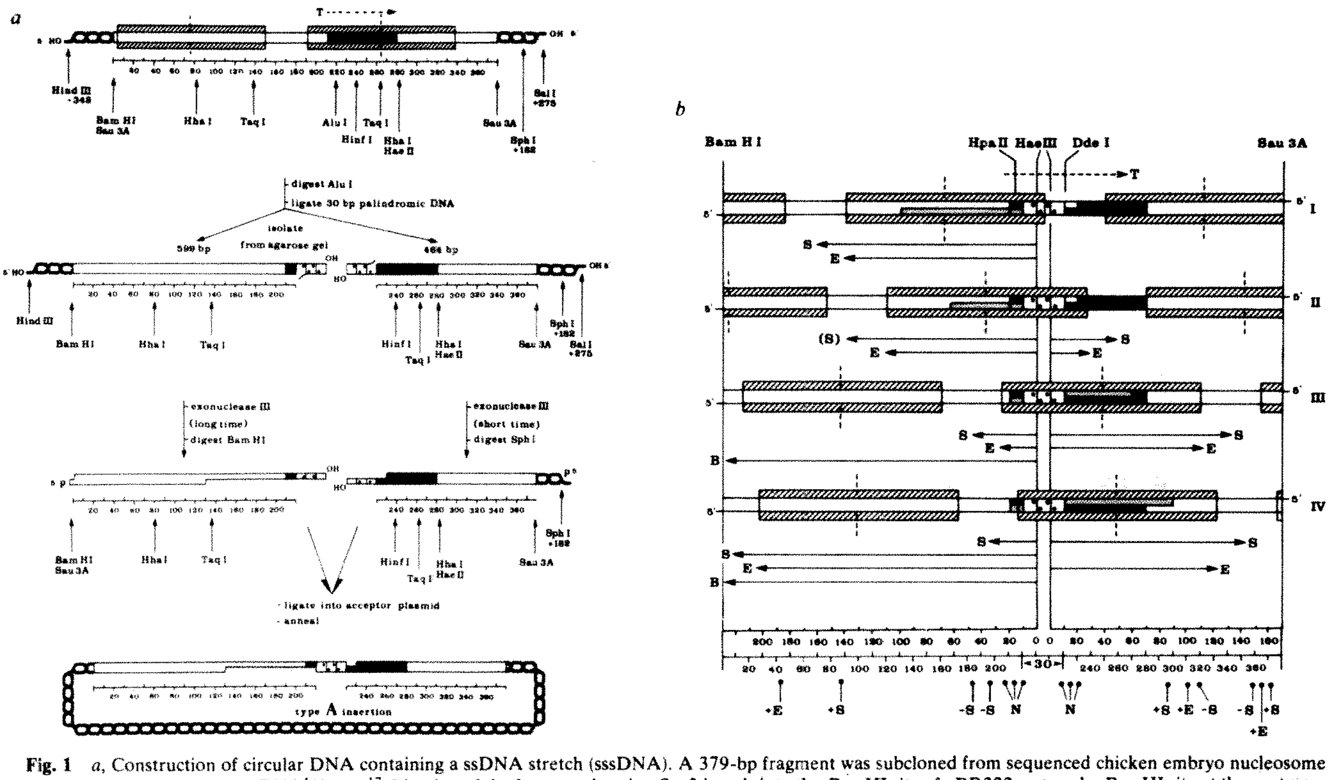

Fig. 1 *a*, Construction of circular DNA containing a ssDNA stretch (sssDNA). A 379-bp fragment was subcloned from sequenced chicken embryo nucleosome tetramer DNA containing a $tRNA_2^{Lys}$ gene[17]. Ligation of the fragment bearing *Sau*3A ends into the *Bam*HI site of pBR322 restored a *Bam*HI site at the upstream boundary of the fragment and left a *Sau*3A site at the downstream boundary. In the subclone used (pBR322 N4 *Bam Sau*) the tRNA gene is oriented clockwise with respect to the tRNA identical strand. Relevant restriction sites within the fragment are shown on a linear scale corresponding to the numbering of the DNA base sequence; restriction sites belonging to the plasmid vector are off the scale. Negative and positive nucleotide numbers indicate the respective distance from the original *Bam*HI site of pBR322. Open box, chicken embryo nucleosomal DNA; solid box, tRNA structural gene; dotted box, 30-bp palindromic DNA (trimer of synthetic *Hind*III linkers). Dots indicate position of ^{32}P-label; cross-hatched boxes, nucleosome cores; helical band, plasmid DNA. *b*, Position of assembled nucleosomes with respect to the tRNA gene. Assembled nucleosomes were either partially digested with *Staphylococcus* nuclease alone, or with *Staphylococcus* nuclease followed by exonuclease III (single strands were trimmed with S_1 nuclease in the isolated DNA). Nucleosome tetramer DNA was isolated by agarose gel electrophoresis, and eluted from the gel[43]. One half of the DNA was restricted with *Hae*III, *Dde*I and *Bam*HI, for the analysis of upstream fragments, then the other half was restricted with *Hae*III, *Hpa*II and *Sau*3A to obtain the downstream fragments. Fragments > 20 bp are single end-labelled radioactively (2.5×10^5 c.p.m. μg^{-1}). Fragments were analysed on long sequencing gels. Assembled nucleosomes were also digested with *Bam*HI, the restricted DNA isolated by Sepharose 2B chromatography and restricted with *Hae*III and *Dde*I. Fragments were analysed by agarose gel electrophoresis. I to IV, four sssDNA samples used for nucleosome assembly. Arrows labelled S, E and B represent fragments generated by *Staphylococcus* nuclease, exonuclease III and *Bam*HI, respectively; *T* indicates the direction of transcription. Dots labelled S represent sequences cleaved preferentially (+) or with low frequency (−) in isolated DNA by *Staphylococcus* nuclease; +E indicates pauses of exonuclease III on isolated DNA; N indicates the location of single-stranded nicks. Shaded area, original location of the ssDNA stretch in sssDNA repaired to double-stranded DNA during nucleosome assembly. Vertical broken lines, nucleosome middle axis.

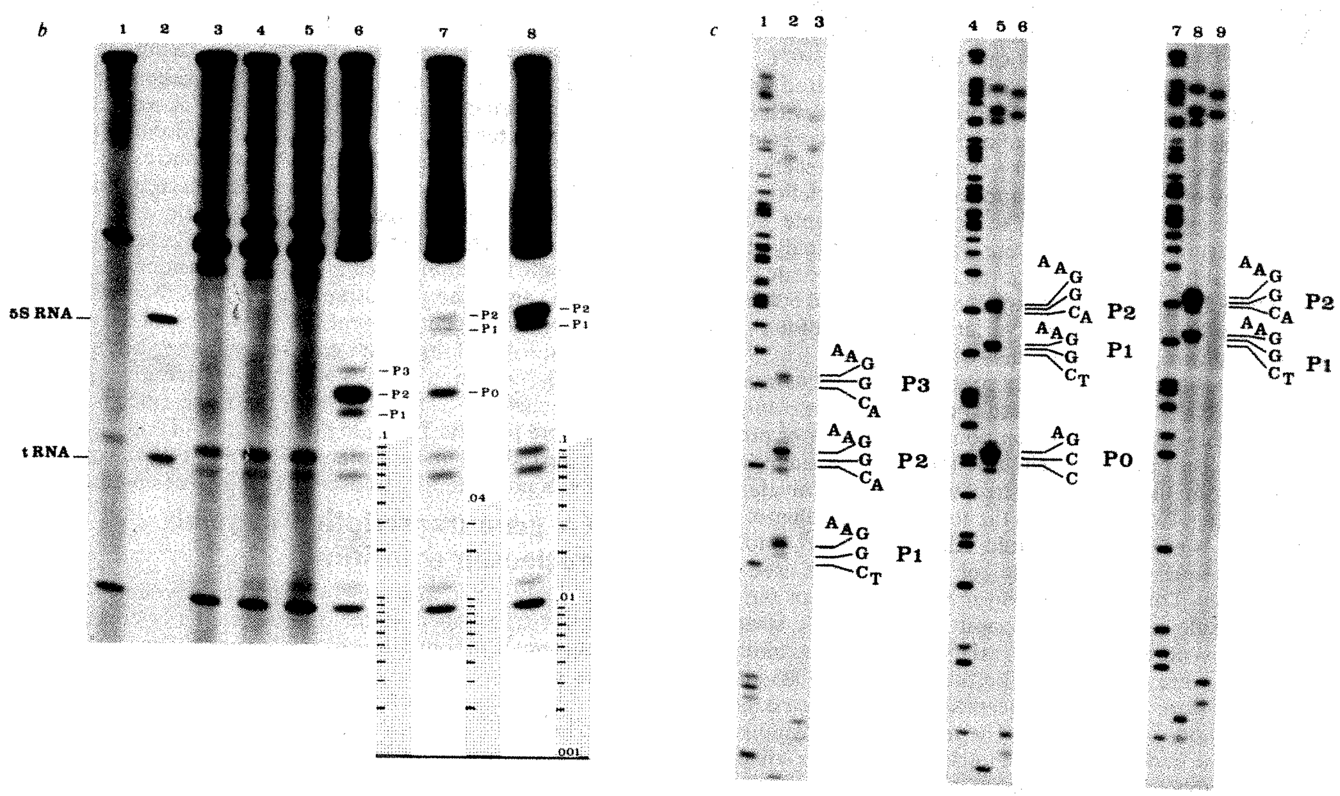

Fig. 2 *a*, DNA base sequence of the 379-bp subclone of a chicken embryo tRNA$_2^{Lys}$ gene. Broken line represents tRNA structural gene sequence; solid lines, 30-bp palindromic DNA. Vertical arrows labelled A and B indicate type A and type B insertions, respectively. *b*, Transcription of the tRNA$_2^{Lys}$ gene within randomly positioned nucleosomes. 1, Assembly extract minus sssDNA; 2, chicken embryo tRNA$_2^{Lys}$ and *E. coli* 5S RNA; 3, isolated DNA lacking 30-bp palindromic insertion (after incubation with assembly extract); 4, isolated DNA with type A insertion; 5, isolated DNA with type B insertion; 6, randomly positioned nucleosomes on DNA without insertion; 7, randomly positioned nucleosomes on DNA with type A insertion; 8, randomly positioned nucleosomes on DNA with type B insertion. The bands representing radioactively labelled tRNA precursors were cut out and quantified by liquid scintillation counting. Efficiencies of transcription (mol tRNA precursor per mol tRNA gene) are indicated by columns on a logarithmic scale shown beside the respective electrophoresis slot. A 25-μl nucleosome assembly extract was diluted to 500 μl with 100 mM KCl, 20 mM NgCl, 10 mM 2-mercaptoethanol, 10% glycerol, 50 mM Tris-HCl *p*H 7.9, and centrifuged at 4 °C in a type 25 rotor (Beckman Instruments) at 90,000*g* for 3 h. The supernatant was pipetted off and immediately 100 μl of 100 mM KCl, 20 mM NaCl, 2 mM $MgCl_2$, 10 mM 2-mercaptoethanol, 10% glycerol, 0.5 mM ATP, 0.5 mM CTP, 0.5 mM UTP, 50 mM Tris-HCl *p*H 7.9, were added and vortexed briefly. Of 0.25 μg sssDNA used in the assembly extract, at least 70% were recovered (as monitored by the ^{32}P-label in the 30-bp palindromic DNA) together with ~50 μg (5%) and ~2 μg (3%) of residual protein and nucleic acids, respectively, from the assembly extract. 12.5 μl of 250 μM [α-^{32}P]GTP (10 Ci mmol^{-1}) and 12.5 μl of partially purified RNA polymerase III (0.1 U, 20 μg protein) were added and incubated at 37 °C for 100 min. 'Carrier' plasmid DNA (5 μg) was added, and nucleic acids were deproteinized and precipitated, then dissolved in 25 μl of 1 mM EDTA, 10 mM Tris *p*H 7.4, and restricted with *Hin*dIII to cut ^{32}P-labelled DNA (originating from sssDNA) into 10-bp fragments. ^{32}P-RNA was analysed on 6% polyacrylamide, 7 M urea gels (2×250×450 mm). Chicken embryo DNA-dependent RNA polymerase III was purified as described elsewhere[30], and the material obtained after DEAE-Sephadex chromatography was used. *c*, S_1 nuclease hybridization mapping of transcription products. 1, Guanosine-specific partial chemical cleavage (G-ladder) of sense transcription probe from DNA without insertion; 2, randomly positioned nucleosomes on DNA without insertion, sense transcription mapping; 3, as in 2, but anti-sense transcription mapping; 4, G-ladder of sense transcription probe from DNA with type A insertion; 5, experiment IV, sense transcription mapping; 6, expt IV, anti-sense transcription mapping; 7, G-ladder of sense transcription probe from DNA with type B insertion; 8, expt VIII, sense transcription mapping; 9, expt VIII, anti-sense transcription mapping. 1 μg of sssDNA was used in the assembly extract and transcription was performed in the presence of 0.5 mM GTP instead of ^{32}P-labelled GTP. After *Hin*dIII restriction, nucleic acids were precipitated and dissolved in 25 μl of 80% formamide, 0.4 M NaCl, 1 mM EDTA, 50 mM PIPES, *p*H 6.8 containing 1 μg of ^{32}P-labelled DNA hybridization probe. Hybridization was at 55 °C for 16 h. 250 μl of ice-cold 200 mM NaCl, 1 mM $ZnSO_4$, 25 mM Na-acetate *p*H 4.5 and 10 U of S_1 nuclease were added and incubated at 37 °C for 3 h. Nucleic acids were precipitated (5 μg of carrier tRNA were added) and analysed on a 10% sequencing gel. Probes for S_1 nuclease hybridization mapping were prepared from plasmids pBR322 N4 *Bam SauA* and pBR322 N4 *Bam SauB*, containing the 379-bp fragment of nucleosomal DNA (see Fig. 2*a*) with a type A and type B insertion, respectively.

solubilization of class I, II and III DNA-dependent RNA polymerases from chicken embryos[30]. A nucleosome monomer fraction comprising a mixture of core particles and nucleosomes (the histone H1 content being reduced to <20% compared with total nucleosome monomers[31]) served as the histone source. As the chromatin was not digested with RNase before isolation of nucleosomes, considerable amounts of snRNA presumably complexed in snRNP[32] were also present (Chr. Elsner, personal communication).

A suitable DNA fragment containing a $tRNA_2^{Lys}$ gene was subcloned from cloned nucleosome tetramer DNA[17]. The orientation of the fragment with respect to restriction sites of the pBR322 plasmid vector and the position of nucleosomes on the corresponding DNA in chicken embryo chromatin are shown in Fig. 1*a*. To generate ssDNA stretches of defined length and orientation, a 30-bp fragment of radioactively labelled palindromic DNA was ligated to the gene sequence and the DNA upstream and downstream from the ligation site was differentially digested with exonuclease III. The manipulated DNA was ligated to an acceptor plasmid and the ends of the single-stranded stretches were annealed via the 30-bp palindromic DNA. In the ionic conditions used in subsequent experiments, the annealed DNA (sssDNA) was stable up to 40 °C. Oligomerization during ligation reactions was minimized and all recombined fragments had the same orientation within the acceptor plasmid. Moreover, a radioactive label was present at a defined site. The time course of the exonuclease III reaction was monitored by observing the disappearance of restriction sites, when the respective DNA base sequence became single-stranded. Several such sites were spaced in roughly 20-bp intervals or multiples thereof near the 30-bp palindromic DNA. As one restriction site always completely disappeared before the following one began to fade, the variation in length of the single strands at a given incubation time was <20 bp.

For the site-directed assembly process, the soluble nucleoprotein fraction, the histone source and ssDNA were combined to give a highly concentrated solution. The amount of protein provided by the nucleoprotein fraction and the quantity of nucleosomes in the histone source were each equivalent to $\sim 5\times 10^7$ nuclei. Compared with the total nuclear volume, both constituents were only 10-fold diluted; 10^{-10} mol of nucleosomes and $<5\times 10^{-13}$ mol of ssDNA were used in a standard assay. During incubation in the presence of the four deoxynucleoside triphosphates and ATP, double-stranded DNA was synthesized from ssDNA and concomitantly nucleosomes were assembled. The positions of the assembled nucleosomes were determined accurately using three complementary methods[33-35] (Fig. 1*b*). The nucleosome position map reveals that the middle axis of one nucleosome always coincided roughly with the midpoint of the ssDNA stretch in the ssDNA used. Single-stranded stretches longer than 120 nucleotides were degraded during incubation and if <40 nucleotides were single-stranded, the assembled nucleosomes associated randomly with respect to DNA base sequence. These data indicate that the stretch of ssDNA itself and/or a protein temporarily bound at about that position direct one nucleosome to a defined site.

tRNA gene transcription within randomly positioned nucleosomes

The soluble ribonucleoprotein fraction of the assembly extract should provide at least 0.02 units per assay of DNA-dependent RNA polymerase III (1 unit incorporates 1 nmol UMP into RNA in 10 min using calf thymus DNA as template[30]), but no such activity was detected in a complete assembly extract, and partially purified RNA polymerase III was soon inactivated when added to the extract. Therefore, after nucleosome assembly we removed most of the components of the assembly extract by brief ultracentrifugation. This did not yield a pure preparation of assembled nucleosomes but the added RNA polymerase III was now active. The concentrations of protein and DNA in the transcription assay were over one order of magnitude lower than in the assembly extract whereas the final concentrations of buffer components were the same. Higher Mg^{2+} concentrations led to precipitation of the assembled nucleosomes, and Mn^{2+} as the divalent cation did not allow for specific transcription. The amounts of RNA polymerase III added provided enzyme saturation.

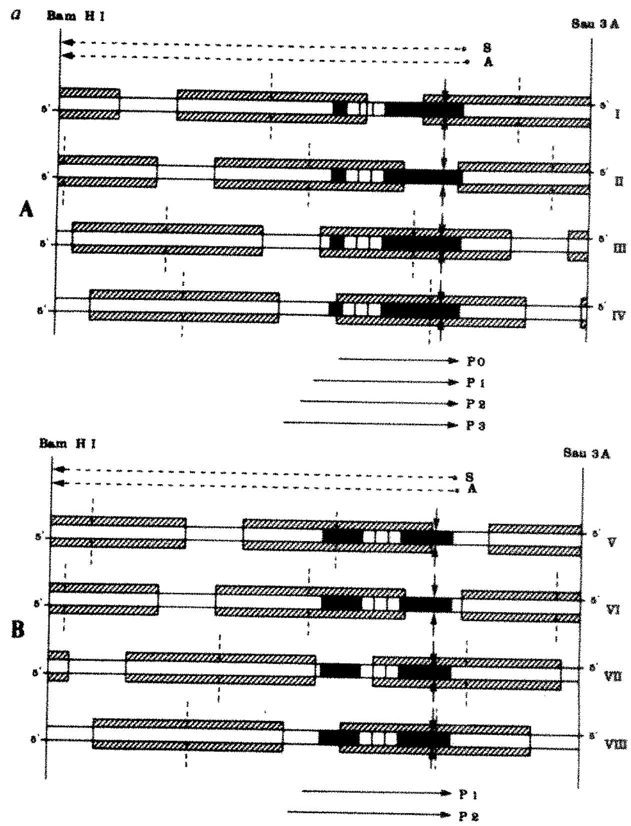
To evaluate transcription experiments, the reference used was transcription of randomly positioned nucleosomes; these were obtained by incubating double-stranded circular DNA with the reconstitution extract. The DNA either had no palindromic insertion or the 30-bp palindromic DNA was inserted into restriction sites for *Alu*I (type A insertion) and *Hin*fI (type B insertion), respectively (Fig. 2*a*). These templates within randomly positioned nucleosomes were transcribed by the added RNA polymerase III into several discretely sized RNA molecules (Fig. 2*b*) but there was no apparent mature tRNA synthesized. Nevertheless, several tRNA precursor samples were identified by S_1 nuclease hybridization mapping[36] (Fig. 2*c*).

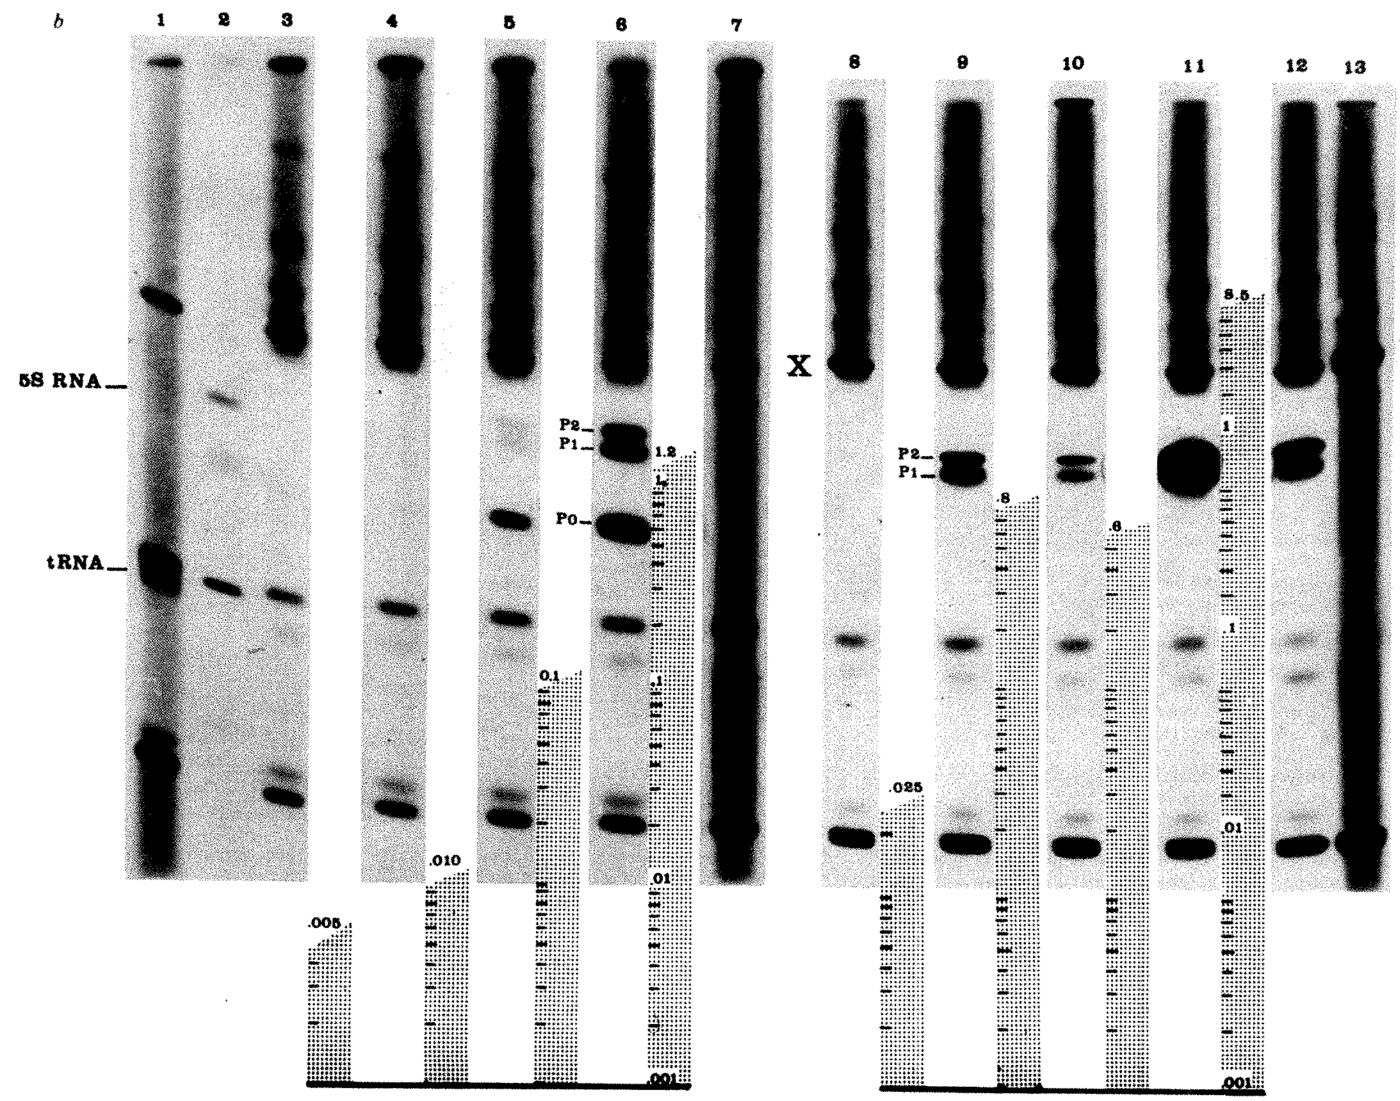
DNA lacking a palindromic insertion was transcribed to give three kinds of tRNA precursors denoted P1, P2 and P3; these amounted to 22.5% of total RNA synthesis, at a ratio of 3 : 6 : 1, respectively. Efficiency of transcription was low, only 1 in 10 tRNA genes being transcribed in 100 min. The precursors each began at the first guanosine residue of the sequence $AGGC^{A}_{T}$, which is repeated 10 (P1), 21 (P2) and 33 (P3) bp in front of the tRNA structural gene. Assay of randomly positioned nucleosomes containing the type A insertion revealed that P1 and P2 were 30 bp longer, P3 was not detected, and another precursor (P0) was predominant (the ratio P0/P1/P2 was 6 : 2 : 2). P0 starts within the tRNA at the 5′ end of the 30-bp palindromic insertion which gives in this position the sequence AGCCA; again the guanosine nucleotide is the initiation site. The amount of precursors synthesized was 9% of the total RNA synthesis; ~4% of the tRNA genes were transcribed in 100 min. Type B insertion DNA within randomly positioned nucleosomes was transcribed with the same efficiency as if no insert were present. P0 could not be detected and P2 was again the preferred precursor. Isolated DNA alone of any of the three types was not faithfully transcribed by RNA polymerase III.

tRNA gene transcription depends on nucleosome position

A strikingly different picture was obtained when the $tRNA_2^{Lys}$ gene was transcribed within site-directed nucleosomes. Four nucleosome positions were assayed which differed with respect to the sequence TTCGA. The four template situations were assembled using sssDNA and type A as well as type B insertions (Fig. 3*a*). TTCGA was either located near the border of a nucleosome (templates I and V); in the linker DNA (II and VI); ~20 bp from the nucleosome middle axis (III and VII); or very close to the middle axis (IV and VIII). Transcription of tRNA precursors was heavily suppressed in templates I and V (Fig. 3*b*) although total RNA synthesis corresponded to randomly positioned nucleosomes. Only 0.5% (I) and 2.5% (V) of the tRNA genes were transcribed. In contrast, when TTCGA was located close to the middle axis of a nucleosome (IV and VIII), transcription of tRNA precursors showed dramatic increases of 30-fold for template IV and 85-fold for template VIII, compared with corresponding control experiments using randomly positioned nucleosomes. This is equivalent to one and eight rounds of transcription, respectively, for each tRNA gene. The predominant precursors were P0 for type A insertion DNA (IV) and P2 when type B insertion was used to construct ssDNA. When the nucleosome middle axis was shifted only 20 bp to the right or left of the TTCGA sequence (experiments III and VII) the transcription of tRNA precursors decreased by one order of magnitude (this in turn demonstrates the accuracy of the nucleosome position analysis). Location of TTCGA in the nucleosome linker DNA yielded elevated precursor transcription with the type B insertion only. The amounts of tRNA precursors transcribed were varied over two orders of magnitude by site-directed assembly of nucleosomes. The $tRNA_2^{Lys}$

Fig. 3 *a*, Scheme of templates used for transcription: I–VIII. A, type A and B, type B insertion of 30-bp palindromic DNA; broken arrows labelled S and A, hybridization probes for sense and anti-sense transcription mapping, respectively; arrows labelled P0, P1, P2 and P3 represent mapping of tRNA precursors; vertical broken line, nucleosome middle axis; vertical arrows indicate location of TTCGA sequence. *b*, Transcription of the $tRNA_2^{Lys}$ gene within site-directed nucleosomes. 1, Assembly extract minus sssDNA; 2, chicken embryo $tRNA_2^{Lys}$ and *E. coli* 5S RNA, respectively; 3, expt I; 4, expt II; 5, expt III; 6, expt IV; 7, isolated DNA from expt IV; 8, expt V; 9, expt VI; 10, expt VII; 11, expt VIII; 12, expt VIII, $\frac{1}{10}$ of sample applied to electrophoresis; 13, isolated DNA from expt VIII. tRNA gene transcription was quantified as for Fig. 2*b*. A sheet of Whatman 3 MM paper was placed between the gel and film covering the area below band X for 2–6 and 8–12 (see also slots 6–8 in Fig. 2*b*). This allows better photographic documentation of the intensity range of tRNA precursor bands by improving the signal-to-background ratio in the relevant area of the gel.





gene investigated was most efficiently transcribed when the sequence TTCGA was associated with the nucleosome middle axis.

To validate these interpretations, we performed two control experiments (Fig. 4). First, after transcription, an aliquot of the transcription assay was routinely digested with restriction endonuclease *Bam*HI. The enzyme should cause cleavage if its site is located in the nucleosome linker DNA whereas cleavage should be suppressed if the site is associated with the nucleosome core (see Fig. 3*a*). DNA was purified and then restricted with *Sph*I, which cleaved once in the acceptor plasmid downstream from the chicken embryo DNA (see Fig. 1*a*). Positive *Bam*HI restriction in assembled nucleosomes yielded a radioactively labelled 591-bp fragment after subsequent *Sph*I restriction. In the case of suppressed cleavage, the circular DNA was just linearized by *Sph*I restriction.

Another aliquot of the transcription assay was digested extensively with *Staphylococcus* nuclease to analyse the amount of radioactive label (residing in the 30-bp palindromic DNA) that could be recovered in the nucleosome core DNA. Autoradiographs of the respective fragments separated by agarose gel electrophoresis are shown in Fig. 4*a*. Obviously, *Bam*HI cleaves template VIII but not template V. The strong band of radioactively labelled nucleosome monomer DNA indicates that in both templates the 30-bp palindromic DNA is associated with the nucleosome core. Taken together, these constitute good evidence that nucleosomes are still in position after transcription. Liquid scintillation counting of the excised agarose gel bands revealed that at least 90% of the nucleosomal templates used belong to the depicted population (Fig. 3*a*). If an unrecognized fraction representing <10% of the material, although having a pronounced effect, were the template, the efficiency of transcription would increase to unrealistic values[37]. We also consider it unlikely that small amounts of ssDNA stretches, persisting after site-directed nucleosome assembly, were the active templates. Templates VI and VII were transcribed with equal efficiency although the coding strand of VI and the noncoding strand of VII, respectively, had to be rendered single-stranded for site-directed nucleosome assembly.

The second control experiment was designed to elucidate further the proteins forming the template. To do this, quantitative amounts of nucleosomes were isolated from the template region. Although several restriction sites seemed suitable to excise the nucleosomal templates by cutting within the respective upstream and downstream nucleosome linker DNAs, only *Bam*HI was active in the transcription assay. Therefore, a subclone was constructed containing an additional *Bam*HI site instead of the downstream *Sau*3A site. Type VIII templates were assembled, incubated for a short period in transcription assays and the excised dimer nucleosomes were purified after *Bam*HI digestion. The yield of protein from 50 such assays (each containing 1 μg of sssDNA) was in the range expected for the dimer nucleosomes (~3–5 μg). SDS-polyacrylamide gel electrophoresis clearly showed (Fig. 4*b*) that the four nucleosome core histones are the predominantly extracted protein fractions. If other proteins were present in molar concentrations of only half those of the core histones, they would be detected on the

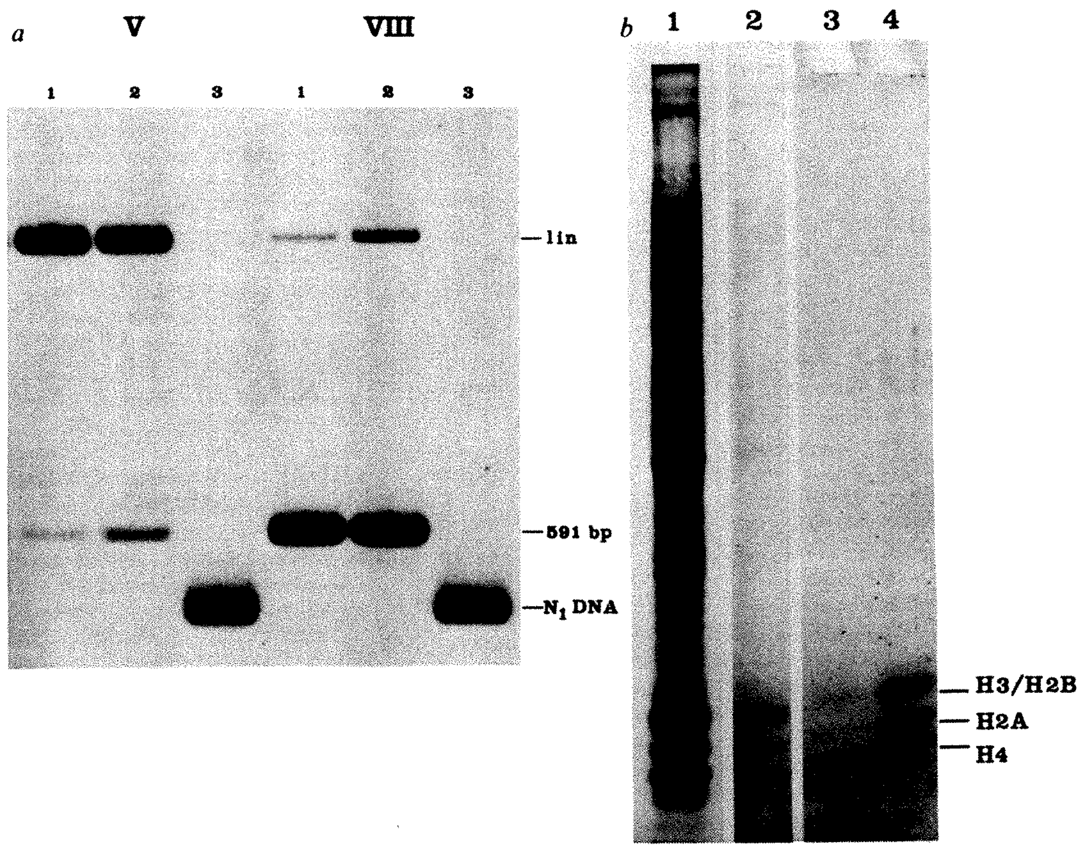


Fig. 4 *a*, Screening of nucleosome positions after tRNA gene transcription. V and VIII refer to the respective nucleosomal templates (see Fig. 3*a*). 1, 10 μl of transcription assay restricted with *Bam*HI; 2, 20 μl of transcription assay restricted with *Bam*HI; 3, 10 μl of transcription assay digested with staphylococcal nuclease. Lin, linearized DNA; N1 DNA, nucleosome monomer DNA. For *Bam*HI restriction, aliquots of the transcription assay were diluted to 50 μl with 150 mM NaCl, 10 mM $MgCl_2$, 5 mM 2-mercaptoethanol, 10 mM Tris-HCl *p*H 7.9. *Bam*HI (10 U) was added and the suspension incubated at 37 °C for 30 min with brief vortexing every 5 min. Nucleic acids were deproteinized and restricted with *Sph*I. For *Staphylococcus* nuclease digestion, aliquots of the transcription assay were diluted to 50 μl (equivalent to 5×10^7 nuclei ml^{-1}) with 0.25 mM EDTA, 20 mM Tris *p*H 7.9, and preincubated at 37 °C for 1 min. 1 μl of 50 mM $CaCl_2$ and 1 μl (1 U) of *Staphylococcus* nuclease were added and incubation continued for 20 min. Nucleic acids were deproteinized and separated on a 1% agarose gel. The gel was dried using DEAE-paper and autoradiographed. Polyacrylamide gel electrophoresis of proteins extracted from the transcription assay and from purified nucleosomal template VIII. 1, Proteins extracted from 15 μl (600 μg protein) of a complete nucleosome assembly extract (25 μl). 2, Total protein extracted from a transcription assay containing a type VIII nucleosomal template. 3, 1.5 μg of the nucleosome monomer preparation (0.7 μg of core histones) serving as the histone source in the site-directed nucleosome assembly system. 4, Total protein extracted from the purified dimer nucleosomes of type VIII nucleosomal templates. Type VIII nucleosomal templates were assembled using sssDNA with a second *Bam*HI site instead of the *Sau*3A site (see Fig. 1 legend). These templates were incubated in transcription assays at 37 °C for 15 min, the $MgCl_2$ concentration was adjusted to 10 mM, and the suspension digested with 100 U of *Bam*HI at 37 °C for 30 min with brief vortexing every 5 min. Fifty such assays were pooled and dialysed extensively against 20 mM KCl, 1 mM EDTA, 5 mM Tris-HCl *p*H 7.9. Samples (1 ml) were layered on to 6–30% (w/w) linear sucrose gradients and centrifuged in a SW41 rotor at 150,000*g* for 15 h. Fractions containing the dimer nucleosomes of interest (identified by the radioactive label residing in the 30-bp palindromic DNA) were recovered, extensively dialysed against H_2O and lyophilized. Proteins were extracted by incubation in 2% (w/v) SDS, 3% (v/v) 2-mercaptoethanol, 0.1% (w/v) phenylmethylsulphonyl fluoride, 10% (v/v) glycerol at 95 °C for 5 min. Proteins were separated on a 5–20% (w/v) polyacrylamide linear gradient gel using as buffer 50 mM sodium phosphate, 0.1% (w/v) SDS. The gel was stained with Coomassie brilliant blue, R-250.

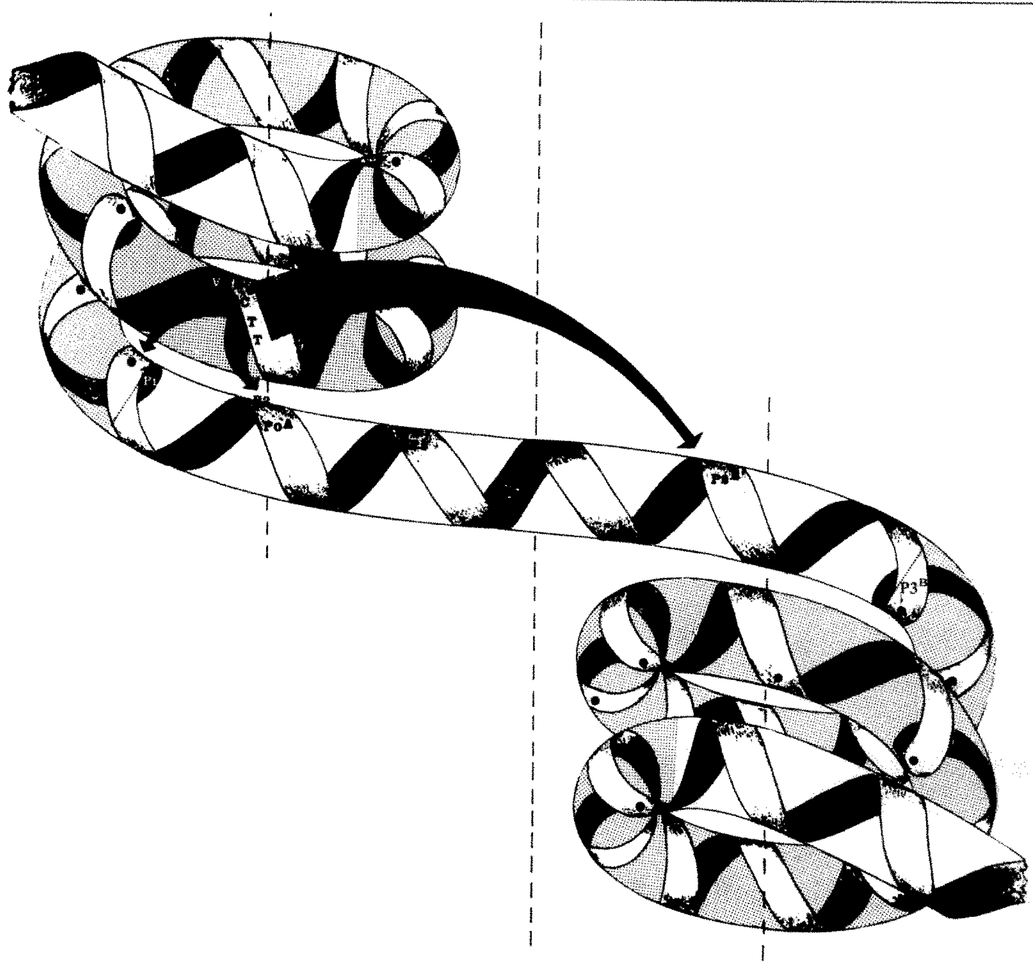

Fig. 5 Functional tRNA gene promoter structure. DNA of the nucleosome core is shown against a shaded background. P1, P2 and P3 represent initiation sites used *in vivo*; $P0^A$, $P1^B$ and $P2^B$ are initiation sites in assembled nucleosomes containing type A and type B insertion DNA, respectively. $P3^B$ is not used for initiation.

gel. Thus, the protection against nucleases which produced the corresponding nucleosome position maps (Figs 1*b* and 3*a*) could not be effected by proteins other than histones.

Nevertheless, additional proteins are required to promote efficient transcription of the tRNA gene within the assembled nucleosomes. The transcription assay contained a heterogeneous mixture of proteins although it was partially purified from excess reconstitution extract and histone source to allow for RNA polymerase III activity (Fig. 4*b*). However, so far any attempt to purify the nucleosomal template further drastically reduced transcription efficiency. When the RNA polymerase III preparation was added to a finally purified template such as the one used for the protein analysis above, faithful tRNA gene transcription was not observed. We are now investigating which components of the assembly extract and transcription assay are ultimately required using immunological methods.

Conclusions

The construction of sssDNA requires the insertion of a 30-bp palindromic DNA fragment into the tRNA gene. The influence of this insertion on transcription efficiency had to be elucidated before the effect of different nucleosome positions could be interpreted. In this context we have found that insertion of unrelated DNA into the 5′-end region of the tRNA gene (type A insertion) decreases transcription of the gene, whereas the corresponding insertion is tolerated near the middle of the gene (type B insertion). These results are consistent with recent data on consequences of sequence substitutions within a $tRNA_1^{Met}$ gene[25].

The three $tRNA_2^{Lys}$ precursors observed were not processed to mature tRNA in the *in vitro* system used. We cannot exclude, however, the possibility that precursor P3 alone represents initiation of transcription and that P2 and P1 are equivalents of processing steps[38–40].

The model[41] in Fig. 5 shows the three-dimensional aspects of a functional tRNA gene promoter. The *in vivo* location of the TTCGA sequence within nucleosomes for chicken embryo tRNA genes is identical to the most efficiently transcribed template of nucleosomes assembled *in vitro*. In both cases the TTCGA sequence—the region of symmetry for a 5-bp complementary palindrome—is associated with a region of symmetry of the nucleosome core, that is, the middle axis in two-dimensional schemes. We assume that this structure is primarily recognized by RNA polymerase III, as a deviation from the coincidence of TTCGA with the nucleosome middle axis decreased transcription of the gene. Location of TTCGA near the middle of the nucleosome linker DNA may have an equivalent function (see template VI) although this situation was not detected *in vivo*. The preferred *in vivo* initiation site, P2, and $P0^A$, the incorrect but preferred initiation site with type A insertion DNA, are located near to the TTCGA sequence. However, the distance to TTCGA is not the main selection principle, as with type B insertion DNA transcription starts predominantly at $P2^B$ and not at the closer $P1^B$ site. The orientation of $P2^B$ with respect to the next nucleosome, which is similar to that of P2 in the first nucleosome, may be the reason for its selection. As we observed no initiation at the hypothesized $P3^B$ site, $P2^B$ may also represent the farthest possible distance from TTCGA. The distance between P1 and $P2^B$, where initiation sites should principally be located, provides sufficient space to tolerate introns in tRNA genes[39,40,42]. (In a recent paper[17] a figure shows two cloned $tRNA^{Lys}$ genes containing introns. From the established sequence we now consider these introns to be artefacts because they are duplications of acceptor stem and dihydrouridine stem sequences. They probably originate from the tRNA gene enrichment procedure which involved repair synthesis of double-stranded DNA by *E. coli* DNA polymerase I. Moreover, we were unable to isolate $tRNA^{Lys}$ genes containing introns from a chicken

DNA library (gift of J. D. Engel), although genes corresponding to the one described in the present article were detected.)

We have shown that the functional state of a tRNA gene can be programmed by nucleosome positions. The conserved short DNA base sequence TTCGA which occurs too frequently in the large chicken genome to have any functional significance, is converted into an efficient promoter through a specific arrangement in the nucleosome.

We thank Dr H. Tiedemann for discussion, Chr. Elsner, S. Hense and Chr. Keitel for help in experimentation, and J. Staubach for the graphic design. This work was supported by the Deutsche Forschungsgemeinschaft through Sonderforschungsbereich 29.

Laboratoire d'Astronomie Spatiale, Les Trois Lucs, 13012 Marseille, France

The galaxy NGC5128, better known as the powerful radio source Centaurus A, is a puzzling object appearing as an elliptical galaxy crossed by a dense lane of dust and gas. Its structure and evolution are not well understood, although this object is quite near (we shall adopt 5 Mpc following Burbidge and Burbidge[1]), bright, and has been widely observed in the past few years. We have obtained the first complete velocity field of the ionized gas in NGC5128, with a 10-km s^{-1} precision, from Perot–Fabry interferometry with the ESO 3.6-m telescope. It shows that the gas is rotating in a thick disk (~1 kpc thickness), without any evidence of the perturbations expected from the encounter of an elliptical and a spiral galaxy. Our observations favour the hypothesis of the evolution of a spiral galaxy in which the formation of the disk is very late compared with the bulge.

The velocities in this object were first studied by Burbidge and Burbidge[1] with a slit spectrograph and a 2-m telescope. It was then observed by Sersic[2] with a 1.5-m telescope, using slit spectrography (mainly for the kinematics of the elliptical component through absorption lines) and Perot–Fabry interferometry (in Hα line) for the kinematics of the gas. Eventually Graham[3] made a good study of the rotation of the gas and of the motions in the elliptical component with a slit spectrograph attached at the CTIO 4-m telescope.

The more recent photometric study by Dufour *et al.*[4] gives mainly photometric parameters of the elliptical component; the gas being more difficult to study because of the high inclination and thickness of the disk, and because of the great quantity of dust.

Our study of the gas in NGC5128 has been made through a narrow bandwidth filter (15 Å FWHM), centred at 6,575 Å, isolating the Hα emission line of the ionized gas. Comte and Georgelin took Hα plates of the galaxy with a focal reducer and an image tube attached at the ESO 3.6-m telescope. Four interferograms of the object taken with the same device and a Perot–Fabry interferometer (see Table 1) gave interesting information on the morphology of the ionized gas and particularly the kinematics of the gas. They provide the first complete velocity field of the ionized gas in this object.

A preliminary analysis[5] suggested that the gas is approximately distributed in a disk inclined at ~75° with respect to the line of sight; the temperature of this ionized gas being quite normal as shown by the relatively thin interference lines (<1 Å wide) which indicate no peculiar turbulence[6].

Such an observation suggests that NGC5128 is not the result of a collision in which a spiral galaxy would have merged into an elliptical galaxy as has been often suggested. The following complete analysis of the velocity field of NGC5128 confirms this opinion.

Another interesting detail is the detection of three bubble-like H II regions[5] of ~200 pc in diameter (assuming that the galaxy is at 5 Mpc). This is quite comparable with bubble regions observed in nearby spiral galaxies such as M31 (ref. 7), M33 (ref. 8) or NGC925 (ref. 9).

Concerning the morphology of the galaxy itself, we obtained a striking image by viewing simultaneously on a screen a Hα plate (projected through a red filter) and a visible plate (projected through a green filter). The two components of the galaxy are quite distinct: the old elliptical component appears as a yellow ball, while the surrounding gas and dust show up vividly in red and black. The plates used for this composite image are I 1864 (40-m in exposure) and I 1886 (30 s exposure), see Table 1. Due to our very narrow Hα interference filter (15 Å FWHM) and our fast aperture ratio, $f/2$ with a 3.6-m telescope, the H II regions are much clearer than on the colour photograph obtained by Dufour *et al.*[4,10] with a larger Hα filter (54 Å FWHM) but with a slow aperture ratio, $f/10$ with a 1-m telescope. This is especially true a long way from the nucleus where

* With RCA image intensifier.

one can see nothing but dust on their photograph (image tubes were used by both teams).

The measurement of the four interferograms gave about 900 velocity points which were averaged in 210 squares of 15 arc s a side on the sky (see Fig. 1). The aim of averaging the velocity points is to reduce the internal dispersion of the measurements and to facilitate the drawing of the isovelocity lines. In each square we computed the dispersion of the measurement (not taking into account the dispersion inside each single interferogram), which gives an idea of the expected precision for the value of the radial velocity. We then computed the statistical error, for each square, defined as $s/\sqrt{n}$ where n is the number of interferograms in the considered square. The average of the statistical error indicates a mean precision of 11 km s^{-1} on the whole velocity field. This allows us to draw the isovelocity lines with a 30 km s^{-1} step.

The general design of the velocity field (see Fig. 2) is quite comparable with the velocity field of spiral galaxies such as M83 (NGC5236) (ref. 11), NGC7793 (ref. 12), or NGC253 (ref. 13) (although there is evidence for non-axisymmetric motions in the central parts of this galaxy, possibly due to a weak bar). This supports the idea that the ionized gas is laying in a disk, as already suggested from the elliptical shape of the distribution of the H II regions[3] and from the colour analysis[4]. The superimposition of all of our interference fringes on the same picture also indicates that the disk is inclined to roughly 75° with respect to the line of sight. This last method is very powerful for the Hα detection because of the high contrast it offers[14], about 1,000 times the contrast of a 250 Å wide colour filter. Nevertheless, both morphological and kinematical points of view rule out the possibility of a cylindrical structure as suggested by Rodgers and Harding[15]. Furthermore, there is no evidence of strong non-circular motions in our velocity field. However, near the minor axis the isovelocity lines are not exactly perpendicular to the major axis, their inclination suggesting some accretion (if one considers that the northern side of the disk is nearer than the southern one, as clearly shown by the dust lane appearance).

The most noticeable perturbation in our velocity field is at ~1 arc min west of the nucleus and can be explained by a strong thickness of the gaseous disk which would be mainly concentrated in a thick belt surrounding the elliptical component. The

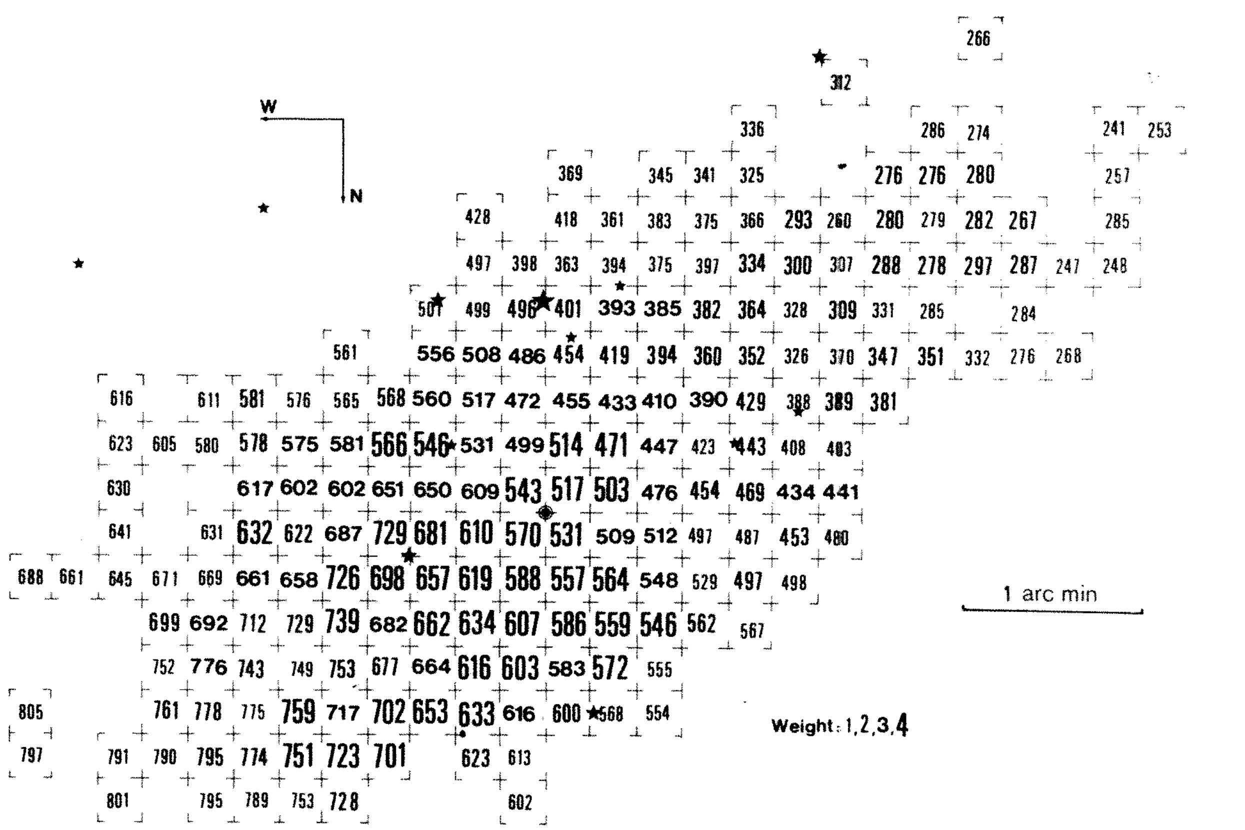

Fig. 1 Velocity measurements in NGC5128 averaged in squares of 15 arc s side. Four different sizes of figures are used, depending on how many interferograms (1, 2, 3 or 4) are averaged in a given square. The position of the nucleus is indicated (dotted circle) also with reference stars.

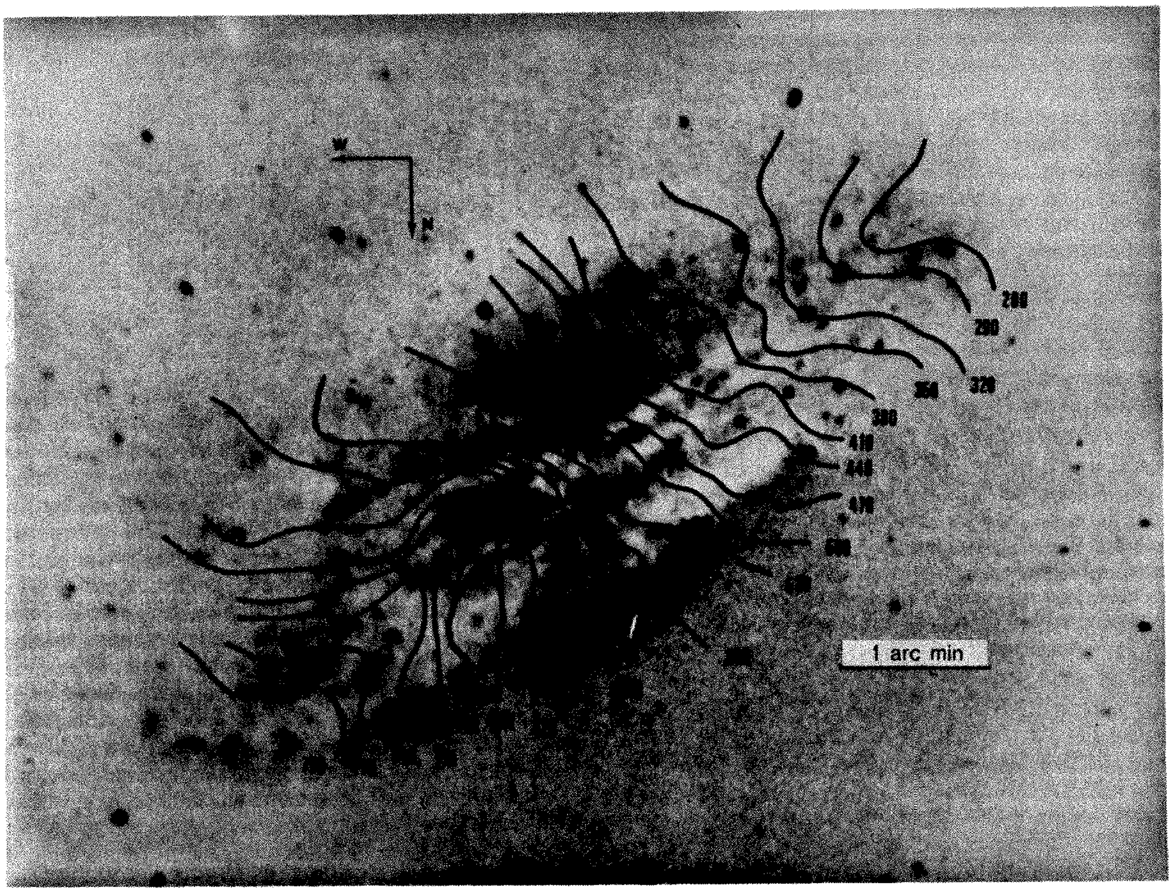

Fig. 2 Isovelocity lines superimposed on a Hα photograph of NGC5128. These lines are eye-estimates from Fig. 1, taking into account the weight of the data.

location of the maximum velocity gradient in this zone indicates that we are looking at gas $\sim$1 kpc above the mean plane of the disk, this gas masking the underlying disk. Such an extension of matter out of the mean galactic plane is confirmed by the morphology of the galaxy where one can see dust high above this plane silhouetted on the elliptical component. This would also explain the velocity anomalies stressed by Möllenhoff[16]. However, we could not confirm the superposition on the line of sight of objects with different radial velocities mentioned by some observers[9,15].

Another interesting detail is the straight chain of dust and H II regions stretching along 2 arc min from the nucleus towards the south-east. This chain also seems to be out of the mean plane (because it is silhouetted in front of the elliptical component while the nucleus is seen slightly under it when looking at the disk from above, with north down) and may be connected to the western part mentioned above. When studying the rotation curve of the disk, the assumption that it is flat would diminish the velocity gradient in the central part of the galaxy because the gas along the major axis is masked by gas above the plane. This gas being out of the plane of the disk, and away from the major axis, indicates slower radial velocities than expected on this line of sight and hence apparently slower rotation velocities. This remark will be helpful when analysing the rotation curve in the first 2 arc min from the nucleus.

Taking into account the squares lying within 33° (in the sky) of the major axis we obtain the rotation curve of Fig. 3 where we also plotted Graham's points[3]. The agreement is fairly good between the two sets of data. The parameters giving the least dispersion for our points are close to Graham's parameters[3]. From these data we have found: inclination of the plane of the galaxy with respect to the plane of the sky, $i = 73° \pm 3°$; position angle (PA) of major axis $= 127° \pm 5°$; systemic velocity $V_S = 545$ km s$^{-1} \pm 5$ km s^{-1} (while Graham[3] found, respectively, $i = 73°$, PA $= 125°$ and $V_S = 548$ km s^{-1}).

These last values of inclination and position angle of the major axis agree well with previous works[1,2,4,16]. The main problem concerns the systemic velocity for which Burbidge and Burbidge[1] found 605 km s^{-1}, Sersic[2] 462 km s^{-1}, Kunkel and Bradt[17] 508 km s^{-1}, Möllenhoff[16] 602 km s^{-1}. Our result, 545 km s^{-1}, is in very good agreement with the most recent papers of Graham[3], 548 km s^{-1}, or Whiteoak and Gardner[18] who find 551 km s^{-1} from H I observations.

Up to 4 arc min from the nucleus the symmetry of the two quadrants of the rotation curve is pretty good. Beyond 4 arc min we have almost no information for the southeastern quadrant, although we observe (somewhat lessened) the same tendency as Graham. That is, we see an increase of the velocity gradient in the outer part of the disk, which is probably due to matter moving out of the mean plane. Between 4 and 7 arc min in the northwestern quadrant the velocity gradient seems, in contrast, to diminish rapidly. Despite the small number of points available there, it seem probable that the rotation curve reaches a maximum between 5 and 7 arc min. The dashed line of Fig. 3 indicates a maximum rotation velocity $V_M = 352$ km s^{-1} at $r = 5.35$ arc min. This symmetric curve is a least square fitting polynomial (of the third degree) obtained from our points within 20° of the major axis to which we added the two outermost points given by Graham[3], also with our outermost point (this last point is in fact at 52° from the major axis but it is in very good agreement with Graham's outermost points[3]). Although their weight is rather poor and they may be out of the mean plane of the disk, it is the only way of extending our rotation curve beyond 4 arc min.

Following the method of Burbidge *et al.*[19] this least square curve indicates a mass $M = 0.9 \times 10^{11} M_\odot$ to $1.0 \times 10^{11} M_\odot$

within 4 arc min and a mass $M = 1.8 \times 10^{11} M_\odot$ to $2.0 \times 10^{11} M_\odot$ within 7 arc min, depending on the excentricity of the ellipsoïds used in the model. This value is smaller than the rough estimate $3 \times 10^{11} M_\odot$ given by Graham[3] from Kepler's law applied to the outermost points.

We have tried a more sophisticated method developed by Monnet and Simien[20] in which a model galaxy is built up from two components: an elliptical bulge and a flattened disk. This model shows that the bulge generally gives rise to a very steep velocity gradient near the nucleus, while our observed rotation curve surprisingly looks like a pure disk rotation curve, thus suggesting at once that we are dealing with a massive disk and a rather light bulge. The photometric parameters used for the spherical bulge were those given by Dufour *et al.*[4] (equivalent radius $r_e = 305$ arc s with a surface brightness $\sigma_B\ (r_e) =$ 22.94 mag arc s^{-2}, which gives a luminosity $I_e = 44.1 \mathscr{L}_\odot\ \mathrm{pc}^{-2}$). For the disk we used the photometric parameters given by Freeman[21] from Sersic's isophotes ($r_e = 336$ arc s, $I_e =$ $34 \mathscr{L}_\odot\ \mathrm{pc}^{-2}$), although, because of the great quantity of dust and because of the high inclination these parameters are not very reliable.

Assuming a constant $M/L_B = 5$ for the bulge, which is the value expected for such an elliptical component[20,22] we find a theoretical rotation curve for the bulge alone where the gradient near the nucleus is five times the observed gradient, with a maximum of more than 300 km s^{-1} near 1.5 arc min, before slowly decreasing. Comparison with Fig. 3 shows that the discrepancy between this model and the observations is much too high, even if we take into account the projection effect mentioned above, which would lessen the gradient in the inner part of the curve. Values of M/L_B between 1 and 3 for the bulge, comparable to what is found in globular clusters[23], are far more acceptable when comparing the model with the observations.

Eventually we found a satisfactory fit with an average $M/L_B \sim 2$ for the bulge and $M/L_B \sim 30$ for the disk, which is rather high but seems acceptable for a spiral galaxy[20]. From the total luminosity of each component we thus deduce a total mass of $1.1 \times 10^{11} M_\odot$ for the bulge, $8.2 \times 10^{11} M_\odot$ for the disk and $9.3 \times 10^{11} M_\odot$ for the galaxy as a whole. An intermediate solution with a varying M/L_B for the bulge (from 1 at the centre, up to 5 around 5 arc min) and a constant $M/L_B \sim 15$ for the disk could give a better fit, but it is not very realistic to assume a varying M/L_B for such an homogeneous stellar population. The mass would be then around $2 \times 10^{11} M_\odot$ for the bulge and $4 \times 10^{11} M_\odot$ for the disk, thus giving a total mass around $6 \times 10^{11} M_\odot$. The result remains much greater than our first estimate, based on the rotation curve, mainly because it relies on the outermost photometric data and hence takes into account a much greater part of the galaxy down to the sky background.

Note that, in any case, the disk component is found to be more massive than the elliptical component, while the bulge is much more luminous.

We will now try to review briefly some of the different hypotheses concerning the possible evolution of NGC5128.

(1) The encounter of an elliptical and a spiral galaxy is strongly suggested by the two clearly different populations (an old stellar population in a bright elliptical bulge and a young stellar population, rich in gas and dust, in a disk). The main problem is that there is no evidence for the encounter, such as strong erratic motions in the gas. Furthermore, there is no significant difference between the systemic velocity we found for the disk, $V_S = 545$ km s$^{-1} \pm 5$ km s^{-1}, and the velocity found by Graham[3] for the elliptical component, 536 km s$^{-1} \pm 30$ km s^{-1}. Also, there is no trace of the nucleus supposed to have belonged to the spiral galaxy as Dufour *et al.*[4] emphasize. Then it is surprising that the main axis of the slightly prolate bulge (PA = 35°)[4] and the rotation axis of the disk (PA = 37°) are the same, within 2°. At least there are many other comparable galaxies having a prolate spheroïd as a bulge, which suggest that they are a peculiar type of object rather than the result of an encounter. For example: NGC5363, NGC1947, Cyg A and PKS1934 − 63 (ref. 24), NGC2865 (ref. 25) (the Spindle galaxy) and NGC612 (ref. 26) which is a radiogalaxy quite similar to NGC5128 in both radio and optical wavelengths.

(2) There are fewer objections to accretion of a gas cloud by an elliptical galaxy than there are for the above hypothesis. Furthermore, as already mentioned by Graham, the huge dust lane on the eastern side of NGC5128 seems to indicate the direction of accretion of matter coming from outside of the disk plane. However, the accretion of a primeval gas cloud can hardly explain why there is so much dust and why the H II regions are as metal rich as normal H II regions of spiral galaxies[4]. Furthermore, this hypothesis would imply a peculiarly favourable accretion angle to make the main axis of the disk and bulge coincide as well. An interesting model of accretion, studied by Tubbs[27], supposes that the mass of the disk is negligible, which is far from being the case as we have seen above.

(3) We prefer the hypothesis of a normal spiral galaxy (with late formation of the disk) of SO or Sa type, composed of a bright bulge and a thick disk. This disk is still under formation, undergoing accretion of dust and gas and slowly settling down. Larson's theory[28] on the evolution of elliptical and spiral galaxies could help explaining such an object if one assumes

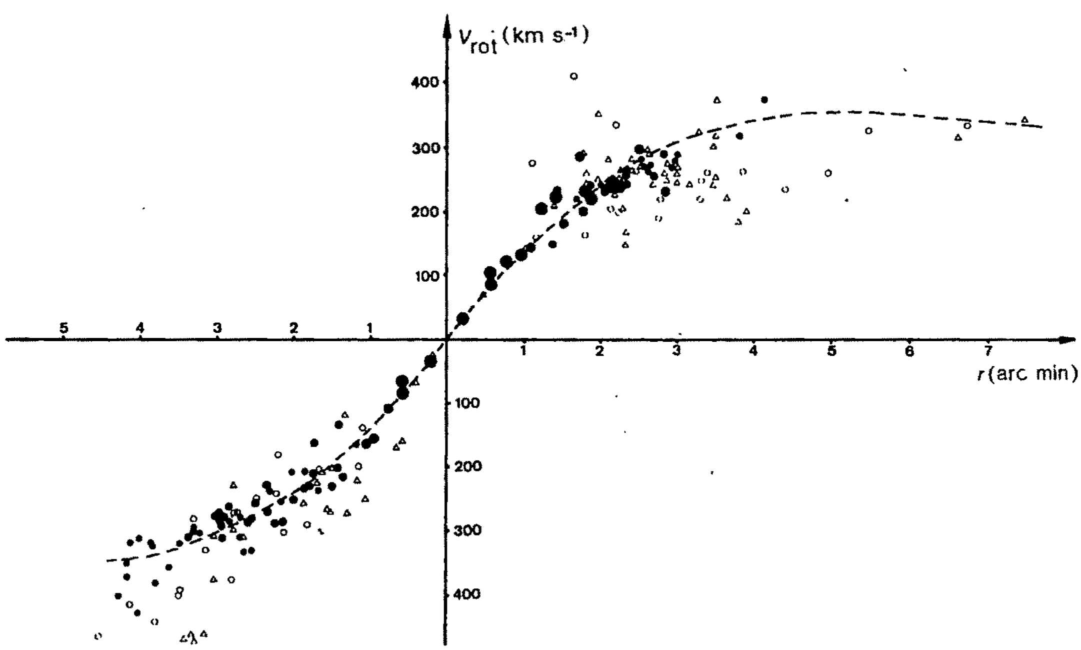

Fig. 3 Rotation curve of NGC5128. ●, Our velocity points within 20° from major axis which have different sizes, depending on their weight on Fig. 1; ○, our velocity points between 20° and 33° from major axis; △, Graham's velocity points. The dashed line is a least square fitting curve (see text).

that the protogalactic cloud was very large with a high density at its centre.

In the Larson's hypothesis[28] of a two-phase structure the dense clouds will rapidly form stars in a spheroïdal component (which may be prolate as showed by Gott and Thuan[29]), while the less dense intercloud gas will take a long time to settle to a disk and form stars. The continuing formation of this disk could explain the activity of NGC5128 and the associated powerful radiosource.

Field stimulated exoelectron emission from borosilicate glass

Terence M. Roberts & D. Brynn Hibbert

Department of Chemistry, Bedford College, University of London, Regent's Park, London NW1 4NS, UK

Exoelectrons, those electrons in energy levels of solids which are not fed by normal conduction mechanisms, have been detected at the surface of various materials[1]. Emission of exoelectrons may occur during mechanical stress[2], chemical reaction[3], or on heating[4] or irradiation by photons of suitable energy[5]. Thermally stimulated exoelectron emission gives rise to so-called glow curves, in which the emitted current goes through a maximum as the temperature is increased. Robertson[1] has suggested that an electric field may stimulate exoelectron emission in an analogous manner to thermal and photo emission. We describe here experiments which demonstrate the phenomenon of field stimulated exoelectron emission (FSEE), and discuss its relation to steady-state emission.

Electron emission from borosilicate glass under the influence of a strong electric field was first demonstrated by Hibbert and Robertson[6,7]. The emission current was continuous, noisy, of low intensity, and occurred from discrete 'active sites' on the glass surface. Further work[8] revealed that the total current is made up, in part, of fluctuating bursts from the active sites, whose characteristics are similar to each other. We have observed that on applying a high voltage to the glass emitter, a pulse of electrons is emitted, after which the steady-state emission is recorded. We suggest that the initial pulse of electrons is due to FSEE.

The apparatus (Fig. 1) for detecting FSEE was an evacuated (10^{-4} Pa) chamber containing a clean (trichloroethylene, chromic acid, distilled water), cylindrical Pyrex glass emitter surrounded by an earthed nickel gauze having 80 spaces per inch. The field at the surface of the glass for an applied voltage V is:

$$E = V\varepsilon_1/[r_1\varepsilon_2 \ln(r_1/r_0) + r_1\varepsilon_1 \ln(r_2/r_1)]$$

where r_0, r_1 and r_2 are the internal and external radii of the glass tube, and the radius of the nickel gauze respectively. ε_1 and ε_2 are the relative permittivities of glass and a vacuum ($\varepsilon_1 = 4.8$). For $r_0 = 5.5$ mm, $r_1 = 6.5$ mm and $r_2 = 9.5$ mm, $E = 370\,V$ V m^{-1}. The range of voltages applied in these experiments was 3–15 kV. Electrons which passed through the gauze were detected by a channel plate electron multiplier (Mullard G40/25) and a pattern of the emission from a section of the glass surface was displayed on a phosphor screen. A photomultiplier detected the light output from the screen. By suitable masking and focusing, the emission from a single active site was recorded. The photomultiplier output was calibrated and found to be proportional to the emission current in the range studied. Steady-state emission followed a Schottky-like equation[6]:

$$I = N \exp[-(\phi - aE^{1/2})/kT]$$

where N and a are constants (experimentally $a = 1.8 \times 10^{-4}$ eV V$^{-1/2}$ m$^{1/2}$), k is Boltzmann's constant, E the electric field strength, ϕ(= 0.97 eV) the energy difference between the electron levels and the vacuum level in the absence of an electric field, and T the absolute temperature. Exoelectron emission was studied by applying a voltage step to the glass emitter, and following the time development of the emission current on an oscilloscope. In addition, a ramped voltage was applied in an attempt to produce a glow curve of exoelectrons.

Figure 2 shows the steady-state emission pattern at 7 kV from a section of the borosilicate glass emitter. On stepping from 0 kV to the operating voltage each site showed a pulse of brightness which was recorded on the oscilloscope (Fig. 3).

Fig. 2 Emission pattern of 13 mm diameter glass tube showing 2.5 mm diameter central area. Field at surface 2.59 MV m^{-1}.

0028-0836/82/180042—02$01.00

The height of the current pulse was dependent on the recovery time from switching off the previous voltage step. For a recovery time of <100 ms no exoelectron emission could be detected; ~10 s was required for the pulse to be restored to its maximum height (Fig. 4). The height of the pulse increased with both applied voltage and temperature. Such pulses were detected at the lowest voltage of 3 kV. A ramped voltage (0 V to 10 kV at 300 V s^{-1}) gave no glow curve. We attribute this to the ease at which exoelectrons are emitted by electric fields and the existence of a steady-state emission current which would mask any glow curve.

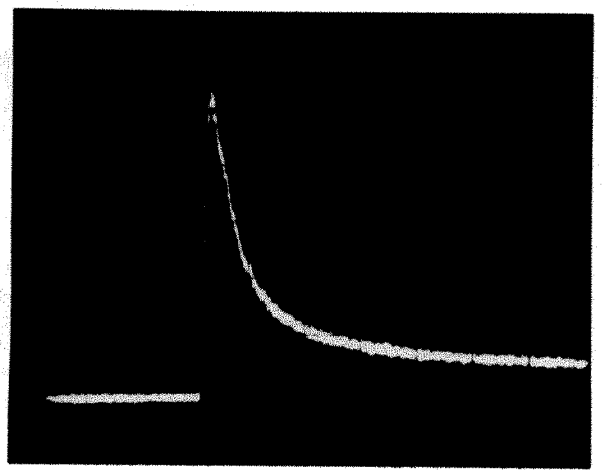

Fig. 3 Oscilloscope trace of the photomultiplier output of a burst of electrons from a single site, on stepping the emitter voltage from 0 V to 15 kV; 1 division on time axis = 0.5 s.

The connection between the exo and steady-state emission is still to be fully determined. Although steady-state emission may come from discrete energy levels in borosilicate glass[6] (there being no recognized conduction electrons), because of the slow, activated replenishment of exoelectrons, it is unlikely that the two types of emission occur from the same levels. Exoelectron emission has also been shown to depend strongly on surface conditions, and may disappear entirely in ultra-high vacuum[9]. Steady-state emission from glass is, however, maintained in ultra-high vacuum[7].

In conclusion, the pulse of electrons observed on applying a high voltage appears to be of exoelectrons; they are weakly held at the surface, and are only slowly replenished after emission. It should now be possible to investigate exoelectrons from other materials by the voltage step method. In particular, metals used as catalysts may be studied by this technique.

Helium isotopic systematics of oceanic islands and mantle heterogeneity

M. D. Kurz & W. J. Jenkins

Department of Chemistry, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

S. R. Hart

Center for Geoalchemy, Department of Earth and Planetary Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Isotopic variations in oceanic igneous rocks provide important constraints on models of oceanic mantle structure. Of particular interest is the global negative correlation between $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$, which has been used to estimate 'bulk earth' values[1–3] for $^{87}Sr/^{86}Sr$, $^{87}Rb/^{88}Sr$ and $^{143}Nd/^{144}Nd$. Simple two-reservoir models have failed to explain all the isotopic variations, however, because of the complicated trends in Pb isotopes[4–6]. This has led to suggestions that recycled oceanic crust or sediments must be considered in these models[7–9]. We report here the results of helium isotopic analyses in basaltic phenocrysts from the islands of Gough and Tristan da Cunha. Because basalts from the islands lie near bulk earth on the Sr–Nd correlation diagram[3], the study was initiated to characterize the helium isotopic signature of this component. Whereas the ^{3}He in mantle gases is mostly primordial, the ^{4}He is primarily radiogenic, having been produced by decay of ^{238}U, ^{235}U and ^{232}Th. High $^{3}He/^{4}He$ ratios in igneous rocks therefore indicate primordial volatiles[10,11]. We believe that the present results are inconsistent with the notion that the mantle beneath Gough and Tristan da Cunha is primitive or undepleted relative to mid-ocean ridge basalt (MORB). Helium isotopic results on basaltic glasses and phenocrysts from the rift zone of Kilauea confirm the previously reported high values from this area[12–15]. We also report new analyses from Loihi Seamount (40 km south-east of Kilauea), which does seem to be derived from a more primitive source. When these data are combined with values for MORBs (from ref. 16) and plotted with respect to $^{87}Sr/^{86}Sr$, the observed trends offer insight into the different source regions for oceanic island basalts and the nature of mantle heterogeneity.

As sub-aerial basalts are largely degassed, they are of little use in the analysis of magmatic gas. This contrasts with MORB glasses, which are quenched rapidly enough on the ocean floor to trap substantial quantities of the magmatic gas[17,18]. Kaneoka *et al.*[12], however, have shown that the olivine phenocrysts from Kilauea basalts trap some of the magmatic gases that existed during crystal growth. The present results confirm the high $^{3}He/^{4}He$ ratios they reported for Kilauea phenocrysts, and we extend the approach to basalts from several other islands.

The samples were lightly crushed in a steel mortar, sieved, and the phenocrysts in the 20–40 mesh size range were separated by 'Frantz isodynamic' separation and hand-picking. Glassy samples were handpicked to exclude alteration, oxide

0028–0836/82/180043—05$01.00

crusts and non-vitreous chunks. Because the vesicles in submarine basalts can be a source of gas loss, chips >2 mm in size were selected[19]. After sonic cleaning, 1–2 g of the phenocrysts, or 400–500 mg of glass, were placed in a stainless-steel vessel designed specifically for *in vacuo* crushing[19]. The details of the gas mass spectrometry are similar to those reported earlier[19], except that the released helium was purified and expanded directly into the mass spectrometer, which resulted in a lower procedural blank ($1.0\text{–}2.0 \pm 0.3 \times 10^{-9}$ cm^3 STP ^{4}He with atmospheric $^3He/^4He$). Due to the small sample size, variability in the blank is the primary contributor to the experimental uncertainty (see Table 1).

Strontium isotopic analyses of several of the samples were performed using techniques that have been described elsewhere[20]. The measured $^{87}Sr/^{86}Sr$ ratios for Loihi Seamount samples KK 20-4 and KK 23-3 were both 0.70358 ± 0.00002, and Staudigel *et al.*[21] reported a value of 0.70358 ± 0.00004 for sample KK18-8. Gough Island samples ALR 26G and ALR 41G had $^{87}Sr/^{86}Sr$ ratios of 0.70527 ± 0.00004 and 0.70521 ± 0.00005 respectively; the Prince Edward sample WJ21E had a ratio of 0.70305 ± 0.00004. These values are reported relative to an Eimer and Amend standard value of 0.70800; the errors are 2σ for in-run statistics.

The helium results are reported in Table 1 for phenocryst samples from Tristan da Cunha, Gough, Prince Edward, Jan Mayen and Kilauea. We also report the analyses of submarine basaltic glass from the Loihi Seamount and the east rift of Kilauea, and the rock type and sample source for each sample are listed; a more detailed description is given in ref. 22.

Examination of the phenocryst samples in thin section shows that the most likely residence site for the helium is in the ubiquitous melt inclusions. In most cases these inclusions have undergone some post-entrapment crystallization, which explains why most of the helium is released by crushing *in vacuo* (see Table 1). Crystallization excludes the gas from the melt, but helium is still trapped in the phenocryst. The absence of xenocrysts in these samples was verified by petrographical examination[22].

In testing whether phenocrysts can be used for gas analysis, the samples from Kilauea were chosen because they are well characterized, and because they allow comparison of the phenocryst helium with the magmatic helium. The good agreement between the phenocrysts from the Kilauea picrite (H66050) and the two submarine glasses from the same volcanic rift supports the use of phenocrysts to indicate magmatic $^3He/^4He$ ratios. Our results also confirm the relatively high ratios in Kilauea phenocrysts reported by Kaneoka *et al.*[12], and by several laboratories for the Kilauea fumaroles[13,14]. The Loihi samples have even higher $^3He/^4He$ ratios, up to 31.9 times atmospheric, but have $^{87}Sr/^{86}Sr$ ratios that are indistinguishable from the values for the Kilauea samples[23]. Note that Kaneoka and Takaoka[15] have reported even higher $^3He/^4He$ ratios (up to 37 times atmospheric) for phenocrysts from Haleakala (Maui).

In contrast, the Tristan da Cunha and Gough samples contain helium with $^3He/^4He$ ratios significantly lower than the MORB values. As it was impossible to separate the amphibole in TK 26 from the interstitial opaque oxides and other accessory minerals, and because there is some question about the origin of these gabbroic nodules[24], we also analysed a basalt from Tristan da Cunha that contained large phenocrysts (TK 46A). Special care was taken to avoid opaque oxides and possible host rock contaminants (U and Th rich phases). The similar $^3He/^4He$ ratio for two different phenocryst phases from the same sample (TK 46A and ALR 26G) and between different volcanic eruptions suggests that this is not a problem.

While Kilauea, Loihi Seamount, Tristan da Cunha and Gough all have $^{87}Sr/^{86}Sr$ ratios higher (more radiogenic) than MORB values, the Hawaiian samples have higher $^3He/^4He$ ratios and Tristan and Gough have lower $^3He/^4He$ ratios. As shown in the plot of $^3He/^4He$ against $^{87}Sr/^{86}Sr$ (Fig. 1), the results fall into two distinct trends. For reference, we also show MORB

All samples were crushed *in vacuo* except those denoted*, which had the helium extracted by melting *in vacuo* after crushing. All $^3He/^4He$ ratios are reported relative to atmospheric (R/R_a) using an atmospheric value of 1.384×10^{-6}. Sample sources: †Dr S. Humphris; ‡Dr A. le Roex; §Dr S. Maaloe; ‖Dr W. J. Voerwoerd, see ref. 50; ¶Dr S. O. Agrell; #Dr J. Moore, see refs 51 and 23, sample numbers refer to Table 2 of ref. 51; ††Dr D. Clague, see ref. 52.

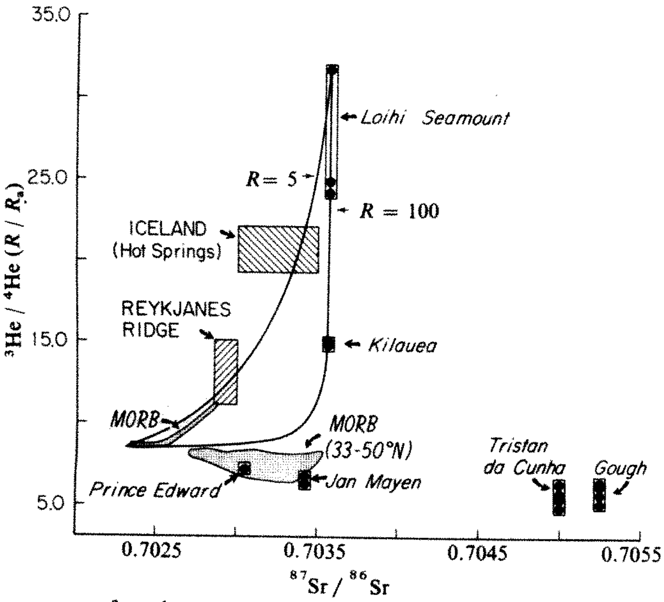

Fig. 1 $^{3}He/^{4}He$ (relative to atmosphere) plotted against $^{87}Sr/^{86}Sr$ for oceanic volcanic rocks. Data sources: Mid-Atlantic Ridge (MORB)[16]; Reykjanes Ridge[26,40]; Iceland[26,27,40,41]; Kilauea this study and ref. 23; Loihi Seamount, this study; Prince Edward, this study; Jan Mayen this study and ref. 42; Tristan da Cunha this study and ref. 3; Gough Island, this study. Note that the Gough, Prince Edward, MORB, Kilauea, and Loihi samples had helium and strontium isotopic analyses run on the same samples; in all other cases, the fields indicated represent ranges of values for similar samples from the references listed above. For the Icelandic hot springs, the highest reported $^{3}He/^{4}He$ ratios[26,27] were selected to minimize atmospheric effects. The highest terrestrial $^{3}He/^{4}He$ ratios (37 × atmospheric) reported by Kaneoka and Takaoka[15] are not plotted because they do not report $^{87}Sr/^{86}Sr$ ratios. The two mixing lines were calculated assuming component 1 has $^{3}He/^{4}He = 8.5 \times R_a$, $^{87}Sr/^{86}Sr = 0.70230$ and component 2 has $^{3}He/^{4}He = 32.0 \times R_a$, $^{87}Sr/^{86}Sr = 0.70358$. As shown by Langmuir *et al.*[28], curvature is determined by the ratio R, where in the present case:

$$R = \frac{{}^{4}He_1 \, {}^{86}Sr_2}{{}^{4}He_2 \, {}^{86}Sr_1}$$

with age of the Earth. This contrasts with continental crust, which is greatly enriched in U and Th and degassed of ^{3}He values for the North Atlantic, which are discussed in detail elsewhere[16], and literature values for Icelandic hot springs and the Reykjanes Ridge[25,26].

To explain these trends, we can immediately eliminate *in situ* (post-eruptive) decay of U and Th isotopes to produce the low $^{3}He/^{4}He$ trend, as all the samples are of essentially zero age and the phenocrysts analysed contain low U contents. This is also supported by the analyses of olivine and clinopyroxene from the same sample, which yielded similar results. We believe that the trends in Fig. 1 are most easily accounted for by three component mixing. One component, with $^{3}He/^{4}He$ of $\sim 1.17 \times 10^{-5}$ (8.5 × atmospheric) and $^{87}Sr/^{86}Sr$ of ~0.7025, would then be identified as the 'typical MORB' reservoir. A second component, characterized by high $^{3}He/^{4}He$ and higher $^{87}Sr/^{86}Sr$ ratios, would be consistent with a more primitive source derived from 'mantle plumes', as has been suggested for Hawaii and Iceland[15,27]. The third component is characterized by low $^{3}He/^{4}He$ and high $^{87}Sr/^{86}Sr$ ratios, as indicated by the results for Tristan and Gough.

The curve defined by the MORB–Loihi trend in Fig. 1 is consistent with mixing, as ratio–ratio plots do not always display straight lines for binary mixing[28]. Several mixing lines (calculated for different He and Sr concentrations in the end-members) are shown for reference in Fig. 1. The helium isotopic ratio of a possible primordial end-member (either 'planetary' or solar) is shown in Fig. 2. Because of the high He/(Th + U) ratio characteristic of the Sun and meteorites, there is little change in the $^{3}He/^{4}He$ ratio (due to addition of radiogenic ^{4}He) during formation, resulting in quite low present-day $^{3}He/^{4}He$ ratios (see Fig. 2). The primordial end-member would then lie between the Loihi seamount point and bulk earth as plotted in Fig. 2. Because it is not clear that there is a genetic relationship between the Earth and the meteorites, or whether any undifferentiated terrestrial mantle still exists, the true end-member must remain uncharacterized[16].

The low $^{3}He/^{4}He$ samples for Gough and Tristan da Cunha require mixing with a reservoir that has been enriched in Th and U relative to ^{3}He for time periods long enough to lower the $^{3}He/^{4}He$ ratio. The time required depends on the $^{3}He/(Th + U)$ ratio[16]. Our data cannot distinguish between seawater, subducted oceanic crust plus sediment, or old continental crust as a source for this component. As shown in Fig. 2, any of these would serve as an appropriate end-member if the mixing hypothesis is used to explain the variations. However, given the Sr-Nd correlation and the expected effect of seawater addition on these isotopes, seawater seems unlikely[29]. Seawater also contains small quantities of helium relative to basaltic melts, so addition of large quantities would be required to lower the $^{3}He/^{4}He$ ratio, and would result in extreme variations in $^{87}Sr/^{86}Sr$.

The suggestion[30] that an important source of isotopic variation in oceanic basalts is contamination from the oceanic crust through which the eruptive basalts must pass is plausible in that oceanic crust should separate ^{3}He from Th and U by degassing. However, this mechanism seems unlikely for several reasons. First, volcanics on Tristan da Cunha, Gough, Jan Mayen and Prince Edward are erupted through oceanic crust that is much younger (and thinner) that the crust beneath Hawaii, and yet the $^{3}He/^{4}He$ ratios are lowest. If contamination were significant, one would expect the oldest, most radiogenic crust to lower the ratio the most. Second, special conditions would be required to lower the magmatic $^{3}He/^{4}He$ ratio by this mechanism. The contaminating crust must have lost most of its initial He, and must have produced (and retained) substantial quantities of radiogenic ^{4}He. The generally low U and Th contents of unaltered oceanic crust require extreme enrichment in these

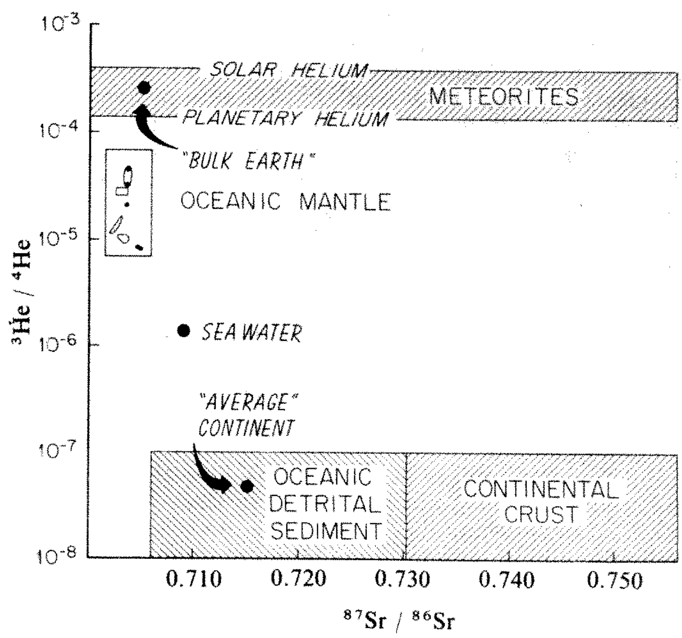

Fig. 2 Simplified plot of $^{3}He/^{4}He$ versus $^{87}Sr/^{86}Sr$ for terrestrial materials and meteorites. Data sources: chondrites[43,44]; bulk earth[3,44]; oceanic mantle (see Fig. 1); seawater[45,46]; continental shield[10,47]; oceanic detrital sediments[48]; and average crust[6,49]. Oceanic detrital sediments, and average crust are assumed to have the same range of $^{3}He/^{4}He$ ratios as continental gases[10]. We have also ignored meteoritic spallation helium, which can have $^{3}He/^{4}He$ ratios higher than 10^{-4}. The upper boundary for the oceanic mantle field is defined by helium analyses by Kaneoka and Takaoka[15].

elements to generate enough ^4He in reasonable time periods. This is particularly true for Tristan de Cunha and Gough, which are situated on oceanic crust that is 10–20 Myr old.

One mechanism that cannot be ruled out is the separation of He from U and Th by multiple melting events. For example, if the mantle beneath Tristan da Cunha and Gough were 'enriched' by the addition of a small amount of melt or fluid (equivalent to metasomatism[31]), it is conceivable that helium would be lost by degassing, while the U and Th would be retained. The $^3He/^4He$ ratio would then decrease, due to extremely low $^3He/U$ and $^3He/Th$ ratios; on melting, this enriched mantle would yield low $^3He/^4He$ ratios. Trace element analyses from Tristan da Cunha and Gough suggest that the lavas are enriched in Th and U relative to chondrites[32], making this feasible. However, the small degree of partial melting, which may generate oceanic island alkali basalts, makes it difficult to determine the source mantle characteristics from the trace element concentrations and ratios[33]. In addition, the physical process by which helium is lost from the mantle without melt removal is unclear.

The subduction of altered oceanic crust and sediments into the mantle has been suggested as an explanation for some of the Sr–Nd–Pb variations[7,8,34], and is quite consistent with our results for Tristan da Cunha and Gough. If the low $^3He/^4He$, high $^{87}Sr/^{86}Sr$ mantle source region is produced by adding subducted crust into the mantle and then remelting, it is important to evaluate the effect on helium isotopes. The $^3He/^4He$ ratio that would result from remelting of this material is a function of the initial helium content of the crust, the amount of degassing it has undergone (both before and during subduction), the helium content of the mantle to which it is added, and the relative proportions of the two mantle types. These formidable uncertainties make a quantitative treatment impossible; however, there is clearly sufficient U and Th present to produce the observed variations, depending on the physical processes occuring. For example, in 200 Myr, $4\times10^{-6}\,cm^3g^{-1}$ of radiogenic ^4He will accumulate in oceanic crust having an average U content of 100p.p.b. (parts per 10^9) and $Th/U=2$ (ref. 35). If we take $1\times10^{-5}\,cm^3g^{-1}$ as an upper limit of the initial helium content of oceanic crust, the $^3He/^4He$ ratio in this crust will decrease by at least 30% in 200 Myr. In addition, it is possible that hydrothermal alteration adds U to the crust, making 100 p.p.b. a lower limit[7,36,37]. The other extreme is an oceanic crust that degasses completely on formation, leaving only radiogenic ^4He to remix with the mantle on resubduction. Craig and co-workers[38] have interpreted low $^3He/^4He$ ratios in present-day back-arc volcanic systems to be a result of mixing between the helium in the downgoing slab and the helium in the underlying mantle, which suggests that degassing continues after crustal formation. In both cases, the $^3He/^4He$ will decrease to some extent, depending on the mixing ratio of the two components. Clearly, there is sufficient U and Th to lower the $^3He/^4He$ ratio significantly even before subduction. If the subducted crust remains in the mantle for long periods, as suggested by Hofmann and White[7], substantial quantities of radiogenic ^4He may accumulate.

All three mechanisms described above (crustal contamination, multiple melting, and remelting of subducted crust in the mantle) could conceivably produce the low $^3He/^4He$ trend defined by the Tristan da Cunha and Gough points. At present, we believe that the subducted crust hypothesis most easily accounts for the trend. In contrast to the other two processes, subduction is a commonly observed phenomenon. The mechanism for separation of He from U and Th is degassing of the oceanic crust, another presently observable phenomenon[14]. Further, the allowed time periods and U enrichments necessary to lower the $^3He/^4He$ ratio are geologically quite reasonable.

If all the high $^3He/^4He$ islands are produced by two component mixing with the same end-members, then various $^4He/^{86}Sr$ ratios are required, as this will determine the curvature of the mixing line. For example, if the Kilauea isotopic signature is derived by mixing the two end-members shown in Fig. 1, then the high $^3He/^4He$ end-member must have higher Sr contents or lower He contents (or both, see Fig. 1). Alternatively, another end-member may be involved. Note that Tatsumoto[35] observed different Pb isotopic compositions for each of the five sub-aerial Hawaiian volcanoes. He suggested that the linear trend, defined by the Hawaiian volcanoes, on the $^{207}Pb/^{204}Pb$ against $^{206}Pb/^{204}Pb$ plot was a mixing line. To test the mixing hypothesis, a more detailed study of the Loihi Seamount and the island of Hawaii is underway in our laboratories.

It would appear that $^3He/^4He$ measurements, coupled with the other isotopic measurements, are an important discriminant between primordial and 'recycled' mantle source regions. The reason for the large variations is that separation of He and Th + U occurs by degassing, which is not the case for the Rb–Sr, Nd–Sm, and U–Pb systems. Note that the samples lying close to bulk earth on the Nd–Sr correlation line, such as Tristan da Cunha and Gough, are not necessarily representative of undepleted mantle. It is possible to derive the trend by mixing between some crustal components[9,39] and the depleted MORB reservoir, resulting in a coincidental bulk earth value.

Therefore, on the basis of the helium isotopic information, three distinct mantle reservoirs are required: depleted (the MORB source), undepleted, and recycled. The islands displaying the highest $^3He/^4He$ ratios have tholeiitic affinities (Hawaii and Iceland), while the islands consisting of alkali basalts have characteristically lower $^3He/^4He$ ratios (Tristan da Cunha and Gough). More detailed sampling is required to confirm this trend.

We thank the following for providing samples: S. O. Agrell, D. Clague, S. Humphris, A. le Roex, S. Maaloe, J. Moore, R. K. O'Nions and W. Voerwoerd; also A. le Roex, G. Thompson, J.-G. Schilling and H. Dick for interesting discussions, and B. Haskell for editorial comments. M.K. thanks the Education Office of the WHOI/MIT Joint Program in Oceanography for their continuing support. This work was supported by NSF grant OCE-7909379 and USGS contract 14-08-001-G541. This is WHOI contribution no. 4955.

Scaling rules in rock fracture and possible implications for earthquake prediction

C. J. Allègre, J. L. Le Mouel & A. Provost

Institut de Physique du Globe, Université Paris 6, 2 place Jussieu, Paris 75005, France

A major preoccupation in physical sciences has been to interpret macroscopic events from microscopic phenomena. In some cases the change of scale is efficient and fairly easy to perform, but in others it turns out to be difficult and uninteresting. Success or failure is due more to the nature of the events than to the efficiency of the theoretical methods used. Some macroscopic phenomena have their origin in a microscopic organization which can be transferred to larger scales whereas others attain their structure on the macroscopic scale itself. Thus before applying scaling laws techniques[1–4] one must ensure that embedded scales are suggested by physical observations. That this seems to be the case for the fracture of rocks is supported by geological, seismological and rock mechanics observations. We have therefore built a very simple model based on scaling laws which yields a criterion for fragility at different scales and views rupture as a critical point. We use this model here to outline a general approach to earthquake prediction.

Fracturing occurs in rocks at all scales, from the microscale (microcracks) to the continental scale (megafaults), and the geologist can equally well observe embrittlement and rupture phenomena under the microscope as on satellite photographs (Fig. 1). But are the various scales of fracture related to one another? The following observations suggest they are: (1) field geologists know that the great faults of the crust—such as the San Andreas fault—actually consist of anastomosed faults, sometimes arranged *en échelon*, thus weakening a whole domain of the crust, down to variable depths[5]. (2) Seismologists who study source phenomena often have to introduce in their models complex rather than single faults, each one contributing to the observed radiation pattern[6,7]. (3) Rock mechanicists, when studying fracture in the laboratory, observe that it is preceded by the concentration of a swarm of microfissures which are themselves the result of an accumulation of microcracks[8–11]. From this set of observations one can suggest that fracture at the macroscopic scale is a consequence of accumulations of ruptures at lesser scales.

This hypothesis has been actually adopted by Brace and his students[8,9,11,12]. They have submitted rock samples to progressive triaxial loading ($\sigma_1, \sigma_2, \sigma_3$) and studied the increase of microcrack density with increasing load. This increase seems to be the result of two distinct processes: (1) the nucleation of new cracks, that is, the birth of new rupture points in the material; and (2) the growth of pre-existing cracks. In fact, as noted by Brace *et al.*[8] and Tapponnier and Brace[11], the nucleation seems to occur most often from a pre-existing crack. The distinction between the two processes is thus subtle and the increase in crack density can be considered to be ruled by a single phenomenon with a given activation energy.

The law governing the increase of microcrack density with deviatoric stress ($\sigma_1 - \sigma_3$) depends strongly on the confining pressure. But what seems to occur generally is that the macroscopic fracture is not preceded by an accelerated growth of microcrack density as measured over the whole sample. When the sample is examined at different scales one observes that cracks collect in some regions, but that these microscopic regions are roughly homogeneously distributed in the medium, even when the rupture threshold has been reached. On the other hand, the larger the scale the stronger is the spatial heterogeneity. The heterogeneity reaches, of course, a limit which determines the fracture itself whose orientation follows the laws established by Anderson[13].

We will now try to explain those observations with a simple renormalization group (RG) model and examine possible implications of the model for earthquake prediction.

For each elementary domain of rock (say 100 μm), we define two states: when the local microcrack density in the domain is greater than some critical value, it is considered as fragile (f); otherwise it is considered as sound (s).

As shown elsewhere (for example, see ref. 11), the mean microcrack density d depends linearly on ($\sigma_1 - \sigma_3$) (for a given σ_2), but the local density varies considerably within the sample. The probability for an elementary domain to be fragile, p, is directly proportional to d and thus linearly related to ($\sigma_1 - \sigma_3$) (for a given σ_2):

$$d = d_0 + b(\sigma_1 - \sigma_3)$$

$$p = ad = ad_0 + ab(\sigma_1 - \sigma_3) \qquad (1)$$

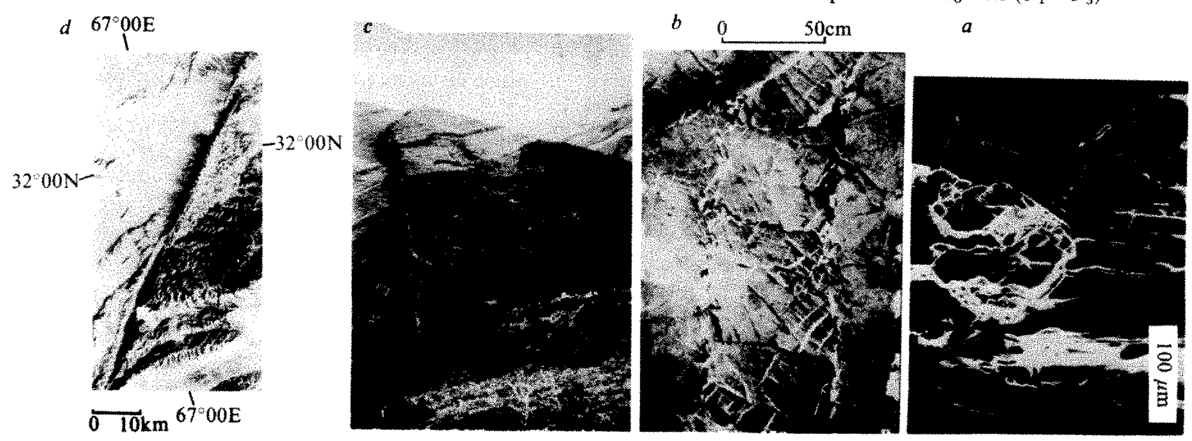

Fig. 1 Examples of fracture at different scales. *a*, Microcracks in quartz grains are induced by intense cracking in magnetite and plastic flow in biotite. (Westerly granite, fracture stress, 35 bar of confining pressure, room temperature.) *b*, Tension gashes, stylolites and micro shear faults in horizontal Mesozoic limestones (near Les Matelles, in Languedoc, France). The microstructures combine to form a fault zone at a larger scale. *c*, Master fault of the El Asnam, Algeria, earthquake (magnitude = 7.3, 10 October 1980). In the hills north of El Attaf, the break, several kilometres long, has up to 4 m of vertical throw. *d*, Landsat image of the Chaman strike-slip fault south-west of the Katawaz basin near the border between Afghanistan and Pakistan. The fault system, ~1,200 km long, may have accommodated as much as 500 km of left lateral displacement of India past Afghanistan in the past 40 Myr.

0028–0836/82/180047—03$01.00

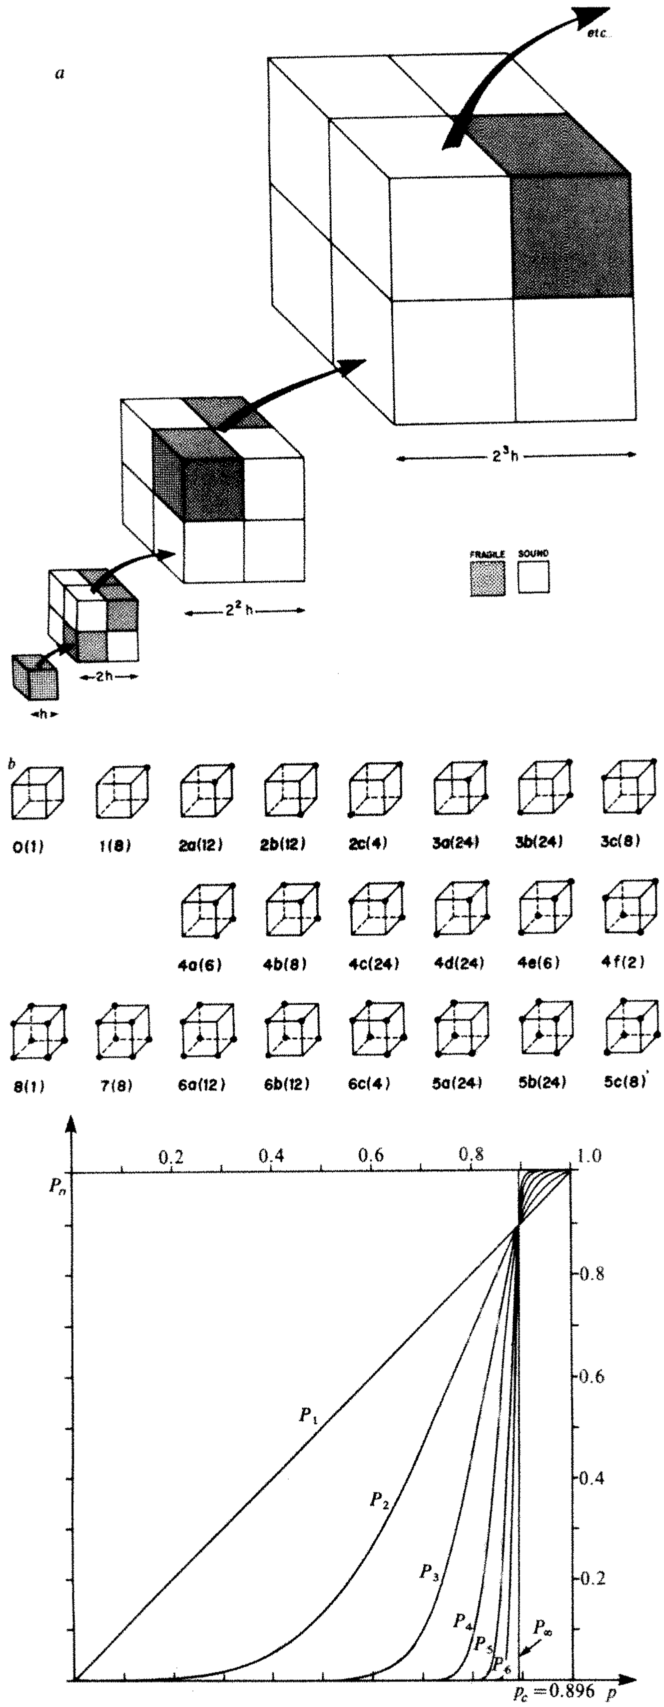

Fig. 2 *a*, Illustration of the renormalization group model. *b*, Now an *n*-order cube is depicted as a simple cube with its corners representing the eight constitutive $(n-1)$-order cubes. Each corner is marked by a solid dot when the corresponding $(n-1)$-order cube is fragile. This defines 22 configurations labelled 0, 1, 2a, . . . 8 with their multiplicities in parentheses. The probability for a configuration with m corners fragile and multiplicity μ is: $\mu(P_{n-1})^m(1-P_{n-1})^{8-m}$. *c*, Probability P_n for an n cube being fragile plotted against the microscopic probability p.

Parameters d_0 and b depend on σ_2, whereas a can be considered purely geometrical.

Let us now develop a criterion for fragility at different scales. Let the elementary domain of order 1 be a cube of unit side (for example, 100 μm). Let the order of 2 cube be composed of 2^3 elementary order of 1 cubes, and so on (Fig. 2*a*).

In terms of $(n-1)$ cubes (we write n cube for the order of n cube), there are $2^8 = 256$ different n cubes. Taking the symmetry group of the cube into consideration, this number reduces to 22 topologically different configurations, each with a given multiplicity (Fig. 2*b*). An n cube will be considered sound whenever there is a 'pillar' of sound $(n-1)$ cubes that links two opposite faces. We thus consider as fragile the configurations labelled 4f, 5c, 6b, 6c, 7 and 8 in Fig. 2*b*. If P_n is the probability for an n cube being fragile, then:

$$P_1 = p, \quad P_2 = \Pi(p), \quad \ldots, \quad P_n = \Pi(P_{n-1}) \qquad (2)$$

with

$$\Pi(x) = 2x^4(1-x)^4 + 8x^5(1-x)^3 + 16x^6(1-x)^2 + 8x^7(1-x) + x^8$$

The polynomial $\Pi(x)$ has the following simple properties: $\Pi(x) = x$ for $x = 0$, $x = p_c = 0.896$ and $x = 1$. It monotonously increases with x on $[0, 1]$, being less than x on $]0, p_c[$ and greater than x on $]p_c, 1[$. Furthermore, $\Pi'(1) = \Pi'(0) = \Pi''(0) = \Pi'''(0) = 0$. This explains the characteristics of the probability law P_n, which are illustrated in Fig. 2*c*. A striking feature is how rapidly the curves converge to the (Heaviside) step-function $H(p-p_c)$ with increasing n. For $n = 5$, P_n positively jumps from 0 to 1 when p passes p_c.

This crude model allows one to account very simply for the observations of Tapponnier and Brace[11]. When counting microcrack density at the lowest scale an increase of this density increases with $(\sigma_1 - \sigma_3)$ is observed, but nothing clearly announces the macroscopic rupture which appears as an 'exogen' discontinuity in a continuous process. The situation is quite different when looking at larger scales: little occurs before p gets to values close to p_c; then the fragility probability P_n jumps rapidly to values close to 1 and rupture occurs (see Fig. 3). p_c is thus a critical probability, the threshold for crack percolation.

Of course, the fragility criterion we have chosen is arbitrary and oversimplified. Other configurations of $(n-1)$ cubes may be supposed to make the n cube fragile. More refined criteria may be built by considering higher-order scaling steps ($3^3 = 27$, $4^3 = 64$, and so on, elementary cubes instead of $2^3 = 8$). In any case we get a recursion relationship between P_{n-1} and P_n of the form $P_n = \Pi(P_{n-1})$, Π being a polynomial with properties analogous to the ones above. Figure 4 illustrates a case in which the renormalization polynomial $\Pi(x)$ has no fixed point except the trivial ones $x = 0$ and $x = 1$. Although such a choice might seem inappropriate ($P_n \to 0$ when $n \to \infty$ for all $p < 1$), it leads to the same conclusions (a step from very low to very high probabilities at the highest scales) due to the fact that there is

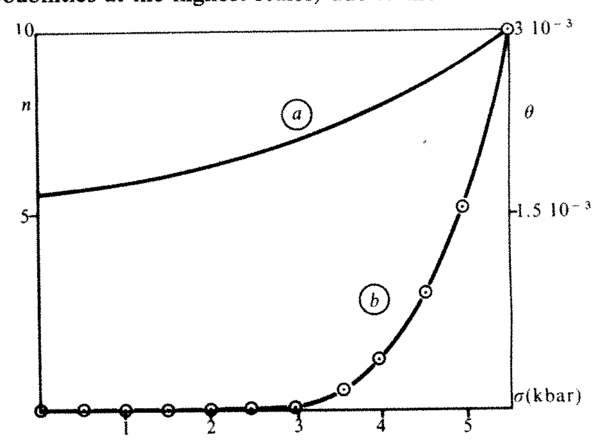

Fig. 3 Schematic representation of some experimental results (adapted from ref. 11). Sample of Westerly granite, confining pressure 500 bar. *a*, Variation with σ of a microscopic property (number of crack intersections/mm, n); *b*, variation with σ of a macroscopic property (volumetric crack dilatancy, θ).

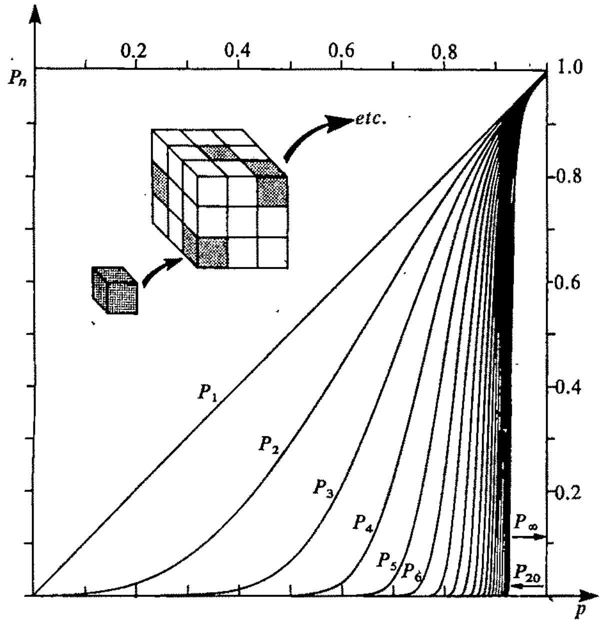

Fig. 4 Now an n cube, made of 27 $(n-1)$ cubes, is considered as fragile when three fragile $(n-1)$ cubes are aligned along one of the three medians of the n cube. Then $P_1=p$, $P_2=\Pi(p),\ldots, P_n=\Pi(P_{n-1})$ with $\Pi(x)=3x^3-3x^5+x^7$. With increasing n, the P_n curves sharpen rapidly to a quasi-step, then shift only slowly to the right. The last curve drawn is that for $P_{20}(3^{19}>10^9)$. This shows that the prediction for megafaulting is not significantly altered by the mathematical absence of a critical probability p_c.

not an infinity of scaling steps from microcracks to megafaults ($100\ \text{km}/100\ \mu\text{m}=10^9$). On the same basis it is also possible to build 'anisotropic models' in which the fragility is relative to a given direction and varies with this direction. But rather than generalizing, we will now draw some inferences about earthquake prediction from the simple model considered above.

The dilatancy theory for earthquake prediction which has been developed from laboratory experiments[8,14,15] has had some success but has failed to provide a general solution. Using a similar approach, we now show how to draw, from laboratory experiments, other useful inferences on earthquake prediction.

Earthquakes are fracture phenomena which most often occur on pre-existing sets of faults. Together with many theoretical seismologists we may assume that the reactivation of a fault system is a fracture phenomenon polarized by the existence of the fault itself[16,17]. Then the approach we propose, which determines a critical fragility, can also apply to earthquakes. One only needs to consider that the macroscopic domain with which our computations are concerned is the domain of the faults.

Earthquakes are probably generated by a strain accumulation under a constant deviatoric stress $\sigma=\sigma_1-\sigma_3$ rather than by a continuous increase of σ with time. Mogi[18] has proposed that, in a medium submitted to a constant σ, the increase in the probability of occurrence of fracture during the time interval $(t, t+dt)$ does not depend on t and is given by $dp=\mu_0 \exp(\beta\sigma)\, dt$, where μ_0 and β are constants. We can also consider the more general case when stress is increasing with time:

$$p(t)=p_0+\int_0^t \mu_0 \exp(\beta\sigma(t))\,\mathrm{d}t \qquad (3)$$

(We may assume, in such conditions, that the microcrack density obeys a zero-order kinetic equation $\mathrm{d}'(t)=\delta_0 \exp(\beta\sigma)$, $\mathrm{d}(t)$ and $p(t)$ being related by $p(t)=a\,\mathrm{d}(t)$, as above.)

It is then possible to compute the curves $P_n(t)=P_n[\sigma(t)]$ by the recursion formula (2). Of course, the shape of those curves is the same as that in Fig. 4, the parameter along the horizontal axis now being the time. For example, in the experiments of Kranz on samples of Barre granite[19], fracture occurs about 150 s after a stress of 2 kbar has been applied. To get the time parametrization, one has only to replace the $(0, p_c)p$ interval by a (0, 150 s) t interval. If σ is supposed to vary with time, a variable contraction or dilation of the horizontal axis can modify the figure of the $P_n(t)$ curves.

Suppose now we have two physical parameters, (x) and (y), which depend in a known way on crack density at different scales n_1 and n_2. It is then possible to predict the critical point $p(t)=p_c$ from the predicted intersection of the two curves $x(t)$ and $y(t)$. So it may be thought that the prediction of earthquakes demands the observation of phenomena characterized by different scales. For example, if one studies seismic waves for periods of 0.1, 1, 10, 100, ... s, one may think that the values of the corresponding attenuation ratios will tend towards some limit at the critical point (the partial failure of the (V_P/V_S) ratio prediction technique may come from the fact that in some circumstances this ratio depends on the scale but not in others, whether pores containing water in the rock are connected or not).

The crude model we propose here may be tested in two ways. First by studying in the laboratory the variation of crack density at different scales as $(\sigma_1-\sigma_3)$ increases; second, by studying the variations of some physical properties which depend on crack density at different scales, especially in the vicinity of fracture.

Despite the extreme simplicity and the limits of our approach, if our basic conjecture is correct, a set of prediction methods could be built up.

We thank T. Madden, P. Tapponnier and V. Courtillot for fruitful discussion. P. Tapponnier provided the photographs in Fig. 1.

Cobalt in north-east Pacific waters

G. A. Knauer, J. H. Martin & R. M. Gordon

Moss Landing Marine Laboratories, Moss Landing, California 95039, USA

Significant understanding has been gained recently about the biogeochemical cycling of trace metals in the ocean. This knowledge has mostly resulted from the accurate measurement of dissolved species in oceanic water columns. We report here that cobalt's vertical distribution is similar to that exhibited[1–3] by Mn; that is, its surface enrichment/deep depletion (Fig. 1). However, amounts of Co (1–7 ng l^{-1}) are ~10–20 times less than those for Mn (Table 1), as might be expected from crustal abundance estimates[4] for these elements (Mn=950; Co = 25 μg per g). The similarity between Mn and Co profiles implies the same biogeochemical pathways. The Co excess in nearshore surface waters probably results from continental weathering input processes, as suggested by the remarkable Co–salinity mirror-image relationship shown in Fig. 1, and the Co–salinity scatter diagram in Fig. 2*a*. The steady decrease in Co concentrations also indicates that Co is usually scavenged rather than regenerated at depth, as is the case with Mn (Fig. 1; Table 1).

Table 1 Dissolved Co levels observed off central California (36° 30′ N 123°05′ W) in June 1981

Cobalt was preconcentrated in two replicates (OE Co 1, OE Co 2) using organic extraction. Replicate values were averaged ($\bar{X}$ OE Co) and are compared with Co amounts obtained using chelex preconcentration (CX Co). Manganese data (CX Mn) for these samples are also shown. Water was filtered using 0.45 μm pore size nucleopores.
* Chelex at pH 6.
† Chelex at pH 8.
‡ Contaminated.

In comparison with those in oceanic waters, Co values can be very high in estuaries. We measured dissolved Co amounts varying between 50 and 1,200 ng l^{-1} in north San Francisco Bay on a Sacramento River/Golden Gate transect during a period of high freshwater flow in March of 1980. The highest concentrations were observed at three stations with salinities between 6.2 and 12.4‰; that is 1,200, 550 and 530 ng l^{-1} (Fig. 2*c*). Cobalt levels immediately outside the above salinity range were markedly lower: 120 and 140 ng l^{-1}, at salinities of 2.2 and 13.8‰, respectively. Amounts of Co more or less steadily decreased in the remainder of the salinity range sampled; that

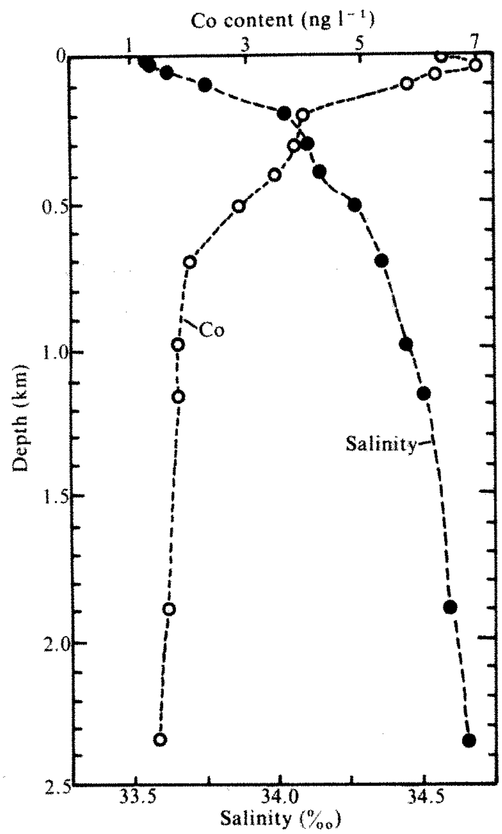

Fig. 1 Salinity (●) and mean organic extraction Co values (○) versus depth (see also Fig. 2*a*).

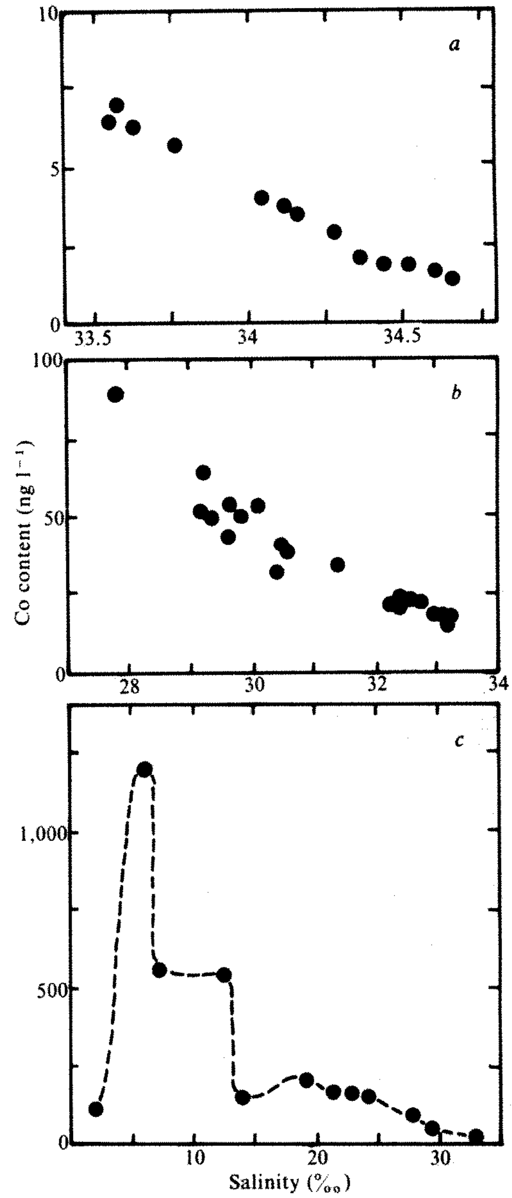

Fig. 2 Cobalt–salinity relationships observed *a*, off central California at depths of 0.2–2,350 m; *b*, in near-surface waters immediately outside San Francisco Bay; *c*, in San Francisco Bay. Correlation coefficients for data in *a* and *b* are −0.93 and −0.99, respectively.

is, from 200 ng l^{-1} at 19.3‰ to 40 ng l^{-1} at 33‰ (Fig. 2*c*). A similar Co–salinity relationship was observed for near-surface waters collected outside San Francisco Bay (Fig. 2*b*). The slight curvature in the plotted points suggests the possibility of Co removal processes occurring within this salinity range, as well as conservative mixing.

The reasons for the very high dissolved Co levels in the San Francisco Bay intense mixing zone (6–12‰ salinity range) waters are not understood. Although the data suggest Co adsorption–desorption reactions occurring with suspended particulates, the exact nature of these reactions is unknown. River–estuarine chemistry is very complicated, involving many competing processes, and is beyond the scope of this paper. Nevertheless, scientists dealing with this complex subject also report similarities between Co/Mn geochemistry[5].

We compared our Co distribution findings with those reported previously[6–13], and in general, values for estuaries and rivers are similar to those we report for near-shore and San Francisco Bay waters, while quantities for various oceanic waters are usually considerably higher. Because most of these data were reported well before the adoption of clean techniques, it is logical to suspect contamination problems for many of the

previously reported oceanic samples, especially those collected at depth.

We avoided contamination by using the same collection, filtration and analytical procedures that we had previously used (with Bruland) for other elements[14]. The organic extraction (APDC, DDDC/chloroform) preconcentration method had yields of 97–98% when checked with carrier-free ^{57}Co, and the precision for two replicates was generally excellent (Table 1). The use of another preconcentration technique (chelex ion exchange at *p*H 6) resulted in similar values (within 1.3 ng) with the exception of the 10 and 520 m samples (Table 1). Analyses of eight individual blanks for the organic extraction procedure resulted in a mean and standard deviation of 0.3 ± 0.04 total ng Co in comparison to 0.6 total ng found in the lowest sample. Cobalt was not detected in the chelex blanks.

In conclusion, the oceanic vertical distribution of dissolved Co appears to be very similar to that of Mn, at least as we now know it. Great variability in near-shore surface waters can be expected and, as is the case with Mn, oceanic removal processes are probably rapid, with resulting residence times in tens of years. This can be illustrated by substituting a world ocean Co concentration of 1 ng l^{-1} in place of the 23 ng l^{-1} used by Bewers and Yeats[15] in their estimates of Co residence times. The results are 52 yr using stream input data and 34 yr using sedimentation rate data.

If the Mn–Co similarity is also true for open-ocean waters, much lower Co levels (~1.0 ng l^{-1}) can also be expected in oligotrophic surface waters, judging by Mn data (~35 ng l^{-1}) reported by Landing and Bruland[2]. Because Co is an important element in many essential biological compounds[16], notably the central atom of vitamin B12, the low amounts of this element in the environment suggest the possibility of its being a limiting nutrient in some conditions, or at least that the massive amounts (5 μg l^{-1}) routinely added to phytoplankton culture media are unnecessary.

We thank S. Fitzwater, S. Tanner and C. Hunter and the captain and crew of R/V *Cayuse* for their help during our Cobalt I cruise. This research was supported by grants from the NSF Biological Oceanography (OCE 80-03200) and Marine Chemistry (OCE 79-09431) programmes, the Ocean Minerals Corporation, and the US Environmental Protection Agency (CR 8077110020).

Beryllium in the water column of the central North Pacific

C.I. Measures & J. M. Edmond

Department of Earth and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The existence of the cosmogenic radioisotope of beryllium, ^{10}Be($t_{1/2}$ = 1.5 Myr), was first confirmed[1,2] almost 25 yr ago. Subsequently, Merrill *et al.*[3] worked out the sedimentary geochemistry of the stable isotope of the element, ^{9}Be. The geochronological potential of ^{10}Be could not be exploited, however, because of its extremely low abundance (global average production rate 1.08 atoms cm^{-2} min^{-1})[4] and the difficulties associated with the analysis of the stable species ^{9}Be, particularly in natural waters. This situation is changing dramatically with the application of accelerator techniques to the detection of the radioisotope[5]. It thus becomes important to obtain a detailed understanding of the geochemistry of ^{9}Be since the potential use of the stable isotope for normalization purposes would significantly enhance the usefulness of the radioactive species in dating studies. We report here the first detailed profile for ^{9}Be in the oceanic water column.

Samples were obtained at 30 °N, 158 °W over MANOP site R (Manganese Nodule Program Red Clay Study Area) north of Hawaii using clean oceanographic procedures. One litre samples were collected in acid-cleaned linear polyethylene containers and immediately spiked with 4 ml of doubly distilled 6M HCl to bring the *p*H to ~1.8. Laboratory experiments with standards indicate that there is no loss of beryllium in these storage conditions. The analyses were made by gas chromatography with electron capture detection of the volatile trifluoroacetylacetonate complex of the element. This was formed in the seawater solution at *p*H 5.4 and extracted into high-purity benzene (details of the method will be reported elsewhere). The detection limit using a 200 ml sample aliquot is about 2 pmol kg^{-1} (2×10^{-12} M); the precision (1σ) is 5.5% at 20 pmol kg^{-1}.

The profile is presented in Fig. 1 together with the associated hydrographic measurements. The numerical data are listed in Table 1. The distribution of beryllium in the water column displays the nutrient-like surface depletion and deep enrichment observed for many of the other accurately determined

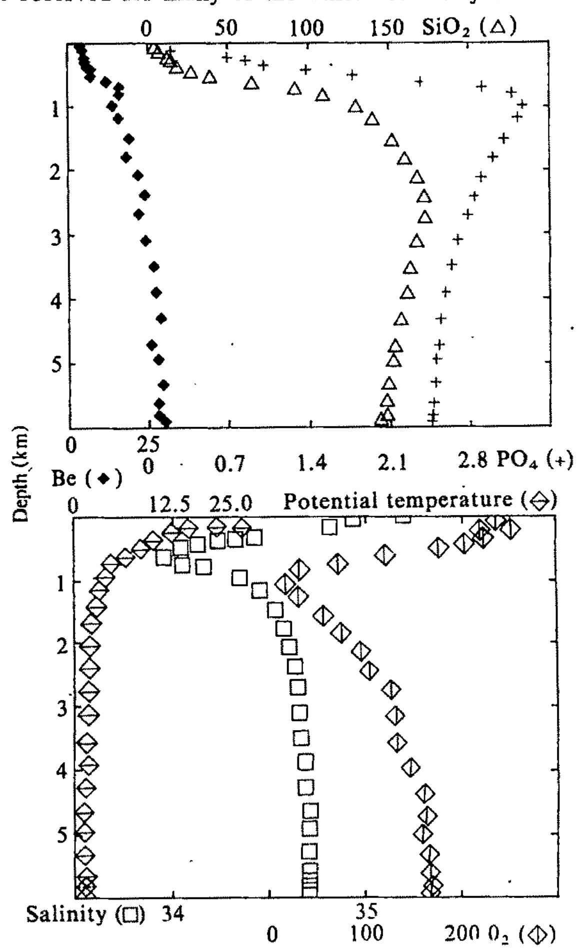

Fig. 1 The beryllium profile from MANOP R in the Central North Pacific (30° N, 158° W). Also shown are the distributions of silicate, phosphate, potential temperature, salinity and oxygen.

trace elements. The mixed layer value is 4 pmol kg^{-1}; the concentrations rise through the main thermocline to values of 25–30 pmol kg^{-1} in the deep and bottom waters. Although there may be a secondary maximum associated with the oxygen minimum at 900 m (Fig. 1), the sampling density is inadequate to resolve it fully.

MANOP R is located beneath the tongue of Antarctic Bottom Water that penetrates north around Hawaii[6]. It is the hydrographic feature responsible for the induced maximum in the silica profile that characterizes the North Pacific Deep Water (Fig. 1). The beryllium profile, in contrast to those of the nutrients, increases with depth. The potential temperature–

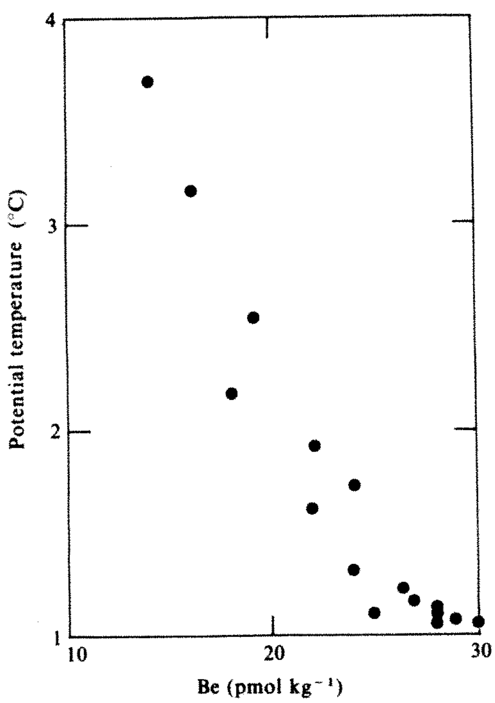

Fig. 2 The beryllium–potential temperature relationship for the deep and bottom waters.

concentration relationship below 1,000 m (Fig. 2) is concave-up indicating mid-water scavenging[7] as has been observed for copper[8]. The fit to a simple one-dimensional diffusion advection model[7] gives a value for the ratio of the scavenging rate, J, to the vertical advection velocity, w, of $J/w = 2.49 \times 10^{-3}$ pmol kg^{-1}yr^{-1}m^{-1} with a standard error of 1.90. Assuming that the upwelling velocity is 3 m yr^{-1} (ref. 7) then the scavenging rate, J, is 7.5×10^{-3} pmol kg^{-1}yr^{-1}. The half life with respect to scavenging is thus estimated to be 1,850 yr. As the concentration of beryllium increases with depth there must be a source of input from the bottom to maintain the profile against removal by scavenging. This can be crudely estimated[9] at 1.5 pmol cm^{-2}yr^{-1}. Assuming an effective pore water diffusion coefficient of 10^{-6} cm^{-2} s^{-1} then this flux requires a gradient in the sediments of ~60 pmol kg^{-1} cm^{-1}. As in the case of copper, such high gradients cannot extend very deep into the sediments because the solubility of any existing beryllium compounds will be exceeded[10]. Thus a strong source is required near the surface.

Beryllium exists in the oceans at concentrations as low as those reported for any other trace element (see Fig. 3). The levels in rivers, however, are substantially higher. Merrill *et al.*[3] reported values of a few nmol kg^{-1}(10^{-9}M), which we have confirmed. Three samples from the main channel of the lower Amazon give values of 1.6, 1.7 and 1.8 nmol kg^{-1}, while an estimate from the mouth of the Orinoco is 610 pmol kg^{-1}. The Yangtze gives lower values: 140 pmol kg^{-1} at the mouth and 150 pmol kg^{-1} at Wuhan in the central part of the flood plain. If the global average value is taken as 1 nmol kg^{-1} then the fluvial flux is 33×10^6 mol yr^{-1}. Assuming that the element behaves conservatively during estuarine mixing and that the average oceanic concentration is 20 pmol kg^{-1}, then the residence time for the element is about 800 yr. As this is shorter than the oceanic turnover time it is important that the value be confirmed in future work.

Crucial to the application of ^{10}Be in marine geochronology is the degree of uniformity of the ^{10}Be/^{9}Be ratio in the oceanic water column. If tracer equilibrium is achieved during oceanic mixing then changes in the initial uptake of the radioisotope in the sedimentary substrate caused by changes in, for example, composition and accumulation rate can be corrected for directly. The concentration of ^{10}Be in seawater has been

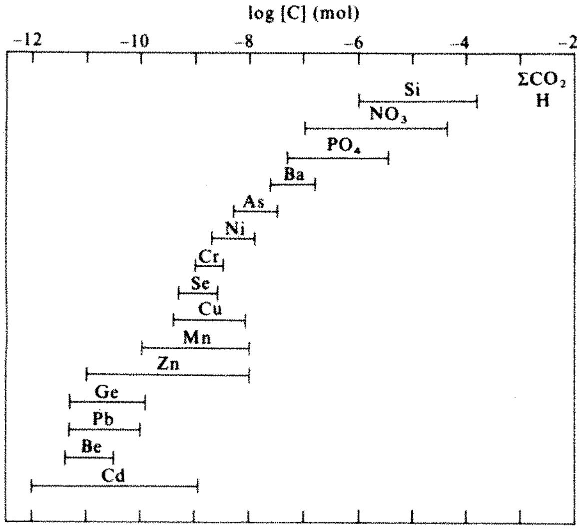

Fig. 3 Published concentration [C] ranges for oceanic trace metals. The nutrients and CO_2 are shown for comparison. Data sources: Ba, ref. 15; As, ref. 16; Cu, Ni, Cd and Zn, ref. 17; Cr, ref. 18; Se, ref. 19; Mn, ref. 20; Ge, ref. 21; Pb, ref. 22.

measured using accelerator techniques[11,12]. An average value for nutrient-depleted Pacific surface waters (two samples) is $1.2 \pm 0.3 \times 10^{-18}$ mol kg^{-1} (ref. 11). On the assumption of a ^{9}Be concentration of 4 pmol kg^{-1}, the ^{10}Be/^{9}Be ratio becomes $300 \pm 75 \times 10^{-9}$. A ^{10}Be concentration of $10.2 \pm 2 \times 10^{-18}$ mol kg^{-1} reported for a single sample from a depth of 4,100 m south-east of San Diego[12], coupled with the deep-water ^{9}Be value of 27 pmol kg^{-1} at MANOP R, give an isotope ratio of $377 \pm 75 \times 10^{-9}$, which is consistent with the surface value.

Yokoyama *et al.*[13] and Krishnaswami *et al.*[12] have reported isotope ratios in manganese nodules (extrapolated to zero age) of 85×10^{-9} and 114–$1{,}215 \times 10^{-9}$ with a mean of 255×10^{-9} respectively. Given the present accuracy of the ^{10}Be measurements ($\pm 20\%$)[12,14] the overall similarity of the water column and nodule data suggests that the two isotopes are indeed equilibrated in the oceans. Much more work is needed, however, before this important conclusion can be taken as firmly established. In particular, the two isotopes need to be measured on the same water samples. In addition, leaching experiments must be carried out on sediments and nodules to establish that only authigenic beryllium is being analysed rather than an additional component of 'dead' detrital beryllium.

We acknowledge the support and encouragement of our colleagues in the MANOP Program of the NSF/IDOE. We also thank the Office of Naval Research for general support of our analytical program, and Professor K. K. Turekian for helpful discussions.

Hindered bedload settling as a model of sand bed planation by water waves

Robert J. Hallermeier

Coastal Engineering Research Center, Fort Belvoir, Virginia 22060, USA

The interrelationships between fluid flows and the surface forms of underlying movable beds are crucial in interpreting sedimentary structures and in predicting hydraulic drag. Energetic flows can erode all features from a sediment bed, and transition to such a planar bed is important to the processes of sediment transport by waves[1]. The following analysis connects bed planation to a threshold effect in hindered settling with increasing concentration of noncohesive sediment moving near the bed. Calculated fluid velocity from the resulting quantitative criterion for this bed transition agrees with extensive laboratory data[2,3] in oscillatory flows.

The present model of the planation process utilizes simple empirical forms of several of the relationships that are needed. As Reynolds numbers for bed planation are usually large enough for the near-bed flow to be intensely mixed rather than laminar[4], inertial (non-viscous) asymptotes are suitable for most elements of the model. However, fully-developed turbulent flow is absent in the laboratory situations and Jonsson[5] has pointed out the persistent empirical accuracy through this transitional range of one result [equation (4)] from laminar flow.

The primary element in the model is an expression[6] for transport rate of sediment moving near the bed in oscillatory flow:

$$Q/\omega D^2 = [\Phi/10]^{1.5} \tag{1}$$

where Q is average bedload sediment volume per unit time and bed width (moving to and fro colinear with the flow), and $\Phi = [(a\omega)^2/\gamma' gD]$ measures sediment agitation by flow energy. Here ω is flow (wave) frequency, D is median sediment diameter, $a\omega$ is peak near-bed horizontal velocity, g is gravitational acceleration and $\gamma' = (\rho_s/\rho - 1)$, where ρ_s is sediment density and ρ is fluid density. Note that bedload rates reported by Manohar[2] agree with equation (1) in a range of conditions through the transition from rippled to planar bed[6].

Conversion of the bedload rate Q into volumetric transport concentration, the ratio of sediment to fluid discharge, requires

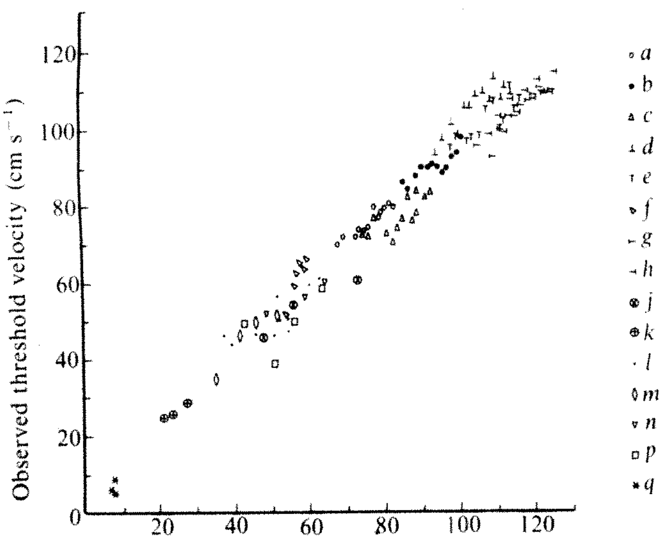

Fig. 1 Threshold velocities for bed planation observed in 120 laboratory tests[2,3,18] compared with calculations using equation (11). See Table 1 for description of the 15 sediments represented.

division by Λ, a characteristic thickness of the bedload layer, and by Ψ, a characteristic fluid velocity within the layer. Bagnold[7] reported that the elevation above the bed of this layer's centre (in unidirectional flow) is mD, where

$$m = 1.4(u_*/u_{*0})^{0.6} \quad (2)$$

and the estimate adopted here is $\Lambda = 2mD$. Here u_* is the friction velocity and u_{*0} is critical friction velocity for sediment motion initiation (zero transport). The peak friction velocity is related to peak velocity by[5]

$$u_* = a\omega(f_w/2)^{0.5} \quad (3)$$

where f_w is friction factor, depending on boundary roughness and on the Reynolds number $(a^2\omega/\nu)$, ν being fluid viscosity. For the situations of interest with a nearly plane bed, boundary-layer flow is transitional between laminar and turbulent[8], but the analytical form for a smooth boundary

$$f_w = 2/(a^2\omega/\nu)^{0.5} \quad (4)$$

remains empirically valid although derived for laminar conditions[5]. The proper inertial relation for sand motion initiation in oscillatory flow is[9]

$$(a\omega)_0 = (8\gamma' gD)^{0.5} \quad (5)$$

so that

$$u_{*0} = (a\omega)_0^{0.5}(\nu\omega)^{0.25} = (8\gamma' gD\nu\omega)^{0.25} \quad (6)$$

A suitable velocity profile for estimating Ψ is problematical even in steady transitional (intermittently turbulent) flow[10]. The fairly thick bedload layer would appear to be dominated by peak-flow effects here, so the appropriate approximation seems to be an inertial profile with logarithmic variation of velocity, as occurs beyond the viscous sublayer for fluid flow above moderately large Reynolds number [10]. The mean horizontal fluid velocity is taken as[7]

$$u = 5.75\, u_* \log(30z/k) \quad (7)$$

where z is distance from the boundary and k measures boundary roughness. For a nearly plane bed $k = 2.5\,D$ is appropriate[8,11], and the characteristic velocity is[7] that at elevation $z = 0.37\,\Lambda$. With these relationships

$$\Psi = 5.75\,(a\omega)^{0.5}(\omega\nu)^{0.25}\log[12.4(u_*/u_{*0})^{0.6}] \quad (8)$$

The postulated link between bed planation and hindered sediment settling is pursued by regarding the right side of equation (1). The agitation index Φ has[12] an inverse dependence on the square of inertial sediment settling velocity, so that equation (1) indicates an inverse dependence between bedload rate and the cube of settling velocity[6]. The terminal settling velocity, w, of an isolated sphere in still fluid is described[13] as a variation of (wD/ν) with the buoyancy index $A = (\gamma' gD^3/\nu^2)$, having asymptotic behaviours of viscous settling for $A < 20$ and inertial settling for $A > 10^5$. A homogeneous dispersion of cohesionless spheres settles more slowly than an isolated sphere, with velocity given as[14]

$$w_C = w(1-C)^n \quad (9)$$

where C is volumetric particle concentration, and the exponent n has a smooth variation between $n = 4.6$ for viscous settling and $n = 2.3$ for inertial settling. An isolated natural sediment grain usually settles[15] at slightly smaller velocity than a sphere of the same mass due to increased drag, and inertial settling arises for $A > 10^4$. Effects with natural grain dispersions presumably follow equation (9) if adjustment is made for n between more closely spaced asymptotes.

No data are available for entrained sediment concentrations near a planar bed, but a critical concentration for appreciably hindered settling apparently should be related to grain interactions and the threshold for significant grain–grain collisions has been reported[16,17] to be C near 0.09 or 0.02. Here $C_{cr} = 0.075$ is adopted; this value is one-eighth of 0.6, the usual maximum possible sediment concentration. Thus the postulated threshold for bed planation becomes

$$(Q/\Lambda\Psi)_{cr} = C_{cr} = \omega D^2(\Phi/10)^{1.5}(1-C_{cr})^{-3n}(\Lambda\Psi)^{-1} \quad (10)$$

or

$$(a\omega)^{2.2} = 28\,\frac{(0.925)^{3n}\nu^{0.25}(\gamma' g)^{1.35}D^{0.35}}{\omega^{0.75}}\log\left[\frac{12.4(a\omega)^{0.3}}{(8\gamma' gD)^{0.15}}\right] \quad (11)$$

With given material characteristics, equation (11) is an implicit relationship for flow conditions at the postulated threshold of bed planation: specifying either flow frequency (ω) or near-bed horizontal flow amplitude (a), the critical value of the other variable is determinable by root-finding. To clarify the dependences of the above threshold, an approximate explicit form is

$$a\omega = 2.8(\gamma' g)^{0.64}D^{0.22}\nu^{0.07}\omega^{-0.35} \quad (12)$$

For the test conditions considered here, equation (12) regularly gives a threshold velocity within a few per cent of that determined by the root of equation (11).

Calculated threshold velocities using equation (11) are compared in Fig. 1 with results from 120 laboratory tests of bed planation with the sediments described in Table 1. Calculations are close to the (very low) near-bed threshold velocities reported for three wave-tank tests conducted by Kennedy and Falcon[18] at transition from rippled to planar bed with lightweight spheres. However, only part of the experimental results from the two major oscillatory-flow studies[2,3] are presented in Fig. 1 for the following reasons.

Manohar[2] performed tests by oscillating at fixed amplitudes a sediment tray in still water, and observing the critical frequency for bed planation; analogously, equation (11) has been solved with the specified a to find the threshold ω. Ignoring the independent ω effects, Manohar provided this correlation of results:

$$a\omega = 20.9(\gamma' g)^{0.4}\nu^{0.2}D^{0.2} \quad (13)$$

For accelerated-bed tests, Bagnold[19] reported that general sliding of sediment can occur at large accelerations, depending on ρ_s/ρ and the angle of sediment repose. Consequently a minority of these tests with large $a\omega^2$ has been disregarded, with the cutoff values of $a\omega^2/g$ listed in Table 1; Manohar's tabulated results at small amplitude increments exhibit in each test series a sizeable gap in $a\omega^2$ and $a\omega$ around the stated $a\omega^2/g$. For the remaining 90 tests, with appropriate values of n (Table 1),

agreement is evident between experimental and calculated results, although there is a tendency with some sediments for observed threshold velocity to be ~10% less than that calculated.

Calculations show agreement only with a quite limited segment of results from the other major study. Chan *et al.*[3] executed tests by oscillating fluid at fixed frequencies above stationary sediment in a 5-cm diameter pipe, observing critical fluid amplitude for bed planation; equation (11) has been solved by a corresponding procedure. About one-third of the material combinations tested are represented in Fig. 1; these correspond to A values for subaqueous fine and medium quartz sands (although some results for both water and ethanol are shown). More scatter is to be expected here because results have been scaled off a log-log plot for the present use. The agreement of these 27 measurements with calculations by equation (11) is about as ideal as with transition calculations by the following expression, provided as an empirical correlation of all results by Chan *et al.*[3]:

$$a\omega = 6.6(\gamma' g)^{0.5}\nu^{0.2}D^{0.1}\omega^{-0.2} \tag{14}$$

On the other hand, equation (14) is clearly superior to equation (11) in agreement with the data for other sets of tests with: large D, large ν (glucose) or iron ore. The causes for the present model's failure are not certain, but these cases might be explained by the facts that: equation (4) is inaccurate for relatively large D/a (ref. 8); the small test facility gives[20] laminar flow of glucose, making equation (7) inapplicable; and iron ore exhibits cohesion by its magnetism, making equation (9) incorrect. Also, no heavy minerals such as iron ore are represented in the data base[6] supporting equation (1).

I conclude that the model of bed planation providing equation (11) is consistent with laboratory results for 15 sediments having A values corresponding to quartz sand in water, and segments of the two major data sets[2,3] show some congruence, whereas these results had appeared disjoint[3,21]. Note that this analysis has a markedly different viewpoint from that of Bagnold's criterion for planar bed occurrence[7,22], and that the latter has been supported in data reviews[1,23] for unidirectional and oscillatory flows. The present results are established for laboratory transitions to a planar bed from ripples with wavelength governed by a, rather than from bedforms occurring in flows at lower frequencies[21].

The results reported here, unless otherwise noted, are based on research conducted at the Coastal Engineering Research Center, US Army Corps of Engineers. The findings are not to be construed as an official US Department of the Army position unless so designated by other authorized documents. Permission to publish the present results is appreciated.

Acid rain on Bermuda

Timothy Jickells*, Anthony Knap*, Thomas Church†, James Galloway‡ & John Miller§

* Bermuda Biological Station, Ferry Reach 1-15, Bermuda
† College of Marine Science, University of Delaware, Newark, Delaware 19711, USA
‡ Department of Environmental Science, University of Virginia, Charlottesville, Virginia 22903, USA
§ Air Resources Laboratory, NOAA, Washington DC 20910, USA

Increased acidity of precipitation due to combustion of fossil fuels has been well documented for both the eastern USA[1] and Canada[2]. The SO_2 and NO_x emitted by the burning of coal, natural gas, fuel oil and petrol are oxidized in the atmosphere to sulphuric and nitric acids which subsequently give rise to acid precipitation[1]. However, the SO_2 and NO_x emitted, and their oxidation products, are not all removed by atmospheric deposition over the North American continent; a large fraction is advected east out of North America[3]. In a study between 1 May 1980 and 30 April 1981, we have detected acid precipitation (pH < 5.6) on the island of Bermuda, which is ~1,000 km east of the Atlantic seaboard of the USA. We report here that the acidity of such precipitation is eight times greater on a volume-weighted annual average than rainwater in natural atmospheric equilibrium, and that the acids present are almost wholly sulphuric with a small nitric acid contribution. There is a strong correlation between the presence of these strong acids and the meteorological back trajectory of Bermuda storm systems to the North American continent, which suggests long-range atmospheric transport of acid rain precursors to Bermuda, these having similar anthropogenic origins (that is, from remote fossil fuel combustion) to acid rain precursors on the continent.

Preliminary studies of rainwater in Bermuda from February 1979 to April 1980 suggested the existence of acid rain in Bermuda with a possible seasonal element[4]. To document these observations further, we have sampled all rainfalls in Bermuda from 1 May 1980 at a site at the eastern end of the island, 60 m above sea level, which is thought to be remote from local pollution. We discuss here the data collected up to 30 April 1981.

Samples were collected on an event basis using a wet-only HASL collector[5] for all months except from late August to mid-September 1980 when the collector malfunctioned. During this period we used a bulk collector manned on an event basis. During the year there were 109 rainfalls for which we measured the pH. In addition, 70 of these rainfalls provided sufficient samples to determine concentrations of all the major anions and cations. Total rainfall during the year was 150.22 cm compared with a long-term average of 146.46 cm (ref. 6). Samples were analysed for pH, strong and total acidity[7] and all major anions and cations, using standard colorimetric, atomic absorption and ion chromatographic techniques. In all cases the analyses and pH measurements are accurate to better than 10% and ±0.1 pH units, respectively. The results for all wet-only samples are presented in Table 1.

We have found that precipitation in Bermuda is acidic (Fig. 1): For the entire sampling period, the volume-weighted mean pH of all wet-only samples was 4.74. Gran's titrations[7] were performed on 29 samples having a pH < 4.8. Regression analysis of free acidity, derived from the pH (measured by glass electrode), against strong acidity (determined by Gran's titration) for these 29 samples gave a slope of 0.95 and a regression coefficient, r, of 0.947, indicating that strong acids are responsible for more than 90% of the acidity in Bermuda's rainwater.

The results in Table 1 indicate the presence of excess calcium, potassium, sulphate, nitrate and ammonia over that introduced to the rainwater by sea salts. The calculations of excess are

0028-0836/82/180055—03$01.00

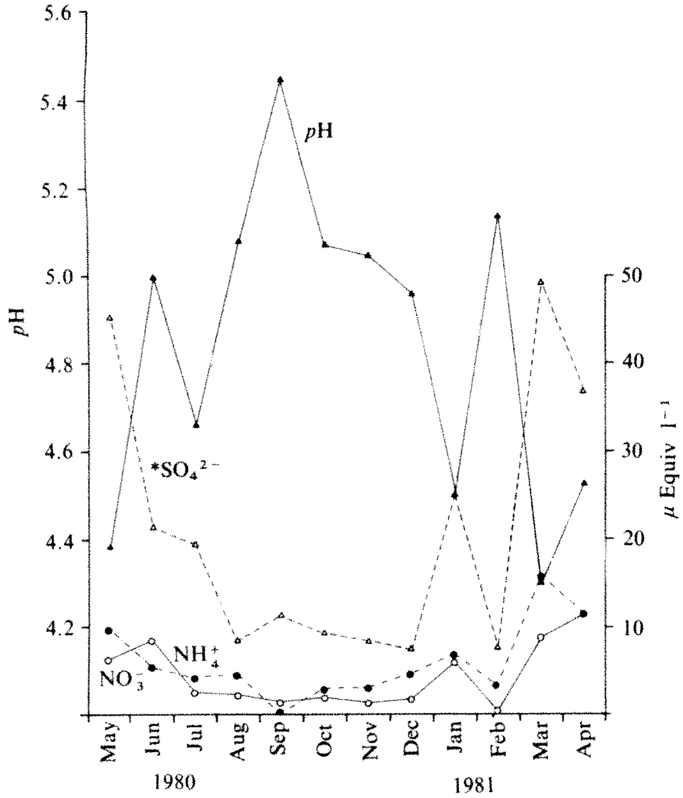

Fig. 1 Volume weighted monthly mean *p*H (▲) and concentration of NO_3^- (●), $^*SO_4^{2-}$ (△) and NH_4^+ (○) of rainfall collected in wet-only samples from Bermuda. * Non-sea salt component. The accuracy of each individual analysis is better than 10% and *p*H measurements are accurate to better than ±0.1 *p*H units.

based on sodium, which is assumed to be derived entirely from unfractionated sea salt. The source of the excess calcium and potassium is believed to be clay and rock particulates of either remote aeolian or local limestone origins. The excess sulphate and nitrate in the rainwater is responsible for the acidity. The amount of basic unfractionated sea salt (bicarbonate and boric acid) is insufficient to cause significant neutralization of the acidity. When protons are correlated with non-sea salt sulphate and nitrate concentrations (12 data points per parameter) the slopes are 0.935 ($r = 0.941$) and 0.257 ($r = 0.909$), respectively. This is interpreted to mean that the upper limits of H_2SO_4 and HNO_3 contributions to free acidity are 94% and 26%, respectively.

There are three possible sources of the sulphuric acid in Bermuda rain: locally derived acids, those produced by natural marine processes, or long-range transport of continentally-derived acids. A locally-derived source of the acids is unlikely to be important because: (1) there is no manufacturing industry in Bermuda; (2) the sampling site was 15 km from the island's only power generating plant and during most storms the site was to windward of the plant. (3) Although the sampling site was near the airport, we do not believe that this affected the precipitation acidity because the acidity is primarily due to H_2SO_4, whereas aircraft exhaust emits mainly NO_x relative to SO_2 and SO_4 (ref. 8). (4) The air mass transit time across the island is very short, giving rapid dispersion and dilution of locally derived pollutants. The meteorology of Bermuda exhibits little or no 'island effect' (ref. 9 and M. J. Nemkosky, personal communication). (5) The observed seasonal pattern described below is incompatible with a local source as power use and air traffic are at a maximum in summer in Bermuda while winds are at a minimum. These factors would produce a summer *p*H minimum if local sources were important, which is the reverse of the pattern observed.

The next possibility is that of natural marine processes giving rise to acidic gases. The emission of various volatile sulphur compounds from seawater has been reported elsewhere[10]. We do not have a direct measure of the significance of these processes, but using the data of Nguyen *et al.*[10], it is possible to make a rough calculation of their significance; the total potential input from the Atlantic to the west of Bermuda can be compared with the anthropogenic flux of sulphur calculated to leave the USA (3.9×10^{12} gS yr^{-1})[3]. We estimate the sea area to the west of Bermuda that is bounded to the north by the Canadian border and in the south by the southern tip of Florida, to be $\sim 2.5 \times 10^{12}$ m^2. By scaling down the global ocean estimate[10] of 35×10^{12} gS yr^{-1}, we estimate that the oceanic emission from the sea area to the west of Bermuda could be $\sim 0.2 \times 10^{12}$ gS yr^{-1}. However, this is probably a maximum value as primary production in this area of the Sargasso Sea is much lower, without upwellings such as those found along the west coast of Africa where many of the measurements of Nguyen *et al.*[10] were made. This figure for sulphur produced by natural marine processes is at least 20-fold lower than the anthropogenic sulphur input calculated by Galloway and Whelpdale[3], thus we consider an anthropogenic source for the excess sulphur in Bermuda's rainwater to be the more important. Indeed, aerosol measurements over Bermuda have suggested the presence of anthropogenic sulphate and some trace metals[11,12].

In addition, the major weather patterns in the North Atlantic move in an easterly direction, thus transporting the USA air mass towards Bermuda[9]. The meteorology of the Bermuda area of the North Atlantic Ocean is dominated by the semipermanent sub-tropical Azores/Bermuda high. During the summer and autumn, this high pressure can prevent many of the frontal systems originating over North America from reaching Bermuda. During winter, with a weak or absent sub-tropical high, frontal systems pass regularly. This situation becomes firmly established over the islands during December and persists for about 3 months. Late autumn and spring are the transitional seasons. During June to December, *p*H values are generally high and the excess sulphate, nitrate and ammonia concentrations are relatively low. However, from December to May the reverse is true (Fig. 1). This agrees with the general meteorological pattern described above, although July 1980 and February 1981 represent exceptions. In July an unusually intense storm left the United States coast and reached Bermuda, stalling over the island and producing exceptionally heavy (20 cm over 3 days) and acidic (*p*H 4.4–4.7) rain which biased heavily the monthly average (Fig. 1). In February 1981, a blocking high pressure was established temporarily, bringing unseasonably mild weather for the first 3 weeks of the month. This North Atlantic meteorological effect is seen in the chemistry of the rain for these months.

Figure 2 shows the average *p*H of rainwater associated with air masses arising in each of the three marked sectors as derived

Table 1 Volume weighted mean annual concentrations of major constituents in Bermuda rain from 1 May 1980 to 30 April 1981

Ion	Conc. (μEquiv l^{-1}) in all wet-only samples
H^+	21.15
SO_4^{2-}	43.0
NO_3^-	6.31
Cl^-	221
NH_4^+	4.22
K^+	4.77

Na^+/Cl^-	0.81
$^*SO_4^{2-}/NH_4^+$	5.10

* Non-sea salt components.

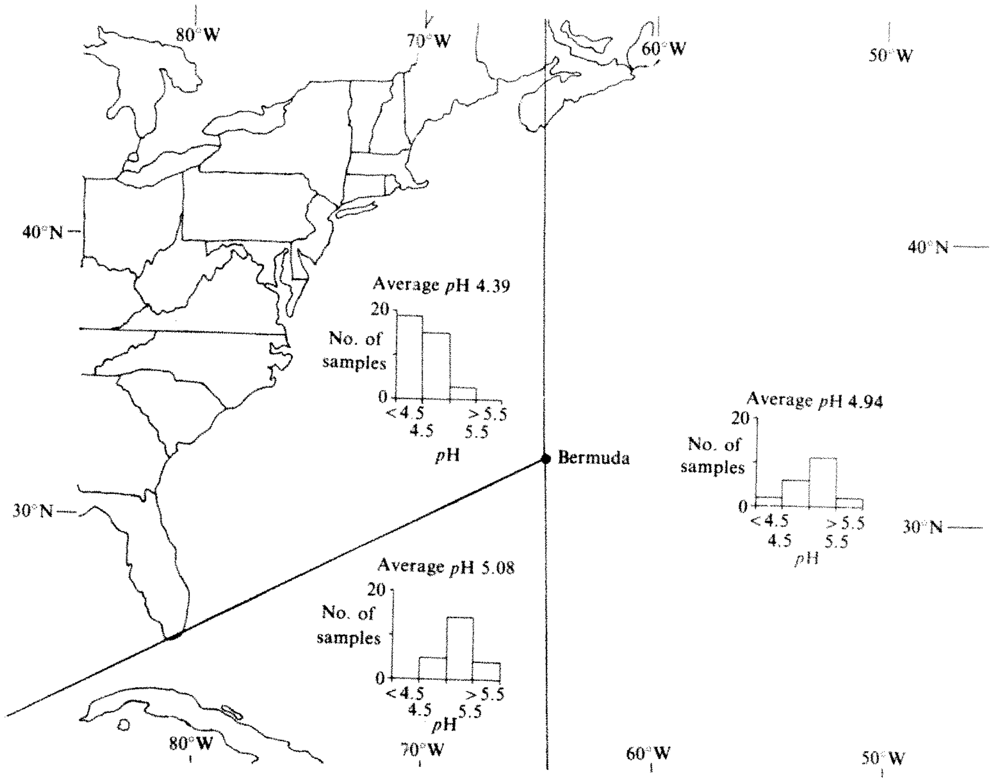

Fig. 2 Map of the north-west Atlantic Ocean showing the three sectors used for ARL back trajectories of Bermuda rain. The average pH of rain originating in each sector is indicated and the distribution of pH values for rain samples from that sector are shown in the histograms.

from ARL back trajectories[12,13]. Clearly, the rainwater originating over continental North America is markedly more acidic than rainfall originating in the other sectors.

A comparison of the composition of rainfall in Bermuda with recently published data from the eastern United States[14] reveals that in addition to a large increase in sea salt concentrations and a reduction in acidity by a factor of 3 during transit from the US coast, there is an increase in the $^{*}SO_4/NO_3$ ratio, indicating an increased relative importance for sulphuric acid. There are several possible reasons for the selective long-range transport of sulphuric as opposed to nitric acid rain precursors to the western North Atlantic from North America—these are discussed elsewhere[15].

In addition to demonstrating the existence and causes of acid precipitation on Bermuda, our results suggest that the dispersion and neutralization of acid rain exported from continents may be a slow process. Over the North Atlantic to the west of Bermuda this appears to be due to the absence of suitable neutralizing agents in the troposphere. In view of this finding, we believe that long-range atmospheric transport of acid rain is possible. Indeed there is growing evidence of acid rain on remote areas[16] although the cause of this acidity is often not as clearly defined as for Bermuda.

We thank Susan Boyd for assistance; Commander M. J. Nemkosky Jr and his staff for meteorological information; and Mr A. Atwood and his staff at Bermuda Harbour Radio. This work was supported by the Bermuda Government, British Petroleum Trading Co. Ltd., ESSO Bermuda, US NOAA, EPA, and US DOE. Radiations and extinctions of plankton in the late Proterozoic and early Cambrian

Gonzalo Vidal

University of Lund, Micropalaeontological Laboratory, Kemicentrum, Box 740, S-220 07 Lund 7, Sweden

Andrew H. Knoll

Department of Geology, Oberlin College, Oberlin, Ohio 44074, USA

The intrinsic palaeobiological importance of planktonic algal microfossils of Proterozoic and early Cambrian age has been widely documented[1–8]. The evidence supporting the biostratigraphical significance of planktonic microfossils in the correlation of Upper Proterozoic and Lower Cambrian sequences has also been assessed[1,4–8]. We contend here that both within-flora (α) and total (γ) taxonomic diversity trends for late Proterozoic planktonic microfossils indicate that a distinct radiation of presumed cyst-forming eukaryotic plankters occurred during late Riphean and early Vendian (used here in the sense introduced in refs 1, 8). Following this, a mid- to late Vendian extinction episode reduced observable plankton diversity by some 70%, extirpating most morphologically complex, pre-existing taxa. A second radiation restored high plankton diversity levels, but not until well into the early Cambrian.

0028–0836/82/180057—04$01.00

Organic-walled fossils of Proterozoic planktonic microorganisms are preserved in a wide variety of sedimentary rocks, ranging from lagoonal mudstones to distal turbiditic shales and greywackes. Microfossil assemblages can be correlated with sedimentary environments, permitting the palaeoecological distributions of both taxa and diversity patterns to be recognized[2–4]. The stratigraphical ranges of many late Proterozoic plankters are similarly discernible and from these has emerged a distinctive series of informal assemblage zones that makes possible the confident biostratigraphical subdivision and correlation of Upper Proterozoic sedimentary sequences[2,4–8]. Because it is possible to observe both diversity patterns within a single time plane and biostratigraphical distributions in successive time intervals, it should be possible to examine planktonic diversity trends through late Proterozoic time. Such analysis reveals both expected patterns of taxonomic diversification and a hitherto unsuspected decrease in taxonomic diversity that took place near the end of the Proterozoic era.

The planktonic nature of Proterozoic microfossils can be inferred on at least four grounds:

(1) The fossils in question tend to be large (10–>500 μm), robust walled, and, often, ornamented vesicles (Fig. 1). Several Proterozoic taxa further exhibit regular median wall splits, polygonal wall openings, or operculate structures, all of which probably represent excystment mechanisms[2,4,7,8]. In all of these morphological traits, the Proterozoic fossils are closely comparable to Phanerozoic fossil plankton, as well as to the zoosporangia of extant cyst-forming plankters such as prasinophycean green algae[8].

(2) The conditions of occurrence and environmental distribution of Proterozoic plankters are also quite similar to patterns reported from their Phanerozoic counterparts[8]. Palaeozoic[9], Mesozoic[10], and modern phytoplankton species tend to have wide facies distributions, but biotas can be resolved into inshore and offshore associations. The same is true for late Proterozoic plankters[8]. Inshore and, especially, lagoonal biotas are characteristically low diversity assemblages dominated by one or a few taxa, while contemporaneous assemblages from open shelf rocks include a diverse and heterogeneous array of morphologically complex forms[2,3,7,8].

(3) When observable, the distribution of Proterozoic plankters is seen to be independent of the distributions of preserved benthic microbial associations.

(4) As viewed in petrographical thin section, fossils interpreted as planktonic are generally more or less randomly distributed within rock samples, in sharp contrast to known microbial mat builders and other microbenthos which tend to be distributed along bedding.

In general, the morphological and palaeocological criteria outlined above parallel those used to infer the nektonic or planktonic nature of such extinct Phanerozoic groups as ammonites, conodonts, or graptolites. Although there is room for error in interpretation, we are confident that virtually all of the microfossils included in this study do represent planktonic organisms that inhabited coastal or shelf Proterozoic seas.

The taxonomic literature on Proterozoic planktonic microfossils contains numerous synonymies, descriptions of degradational forms, contaminants, and pseudofossils, and other problems that preclude the simple lifting of species lists from published reports. Therefore, for our analysis, we examined sequences of microfossil assemblages spanning the interval from the beginning of the Upper Riphean[1] to the mid-Upper Cambrian, using only those species whose type specimens have been examined by one of us[1] (G.V.). Successions examined come from East Greenland, northern and southern Norway, Sweden, the Russian Platform, the southern Urals, and Svalbard. Taxonomic diversity was compiled at the specific level (genera and suprageneric taxa are decidedly artificial), species being here defined, as in most other palaeontological applications, as the smallest morphologically definable units that are consistently recognizable and differentiable in

both time and space[11]. The diversity levels plotted for successive stratigraphical intervals in Fig. 2 represent total (γ) diversity; however, almost all forms examined are cosmopolitan and the within-flora (α) diversity trends for each of our several localities closely mirror the figure presented. Note that while our study centred on the peri-North Atlantic region, sequences in part time-equivalent from as far away as Arizona and Namibia exhibit comparable trends. Further, although individual taxonomic decisions may be disputed by other students of early fossils, we believe that the overall shape of the curve, that is, its qualitative characteristics, is accurate and reflects real events in early plankton evolution.

All but one of the microfossil species used in Fig. 2 (*Bavlinella faveolata*) are undoubtedly eukaryotic, and so Fig. 2 can be viewed as a depiction of the early evolution of nucleated cells. The oldest microfossils that can be interpreted with some confidence as probable eukaryotes are found in ~1,400-Myr old shales of the lower Belt Supergroup, Montana[12]. In addition to filamentous cyanobacterial sheaths and thin-walled spheroidal vesicles (possibly envelopes), this microbiota contains what may be the oldest robust-walled acritarchs. Data for the ensuing Middle Riphean interval are sparce, but available information suggests that diversity rose gradually during this period.

As is evident from Fig. 2, Upper Riphean sequences are characterized by the widespread expansion of sphaeromorphic acritarchs displaying a wide variety of sculptural patterns and possibly excystment mechanisms[7,8]. The succeeding Lower Vendian[1] (perhaps equivalent to the uppermost Riphean Kudashian of the southern Urals) biota is even more diverse. The significance of this expansion is perhaps best understood by analogy to the well known Cretaceous diversification of angiosperm pollen taxa documented by Doyle[13]. Arguments over flowering plant antiquity long centred on the interpretation of scattered and, often, poorly preserved individual plant fossils. Doyle demonstrated that no matter when angiosperms first evolved, the early Cretaceous period marked the evolutionary radiation and ecological rise to dominance of the group. We contend that the late Riphean diversification of marine acritarchs tells a similar story. It is unlikely that this radiation documents the initial appearance of eukaryotic cellular organization. Indeed, most models for eukaryogenesis call for early cells that were wall-less and, hence, virtually unfossilizable. The late Proterozoic expansion does, however, record the initial expansion and rise to ecological importance of presumably cyst-forming eukaryotic plankton, and, thus, the initial radiation of nucleated organisms observable in the fossil record. As far as known, eukaryotes radiated in the late Riphean and early Vendian intervals and, insofar as the fossil record permits us to compare different environments, first established dominance in the planktonic realm[15]. By the end of the Riphean era, the preservable plankton biota included vase-shaped heterotrophic protists, as well as algae[16,17].

A drastic change in the marine plankton biota occurred in mid-Vendian (Varangerian[18]) times, coincident with the widespread Varangerian glacial epoch[8]. Almost 70% of pre-existing taxa disappeared, including almost all of the morphologically complex early Vendian acritarchs and leaving a depauperate biota of simple sphaeromorphs and multi-sphere microfossils interpreted as endosporulating cyanobacteria (*B. faveolata* (Shepeleva) Vidal[2]). *B. faveolata* is known to have dominated glacially influenced marine environments, probably proliferating in ecologically stressed conditions[18,19].

Although the Varangerian plankton record leaves much to be desired because of associated erosional contacts and hiatuses, the reality of the extinctions can be supported on several grounds. (1) Marine Varangerian rocks do exist and contain low diversity assemblages. Such within flora diversity does not depend on outcrop representation in the same way as does total diversity (at least for biotas in which not all forms are cosmopolitan)[20]. (2) One can argue that observed low Varangerian plankton diversities result from a biased sampling of environments—that we are looking at glacially influenced sequences. This is true for the most part; however, immediately superjacent Valdaian (Upper Vendian) strata are equally species poor, and these deposits are widespread and well sampled. Taxa that disappeared at the end of the early Vendian (=Kudashian?) period simply did not reappear, even though non-glacially influenced environments appropriate for their growth and preservation returned. (3) The taxa that disappeared apparently became extinct without issue. Not only do diagnostic acritarchs like *Trachysphaeridium laufeldi* and *Kildinella lophostriata* (Fig. 1) disappear at the end of the upper Riphean–early Vendian period, but younger acritarch assemblages contain no fossils that seem to belong to the same phylogenetic clade. Thus, there is little doubt that the latest Proterozoic eon witnessed a significant extinction episode in the microplanktonic realm. It is tempting to relate this biological event to the Varangerian glaciation(s) because of the time coincidence; however, any hypothesis relating the two phenomena must be speculative.

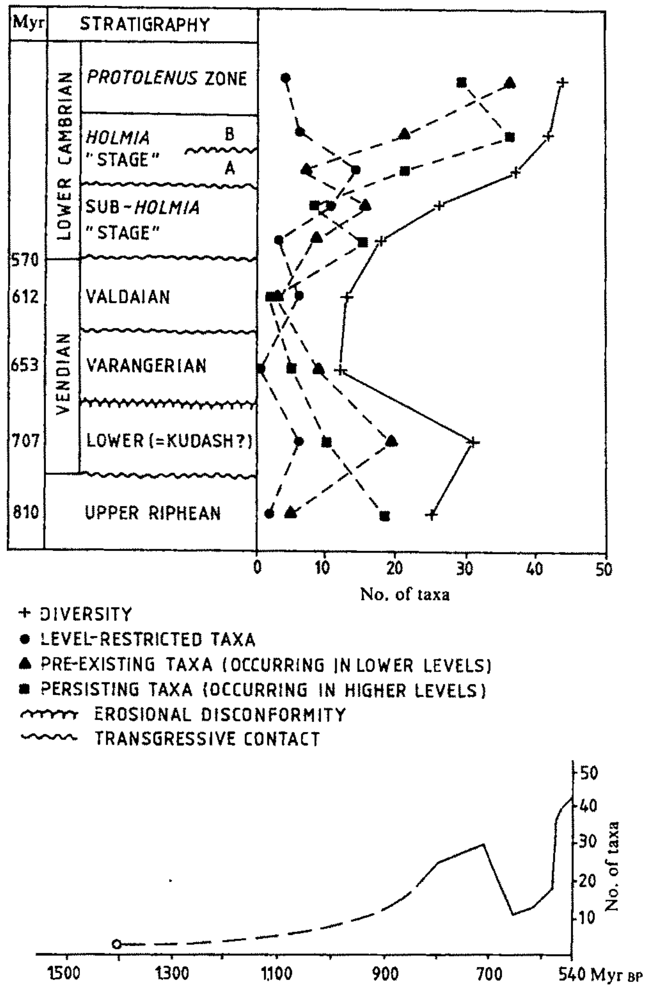

Fig. 2 Diversity changes in the late Proterozoic and early Cambrian plankton record. Upper chart shows details of diversity changes near the Proterozoic–Cambrian (wavy lines between stratigraphical intervals indicate transgressive contacts in Scandinavia; saw-tooth lines indicate erosional disconformities). The lower chart illustrates diversity changes within a broader framework of time. The dotted line is an estimate of the course of eukaryotic plankton diversity from 1,400 Myr BP, the date marking the oldest known probable eukaryotic plankters, to the Upper Riphean (where data become quantitatively reliable). The charts originate from published and unpublished data of continuous Upper Proterozoic–Lower Cambrian sequences in Greenland, Scandinavia (including Svalbard), the Russian Platform, the Urals, and so on, comprising thousands of investigated samples. The microfossil taxa on which the numerical data are based are listed in refs 1, 2, 4–6, 17, 18, 19, 21–23. The Vendian is here used in the sense proposed in refs 1, 8, and comprises pre-Varangerian, Lower Vendian, units in Scandinavia which may perhaps be equivalent with the terminal Riphean (Kudashian) of the southern Urals in the USSR. Definitive proofs for this are, however, missing.

Plankton diversity rebounded sharply in early Cambrian times (Fig. 2), with the radiation of spinose forms attributed to the Palaeozoic acritarch genus *Baltisphaeridium* and other new and morphologically complex acritarch forms. When it occurred, the Cambrian radiation was remarkably rapid; however, note that the most comprehensive radiation does not coincide in time with the beginning of the Cambrian period[21]. Plankton diversity underwent a slow increase throughout the Sub-*Holmia* 'stage'[22,23] of the lower Cambrian system.

We conclude that the fossil record of early eukaryotic plankton has a distinctive and not entirely predictable shape. Late Riphean and early Vendian microplankton assemblages indicate a dramatic morphological (taxonomic) diversification that represents the first recognizable radiation of eukaryotic algae and documents their rapid rise to dominance in coastal planktonic habitats. An equally striking drop in diversity near the end of the Proterozoic era is interpreted as the first recognizable episode of widespread extinction. More data, particularly from sedimentary sequences outside the peri-North Atlantic area will be required to test and refine the arguments presented here.

Mating and song types in the great tit

P. K. McGregor & J. R. Krebs

Edward Grey Institute, Department of Zoology, South Parks Road, Oxford OX1 3PS, UK

We report here the first field investigation of the relationship between the songs experienced by female songbirds early in life and those produced by their mates. Our 6-yr study of the great tit (*Parus major*) showed that females in a ringed population tended to be mated with males singing slightly 'unfamiliar' songs, where 'familiar' songs are defined as those sung by the female's father. This result parallels recent findings on sexual imprinting in birds[1,2].

We recorded the songs of all the breeding male great tits (between 18 and 33 birds in a year) in Marley Wood, Oxford, during 1975–80. Most of the breeding adults and all their young were individually ringed throughout the study. The recordings were made before and during the breeding season (March–May) by visiting all the territorial males several times to record both spontaneous song and song produced in response to playback tapes. Each male had a repertoire of one to six song types ($\bar{x} = 2.98$, $n = 152$). We classified the 454 songs recorded into 41 categories by inspecting narrow band sonagrams. Great tit song is a loud vocalization consisting of rhythmically repeated units (phrases) which are uttered in bursts with intervals of silence between. The major criteria for classifying songs were as follows[3]: (1) number of notes per phrase, which varies over 1–11; (2) type of note (pure or modulated); (3) frequency relationship of notes (for example, in a song with two note types, one pure, one modulated, the pure note could be of higher or lower frequency than the modulated; these two possibilities would count as two different song types); (4) duration of song phrase. We placed less emphasis on variation in duration of notes and modulation rate within notes. When P.K.M. and J.R.K. classified songs independently they obtained 85–95% agreement. The song types about which we did not agree were usually rare ones sung by only one bird in a year and we assigned these to new categories.

Our analysis is based on 17 females for which we knew the repertoires of both husband and father. We compared the songs of the 17 'pairs' of female's fathers and mates in two ways: first by looking at the number of song types shared, and second by

Table 1 Mating and song sharing in the great tit

No. of songs shared with female's father

a

	0	1	>1
Husbands	6	11	0
Other males	242	157	45

b

	0	1	>1
Husbands	6	11	0
Other males	84	50	10

c Degree of difference between father and husband*

	'Similar'	'Intermediate'	'Different'
Observed (husbands)	3	5	1
Expected (other males)	3·15	1·8	4·05

a, The number of females mated to males sharing 0, 1 and more than 1 song with the female's father. This distribution was compared with one obtained by counting all the males (except for fathers) in Marley Wood in the year in which the female in question bred. The table shows overall heterogeneity ($\chi^2_{2\,d.f.} = 6.8$, $P<0.05$), and a comparison of 'one song shared' versus 'no songs' or 'more than one song' is significantly different from expected ($\chi^2_{1\,d.f.} = 6.09$, $P<0.02$). *b*, A similar analysis to that in *a*, but considering only males that nested between 201 and 400 m from the female's birth site. The table shows overall heterogeneity ($\chi^2_{2\,d.f.} = 6.6$, $P<0.05$). Comparison of 'one song shared' versus 'no songs or more than one' $\chi^2_{1\,d.f.} = 5.82$, $P<0.02$. *c*, Of the 17 husbands analysed above, 11 shared one song with the female's father. In nine of these cases other males in the husband's year also shared the song with the father. For these nine songs it was possible to compare the difference in detailed song structure between father and husband with that between father and other males. Husbands fell into the category 'intermediate difference' slightly more often than expected ($P = 0.06$, Fisher exact test). It is reasonable to test the table directly for an excess of 'intermediate' mates because *b* predicts this.

* (1) Take six measures of song structure for all males (including husband) that share the song type in question with female's father. (2) Rank males in order of similarity to father on each measure. (3) Divide rank orders in three equal-sized categories: 'similar', 'intermediate', 'different'. (4) For each male determine which category is commonest. (Ties: share between tied categories.) Use this as estimate of overall similarity. (5) Compare observed distribution of similarity between husbands and fathers with that expected based on all other males.

examining the detailed structure of any songs that were sung by both males.

Table 1*a* shows that females are more likely than expected by chance to be mated with males that share one song type with the father. There is also a slight but nonsignificant suggestion that the 17 females avoid mating with males possessing 'rare' songs (those used by four or fewer males in a year). The observed number of females mated to a male with more than one rare song was 1 out of 17, while the expected number was 3.55 out of 17 ($P \sim 0.1$ Fisher exact test). Rare songs tend to be sung by immigrant males from outside the wood[3]. The females were all born within the wood, hence the observed trend suggests avoidance of mating with males from other populations. This conclusion might be spurious if we have overestimated the availability of unpaired immigrant birds, as might happen, for example, if immigrant birds (mostly young ones) arrive already paired. However, young birds disperse in July–August[4] and usually do not pair until September–February[5], which suggests that any non-randomness of pairing arises after, not before, birds immigrate.

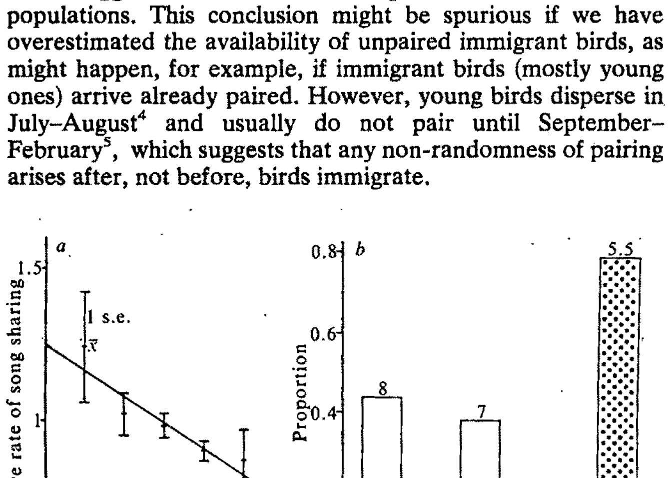

Fig. 1 *a*, The correlation between the rate of song sharing [(N/R), where N = number of songs shared and R = repertoire size of the reference male] by males and the distance between their territories. There are five distance categories and we measured the rate of song sharing in each category for 6 yr (therefore $n = 5 \times 6 = 30$). The results are expressed as rates of song sharing relative to the mean for each year in order to eliminate between-year differences in mean rate. The mean number of songs shared between neighbours (distance category 1) is 0.65 songs. *b*, The similarity of songs shared by fathers and males within the Marley population (open histograms), and fathers and males outside Marley Wood (shaded). The height of the histograms indicates the number of males in each similarity category (see text for calculation) as a proportion of all Marley males ($n = 18$) or all non-Marley males ($n = 7$). Actual numbers are given above each histogram, that is, eight Marley males share a song type which is the same as the father's and is similar in detailed structure. Only two song types were found within and outside Marley; the results for these have been combined.

Table 1 computes the expected distribution by counting the number of males sharing 0, 1 and >1 songs with the father. In this calculation we pooled all the males in Marley Wood during the year in which the female in question bred. This assumes as a null hypothesis that a female is equally likely to mate with any male in the wood. However, it is known that females undertake dispersal from their natal site before breeding and are hence unlikely to mate with males nesting very close to the father's territory. Furthermore, the rate of song sharing between males is correlated with distance between their territories (Fig. 1*a*). We therefore refined our null hypothesis by calculating the expected distribution using only males living between 201 and 400 m from the females' birth site. This corresponds to the average dispersal distance of three territories for females calculated by Greenwood *et al.*[6]. Table 1*b* shows that females are less likely than expected to mate with males sharing 0 or >1 song with the father. However, the slight tendency to avoid husbands with rare songs disappears when dispersal is taken into account (the revised expected number is 0 out of 17, the observed is out of 17).

By correcting for dispersal distance, we have tried to eliminate the possibility that our results could be explained solely as a by-product of dispersal distance. This does not, however, show that song and dispersal are unrelated: for example, young birds could be sensitive to the changing frequency of song types with distance (Fig. 1*a*) in choosing where to settle.

Table 1*b* can be considered in two parts in order to assess the contribution of avoidance of similar and dissimilar repertoires to the final result. Comparison of columns 2 and 3 of Table 1*b* shows only a slight suggestion of avoidance of males with very similar repertoires to the father ($\chi^2_{1 \text{d.f.}} = 2.13$) and a similar comparison of columns 1 and 2 shows that significantly fewer than expected husbands occur in column 1 ($P < 0.05, \chi^2_{1 \text{d.f.}} = 4.7$). Therefore, both effects contribute to the overall level of significance, but avoidance of dissimilar repertoires has a greater effect.

Table 1*c* shows that the bias in favour of 'intermediate degree of difference' shown above for song types also applies to detailed song structure. For 9 of the 11 husbands which shared a song type with the female's father we could compare the degree of difference between husband and father with that between fathers and other males in the population (see Table 1 legend for details of the method). Slightly more females than expected were mated to males of intermediate difference. As in Table 1*b*, we corrected for dispersal distance in constructing our null hypothesis, as the degree of similarity of detailed structure varies with distance between territories[17] (Fig. 1*b*).

Thus, our results are best explained by the idea that females prefer a balance between similarity and dissimilarity. The trends we have observed could be summarized as 'prefer males that share one song type with father, prefer shared song to be slightly different from father's'. A parallel finding for plumage patterns has been found in experiments on sexual imprinting in quail[1,2,7]. This has been interpreted as indicating that females might strike an optimal balance between inbreeding and outbreeding, an effect described in plants[8]. Avoidance of inbreeding[9,10] (which is known to be disadvantageous in great tits[11]) and outbreeding[12] has previously been suggested as a possible consequence of song learning in birds. Although our results are consistent with the predictions of optimal outbreeding, we must still test the three main assumptions of the hypothesis: (1) Females learn paternal songs. (2) Song types influence mate choice in the great tit, as found in other species[13,14]. (Song seems to be important in mate attraction in the great tit because males whose mates have been removed sing more than paired males at the same time of year[15].) (3) There is a cost of outbreeding between populations, as has been shown in some other species[16,18].

Male *Eufriesia purpurata*, a DDT-collecting euglossine bee in Brazil

Donald R. Roberts*†, Wilson D. Alecrim*‡, Jack M. Heller§, Susan R. Ehrhardt§ & Jose B. Lima*

§ Pest Management and Pesticide Monitoring Division, US Army Environmental Hygiene Agency, Aberdeen Proving Ground, Maryland 21010, USA

While studying the ecology of the malaria vector *Anopheles* (*Nyssorhynchus*) *darlingi* Root along the Ituxi River, Amazonas, Brazil, we observed aggregates of bees on the walls of houses that were routinely sprayed with DDT. Several bees collected from DDT-treated house walls in August 1978 were identified as male specimens of *Eufriesia purpurata* (Moscary) of the tribe Euglossini (Hymenoptera: Apoidae). (The bees were identified as *Euplusia purpurata* by Anthony Raw, Laboratorio de Ecologia, Universidade de Brasilia. The change of generic name from *Euplusia* to *Eufriesia* is based on ref. 1.) These bees were well known to the local residents as the insects that eat DDT and we present here the first documentation that they (1) are attracted to DDT, (2) actively collect large quantities of DDT from treated house walls and (3) suffer no apparent insecticidal effects. We also found that the frequency of house visiting is most intense during July to September. Most bees arrive at houses before 12.00 h, remain 2–3 h and return on subsequent days to collect more DDT. Noise produced by bees as they collected DDT was a notable disturbance to 76% of 21 families interviewed along the Ituxi River.

The euglossine bees have been extensively studied due to their important role as plant pollinators. Both males and females provide valuable pollination services, but a more specific relationship has been found for the males in their pursuit of certain flower odours, and many flowers only attract a single bee species that affects pollination[2,3]. The attractants of male euglossine bees are characteristically aromatics and monoterpenes[3].

Five bees collected in 1978 were analysed for DDT residues in accordance with analytical procedures recommended by the United States Environmental Protection Agency[4]. The head, thorax, abdomen and fore-, mid- and hindlegs were processed separately for each specimen (wings were discarded). The body parts were weighed, before DDT extraction, to obtain concentrations of insecticide in parts per million (p.p.m. or μg per g) by body weight.

The sum of the DDT isomers expressed as DDTR, converted to p.p.m. by dry weight, revealed exceptionally high concentrations of DDT (Table 1). Highest concentrations were consistently found in extracts of the hindlegs, indicating that DDT was stored in the hind tibial pouch. This finding was consistent with observations on the storage site of other attractants collected by euglossine bees[3].

During investigations made from September to October 1979, the attractancy of DDT to males of *E. purpurata* was demonstrated by exposing two treated boards for each of the major components of the standard DDT wettable powder formulation. The standard DDT powder consisted of 75% DDT, talc and a wetting agent and was sprayed on house walls as a suspension in water. A common house construction material, slats from açai palm, was used for the 22.5 × 9.0 cm test boards. The surface of two boards was wetted for each of the following treatments; (1) three times with 625 p.p.m. DDT (technical grade) in methanol solution; (2) suspension of talc in water; (3) water; and (4) methanol. The specific wetting agent could not be identified and was not included in the test; as it was a minor component of the spray formulation, we decided that the compound should be identified and tested only if there was no apparent DDT attractancy. The treatments described above provided eight boards which were exposed simultaneously to populations of *E. purpurata*.

Treatments were exposed in random block design (two rows of four boards each) on a tree 0.5 m above the ground. Bees were common around the tree because an ant nest at the tree base had been sprayed with DDT in April 1979. Treated boards were randomly assigned to eight fixed positions and were relocated seven times. Visual counts of bees on the boards were made on 3 days. Eighty-three *E. purpurata* landed on the DDT-treated boards, as determined by 23 separate counts, and no bees landed on any other boards. Analyses for DDT surface residues on the treated and untreated boards revealed DDTR concentrations of 1,236 and <1.0 p.p.m., respectively. That the concentrations on treated boards were lower than expected was probably due to leaching of some DDT crystals by a light rain on the last day of observations. These test results demonstrated the specific attractancy of DDT for *E. purpurata* males.

The daily house-frequenting activities of male *E. purpurata* were also studied, either by conducting hourly counts of bees by location in the house or by collecting all bees as they arrived at the house. Bees were collected using aerial nets and numbers captured were recorded at 15-min intervals. Count and collection data were obtained for a 5-day series with hourly counts performed on days 1 and 3. Continuous collections were conducted on days 2, 4 and 5.

The hourly counts produced a mean of 397 bees per day compared with a mean of 135 bees per day captured during 3 days of continuous collections. The collection data indicated that most of the bees that visited the house on a particular day first arrived before 12.00 h. Studies of in-house distributions of bees and insecticide residues revealed that ~78.6% of the bees were located on the inner walls of the house during the 2 days of hourly counts, the remaining 21.4% being observed on the thatch ceiling, exterior walls and wood superstructure of the house. Wall and ceiling samples were collected from four houses to document the within-house distribution of DDT residues. Average DDTR concentrations in p.p.m. (range limits in parentheses) were as follows: upper ceiling, 152 (36–413); lower ceiling, 5,892 (10–9,225); interior wall, 102,101 (40, 670–170,670); exterior wall, 2,120 (35–8,110). Clearly, the within-house site of highest DDTR concentrations corresponded with the site of most intense bee activity.

Twenty-eight bees from these studies were analysed for DDTR concentrations. The geometric mean DDTR concentrations in bees collected immediately on arrival at the house, specimens marked while collecting DDT and captured 24 h later, and specimens marked in the morning and captured in the afternoon, were 1,197, 4,809 and 2,152 p.p.m., respectively. The DDTR concentrations found in bees captured early in the morning, before they could alight on the DDT-treated walls, indicated that many specimens had collected DDT on a preceding day and survived through the night. Furthermore, 3 of about 50 bees that had been marked with an acrylic paint on day 3 were recaptured on day 4.

In July–August 1980, studies were conducted with mark–capture and bioassay methods to define further the effects of

DDT on bee longevity. The bees were individually marked with USR fluorescent pigment 1953 as they collected DDT from the house walls and were identified with a Blak-Ray, ULV:56, long-wave UV lamp on subsequent capture. This procedure was used in a 6-day series of observations to confirm previous findings on the diurnal activity patterns. The bees were counted hourly and 103 specimens were marked on day 1. Continuous collections of bees were made on day 2; this was followed by a repeat of the first day activities on day 3, when an additional 108 bees were marked. Continuous collections were again made on days 4, 5 and 6. Seventy (33%) marked bees were captured, with 20, 19, 16 and 15 being captured on days 2, 4, 5 and 6, respectively. These results clearly indicate that the bees survived the exposure to DDT and returned on subsequent days to collect DDT from sprayed houses.

Results from this 6-day series of observations on the diurnal activity cycles were in general agreement with the 1979 studies. A daily mean of 188.5 bees were recorded during 2 days of hourly counts whereas the mean number captured per day was 89. The main difference was that proportionately more euglossine bees were captured in the afternoon during the 1980 studies; for example, 60% of the total was captured before 12.00 h in 1980 compared with 92% in 1979. Count and collection data were also used to calculate crude estimates of time that the average bee remained in the house by dividing the mean number collected in the house per day by the mean daily number reported in hourly counts—2.9 and 2.1 h for studies in 1979 and 1980, respectively. These estimates clearly indicated that individual bees actively collected DDT for a considerable length of time.

Table 1 Residue levels of DDTR in male *Eufriesia purpurata* collected from sprayed houses along the Ituxi River, Amazonas, Brazil

	Residue levels of DDTR (p.p.m. or μg per g)						
Bee no.	Fore-legs	Mid-legs	Hind-legs	Head	Thorax	Abdo-men	Total p.p.m. (μg per g) per bee
1	452	930	10,526	124	30	119	12,181
2	1,267	4,245	29,083	359	60	203	35,227
3	2,465	6,222	11,203	839	154	121	21,004
4	2,769	1,685	10,631		99		>15,184
5	10,998	3,706	25,026	1,326	399	173	41,627

The bioassay test consisted of comparing mortalities in bee populations that had been exposed to DDT with unexposed populations. In 1979 we discovered that *E. purpurata* males could be attracted to DDT-treated sheets in the forest. Therefore, at a site ~5 km from human habitations, two screen-encased DDT-treated sheets were used to attract bees, which were captured and subsequently used as normal controls in a bioassay test. Twenty-five bees captured from house walls and 18 captured in the forest were placed individually in tubes, provided with cotton pads soaked with 10% sucrose solution and observed for mortality. All bees were held in a Styrofoam ice chest to maintain a high humidity and protect against temperature extremes. After 54 h, 22% of controls had died compared with only 8% mortality among specimens collected from the DDT-treated walls. When this test was repeated in October 1980, the 48-h mortalities were 20 and 28% for the control and test populations, respectively. Our bioassay test results, plus the mark–capture data, gave no indication that the *E. purpurata* males were in any way harmed by high concentrations of DDT. In addition, we have made observations for many days on hundreds of bees as they collected DDT and no specimens demonstrated insecticidal effects (for example, loss of orienta-demonstrated insecticidal effects (for example, loss of orientation, weakness, paroxysms). This is surprising because the average LD_{50} of *p,p*′-DDT for honeybees is 6 μg per bee[5]. In contrast, the average concentration for this isomer in five specimens of *E. purpurata* was 2,039 μg per bee (Table 1).

Head of household interviews were conducted in July 1980 for 21 families along the Ituxi River. All individuals knew of the bees and 71% had bees in their houses at the time of the interviews. In addition, 100% responded that there had been no house-visiting bees until the malaria control spray programme was begun. There was unanimous agreement on the time of year that the bees appeared in significant abundance—July–September. Noise produced by bee activity reportedly was not disturbing to 5% of those interviewed, more or less disturbing to 19% and was a notable disturbance to 76% of the families interviewed. Fortunately, male euglossine bees are stingless.

Euglossine bees have been reported to frequent houses in other areas of the Amazon Basin, and have also been observed brushing on house walls near Iquitos, Peru (R. L. Dressler, personal communication). That this is a widespread phenomenon was verified by a recent report on sightings of *E. purpurata* in houses in many areas in the state of Pará, Brazil[6].

Simple summary statistics suggest that populations of *E. purpurata* remove significant amounts of DDT from sprayed houses. An average of 112 bees per day were collected from a DDT-treated house during studies in 1979–80. If each bee removed 2,459 μg of DDT (value = average dry weight of bee × average DDTR in μg per g = $0.0982 \times 25{,}044.6$), then a total of 24.8 g of DDT, theoretically, could be removed during 3 months of intense bee activity. This would be equivalent to stripping the DDT from 12 m^2 of wall surface. However, as individual bees make repeated visits to houses, we conclude that our estimate for numbers of bees per day is an overestimate and, thus, they probably do not remove a sufficient amount of DDT to have an adverse impact on the malaria control effort.

Observations reported here demonstrate that male *E. purpurata* are attracted by the odour of DDT, which stimulates their behaviour of brushing the insecticide from walls for storage in a pouch of the hind tibia. The reasons for this behaviour are unknown but it may be that DDT or some aspect of its structural conformation is mistaken by the male bees for an odour substance which they normally collect in nature. Such substances could serve as territorial markers or they may be metabolically altered and secreted as sex attractants[3,7,8]. More recent research on the fate of odour substances provides additional evidence that collected substances are metabolized (or altered) by the male bees (N. H. Williams, personal communication). Clearly, many aspects of euglossine biology remain to be clarified.

Erythrocytes deficient in glycophorin resist invasion by the malarial parasite *Plasmodium falciparum*

G. Pasvol, J. S. Wainscoat & D. J. Weatherall

Tropical Medicine Unit, Nuffield Department of Clinical Medicine,
John Radcliffe Hospital, Headington,
Oxford OX3 9DU, UK

It has been suggested that one of the main factors which determines host susceptibility to different malarial parasites is the interaction of their invasive forms, merozoites, with specific receptors on the red cell membrane[1–3]. Thus the Duffy blood group determinants may be involved in the entry of *Plasmodium vivax* but not of *Plasmodium falciparum* into human red cells. When analysing red cells deficient in various blood group antigens, Miller *et al.* noted[3] that two samples of En(a−) cells showed a reduction of invasion by *P. falciparum*[4]. These cells lack both the major transmembrane sialoglycoprotein, glycophorin A (or MN glycoprotein), and the independently segregating Wright[b] (Wr[b]) antigen and also show increased glycosylation of band 3, the major membrane-penetrating glycoprotein. Despite this, En(a−) individuals are haematologically normal[5]. We have now confirmed that En(a−) cells obtained fresh from three En(a−) individuals are indeed relatively resistant to invasion by *P. falciparum* although they are able to support parasite development. Our results also indicate that these cells may be a useful model in the search for a putative receptor for *P. falciparum*.

We have compared the rates of invasion by *P. falciparum* of normal and En(a−) cells obtained from the British[9] (MEP), Finnish[10] (GW) and Canadian[11] (RL) homozygous En(a−) individuals using an *in vitro* culture system[6–8] (Table 1). The numbers of parasites found in the En(a−) cells were significantly less than in the En(a−) controls using either the continuous asynchronous culture system[6] (incubation period 72 h) or the synchronized short-term (12–18 h) microtissue culture tray system[8]. The fact that parasite numbers are smaller in the longer-term cultures with cells from MEP is probably explained by some parasites being able to go through more than one schizogony, thus amplifying the differences between the En(a−) and En(a+) cells.

Because the reduction of invasion into En(a−) cells was relative rather than absolute, it was particularly important to control for contamination by En(a+) cells unavoidably present in the infected blood. This was achieved by using fetal haemoglobin (HbF) as a marker of En(a+) cells in the parasite culture. By using a modification of the acid elusion technique[12] to stain for HbF, to exclude En(a+) cells from parasite counts[13], we confirmed that there was some invasion of En(a−) cells but much less than of En(a+) cells. The more marked reduction in parasite numbers in GW and RL compared with MEP is surprising because whereas MEP cells, in addition to being deficient in glycophorin A, are also partially deficient in glycophorin B[14], a glycoprotein sharing considerable homology with glycophorin A[15], the cells of GW and RL lack only glycophorin A.

Once inside the En(a−) cells, parasites were able to develop as successfully as in En(a+) cells (Table 2). In these experiments also, HbF was used as a marker to control for contaminating En(a+) cells from the infected blood. These results indicate that defective invasion rather than development is the mechanism whereby parasites fail to interact with En(a−) cells.

Because of previous sensitization by transfusion or during pregnancy, the sera of En(a−) individuals usually contain anti-En[a] antibodies of varying titres. Just as En(a−) cells have several membrane alterations, anti-En[a] sera contain antibodies with at least three specificities—against the portions of the glycophorin A molecule which are respectively sensitive and insensitive to trypsin and against the Wr[b] antigen[5]. The effect of anti-En[a]

Table 1 Invasion of En(a+) and En(a−) cells by *P. falciparum*

				Mean 0.14 ± 0.01

The Uganda–Palo Alto strain of *P. falciparum* used was maintained in continuous culture using previously described methods[6–8]. In the 72-h cultures, cells containing asynchronous parasites were mixed in a 1 : 10 dilution with uninfected En(a+) or En(a−) cells and grown in Petri dishes with changes of medium every 12 h. In all cases, the cells, if not used immediately, were stored at 4 °C in citrate/phosphate/dextrose (CPD). After 72 h, samples from the cultures were smeared and stained to count the number of parasites (all stages) present. At least 1,000 cells were counted. The starting parasite count in these experiments was ~1%. Parasite growth for the short-term invasion assay was synchronized using a 5% sorbitol solution[20]. Schizonts were concentrated with a 3% gelatin solution (Plasmagel)[21] and mixed with uninfected cells at a dilution of 1 : 6–1 : 20 to obtain a 1.5% cell suspension with 2–5% of the cells containing schizonts; 200 µl of the mixture were pipetted into each well of a microtissue culture plate, incubated for 12–18 h at 37 °C in a mixture of 5% O_2/7% CO_2/88% N_2 and then smears were made and stained. Parasite numbers were assessed by counting the number of ring forms in at least 1,000 cells. The relative multiplication in the En(a−) cells was calculated as a proportion of the controls ± s.e.m. Cells from En(a−) individuals were obtained on two occasions from the Sheffield Blood Transfusion Service, UK (MEP), from the Red Cross Blood Transfusion Service, Helsinki (GW) and from the Red Cross Blood Transfusion Service, Montreal (RL). These and control En(a+) bloods taken at the same time were collected in CPD or acid/citrate/dextrose (ACD). (In the experiments with the En(a−) cells of RL, infected blood came from cultures containing fetal haemoglobin (HbF). Thus by staining smears using a modification of the acid elution technique[12] the counting of parasites in the HbF-containing En(a+) cells could be excluded. Figures in parentheses show parasite counts in all cells (adult and HbF-containing).

Table 2 Development of *P. falciparum* in En(a−) cells

	Invasion Parasites per 100 red cells (En(a−)/En(a+))	Development Schizonts per 100 singly infected cells En(a+)	En(a−)	(En(a−)/En(a+))
	0.13*	79	78	0.99
	0.15*	80	79	0.99
	0.15*	80	82	1.03
	0.35	68	70	1.03

	0.16	70	77	1.10
	0.42	71	79	1.11
Mean	0.24 ± 0.04			1.04 ± 0.02

The methods used were as for Table 1. The cells used were from the Canadian En(a−) individual (RL). The medium in the microtissue culture wells was changed at ~15 and 40 h. Development was assessed at 48 h by counting the number of parasites in 100 singly infected cells that had matured to the schizont stage (that is, a large parasite with the chromatin clearly divided into at least two distinct entities).

* In these experiments infected blood came from cultures containing HbF.

					Mean 0.49 ± 0.04

The methods used were as for Table 1 except that 50 µl of the medium per well was substituted with 50 µl of the serum to be tested[22]. Group O-positive cells were used in all experiments. Sera from the En(a−) individuals were obtained on several occasions. The first example from GW(GW_1) contained sodium azide added as a preservative. As azide is toxic to parasites, this serum was dialysed with parallel AB serum (ABS) controls against three changes of 1 l of phosphate-buffered saline *p*H 7.4. The sera from MEP and GW_2 were taken directly from the patients then placed in sterile preservative-free containers. The titres of the sera were determined by indirect anti-immunoglobulin tests carried out on all the sera at the same time. The sera possessing anti-En^a antibodies were absorbed by incubating them with an equal volume of group O +ve cells for 1 h at 37 °C. Similar treatment of ABS did not alter the rates of invasion (data not shown). Successful absorption of these anti-En^a sera was confirmed by indirect antiglobulin testing using En(a+) cells.

* In these experiments the concentration of serum was increased from 50 to 100 µl per well.

sera on parasite multiplication was examined in several experiments (Table 3). The presence of antibodies on the red cell surface was confirmed by direct anti-immunoglobulin testing. There was a significant reduction in the number of parasites in cultures to which sera were added, regardless of the method of collection, either compared with ABS or, more importantly, with the same anti-En^a sera after absorption with En(a$^+$) cells. The greater inhibition of invasion using the serum of GW correlated with its titre in an indirect antiglobulin test. The other sera used were of relatively low titre, having been taken several years after the individuals were sensitized.

To exclude the possibility that coating of red cells with anti-En^a antibody might reduce parasite invasion in a non-specific manner, various other sera directed against commonly occurring antigens present on red cells were examined in the same way. Two of these antibodies were directed against Rhesus antigens (anti-C and anti-c), one against the Kidd system (anti-Jk^a) and another against a Duffy determinant (anti-Fy^a). In no case was the number of parasites found in cells coated with antibody significantly less than in the controls (Table 4). On the other hand, there was a significant decrease in parasite numbers when sera from two patients who had recently recovered from cerebral malaria were added to the cultures. Anti-immunoglobulin tests confirmed the presence of antibody on the surface of the cells incubated with antisera to red cell antigens, but not on the cells incubated with the patients' sera. Antibodies in the latter are thought to act via merozoite agglutination rather than by receptor blockade[16].

Recent structural analysis of glycophorin A indicates that the M and N antigens are determined by its five amino-terminal amino acids and three oligosaccharides[17]. We further examined whether this most external portion of the glycophorin A molecule might be involved in the interaction with the parasite by comparing the relative rates of invasion of *P. falciparum* into cells bearing the M, the N and both antigens. The rates of invasion observed in MN, MM or NN cells were similar, indicating that the merozoite was unable to distinguish between these two antigens (Table 5).

These experiments have shown a significant reduction in invasion of En(a−) cells by *P. falciparum*. This may indicate either that there is a specific receptor site on the major sialoglycoprotein, or that there is a non-specific effect due to rearrangement of the membrane proteins in the absence of this major component. However, the presence of anti-En^a antibody caused

Table 4 Invasion of En(a+) cells by *P. falciparum* in the presence of antisera other than anti-En^a

Strain of parasite	ABS (control)	Parasites per 100 red cells Anti-C	Anti-c	Anti-JK^a	Anti-Fy^a	JG	DH
A	8.2	7.7	8.4	8.2	7.7	4.2	0.0
A	3.8	3.6	4.1	4.0	3.7	0.0	0.0
B	5.7	6.5	7.0	6.5	6.6	NT	NT
C	9.1	7.9	7.8	5.5	8.8	4.5	0.3
C	5.6	2.0	5.3	4.1	5.3	4.8	2.3
	Mean $\frac{\text{Test}}{\text{Control}}$	0.85 ± 0.13	1.05 ± 0.05	0.96 ± 0.08	0.99 ± 0.06	0.47 ± 0.18	0.11 ± 0.10

The methods used were as for Tables 1 and 3. Three strains of parasite were used: A, Uganda–Palo Alto; B, wild West African; and C, wild East African. The wild strains were obtained from infected patients returning to Oxford. Sterile, preservative-free antisera were obtained from the Oxfordshire Regional Blood Transfusion Service. Sera were also obtained, at least 1 month after completing chloroquine therapy, from two patients convalescing after severe *P. falciparum* infections (JG and DH). The relevant typing of the En(a+) cells used was as follows: ABO group O; Rh-positive (C$^+$, D$^+$, E$^+$, c$^+$, e$^+$); M+, N+, Fy(a+), Fy(b+); Jk(a+), Jk(b−), Wr(a−), Wr(b+).

NT, not tested.

Table 5 Invasion by *P. falciparum* of cells expressing either the M or N or both antigens

	Parasites per 100 red cells	
MN cells (Control)	MM cells (Test)	NN cells (Test)
8.8	9.1	9.8
7.5	6.6	7.8
6.4	6.7	6.5
Mean $\left(\frac{\text{Test}}{\text{Control}}\right)$	0.99 ± 0.05	1.06 ± 0.03

The methods were as for Table 1. The cells were obtained in CPD from the Oxfordshire Regional Blood Transfusion Service.

a significant reduction in parasite numbers in En(a+) cells which was prevented by previous absorption with En(a+) cells. This effect was not seen when other antibodies were used to coat the red cells. This finding suggests that the relationship between the parasite and the missing membrane component of the En(a−) cells is more specific. The fact that anti-En^a antibody (GW_2 and MEP) failed to reduce invasion of normal cells to the level found in En(a−) cells may have been due to low antibody titres resulting in insufficient blockade of this high density receptor (glycophorin A), of which there are at least 500,000 copies per cell[18]. Moreover the reduction in invasion caused by the low titre anti-En^a sera cannot exclude the role of the Wr^b antigen which is also recognized by this serum. Although these antisera could act by damaging the mature schizont-infected cell, by merozoite agglutination, or by premature lysis of infected En(a−) cells, these data, together with the reduced invasion of En(a−) cells, are more consistent with the anti-En^a sera acting via receptor blockade.

Of the many types of red cells that have been examined previously, only those containing haemoglobin S or predominantly haemoglobin C have shown rates of invasion inappropriate to their metabolic age[19]. En(a−) cells must now be added to this list. Miller has shown that trypsin-treated red cells are relatively resistant to invasion by *P. falciparum*[4]. Glycophorin A is one of the major targets for cleavage by this enzyme. These findings, together with the present studies, suggest that glycophorin could serve as a receptor for *P. falciparum*. The development of monoclonal antibodies against specific regions of these glycoproteins should allow this possibility to be explored further.

We thank Dr W. Wagstaff, Anna Pirkola, Dr R-M. Guévin, Mr V. Taliano and Mr M. Woodward for providing the numerous samples of cells, sera and reagents. We also thank Drs R. Sanger and P. Tippett for assistance. G.P. was supported by the Wellcome Trust and Rockefeller Foundation.

Note added in proof: Since submission of this letter, Perkins[23] has shown that glycophorin A in solution and Fab′ fragments of antibody against glycophorin A will inhibit merozoite invasion.

Virus-induced diabetes mellitus: autoimmunity and polyendocrine disease prevented by immunosuppression

Takashi Onodera, Usha R. Ray, Kathleen A. Melez, Hoshibumi Suzuki, Antonio Toniolo & Abner Louis Notkins

Laboratory of Oral Medicine, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205, USA

Autoantibodies to cytoplasmic and surface antigens on pancreatic islet cells have been found in many newly diagnosed cases of insulin-dependent diabetes mellitus (IDDM)[1-9]. Various autoantibodies (for example, against islet cells, adrenals, thyroid, gastric mucosa and intrinsic factor) have also been found in patients with polyendocrine disease[1,2,8,9]. What triggers the production of these antibodies and their importance in the pathogenesis of these diseases are still unclear. Recently, we found in an animal model for studing polyendocrine disease[10] that reovirus type 1 (reo-1) infected cells in both the pancreas and pituitary, and produced a disease characterized by hyperglycaemia and retarded growth[10]. Moreover, autoantibodies that reacted with antigens in pancreatic islets, the anterior pituitary and gastric mucosa were found, one of which reacted with insulin and another with growth hormone (GH). Using recombinant viruses[11] we showed that the *S1* gene segment from reo-1 was required for the induction of autoantibodies to GH. We report here our search for additional autoantibodies, especially against surface antigens, and our efforts to evaluate the pathological contributions of the lytic effect of the virus on cells compared with the immunopathological response of the host. Our experiments showed that reo-1 induced autoantibodies that reacted with antigens on the surface of islet cells, thymocytes and a GH-producing cell line. In addition, we found that treatment with immunosuppressive agents depressed autoantibody production and prevented development of the polyendocrine disease.

Except where indicated, male and female SJL mice were infected intraperitoneally (i.p.) at 5–7 days of age with the Lang strain of reo-1 that had been passaged 10–14 times in pancreatic β-cell cultures[10]. Rabbit anti-mouse lymphocyte serum (ALS) and rabbit anti-mouse thymocyte serum (ATS) (MA Bioproducts, Walkersville, Maryland), with cytotoxic titres 1:6,400 and 1:1,600 respectively, and cyclophosphamide (Cy) (20 mg per kg)[12] were used as immunosuppressive agents. Single-point glucose tolerance tests (GTTs) were performed 60 min after i.p. injection of 2 mg glucose per body weight[10]. Plasma GH was measured by radioimmunoassay[10,13], and antibody to reo-1 was determined by a standard haemagglutination-inhibition technique[14]. Indirect immunofluorescence was carried out as described previously[10].

Three different immunosuppressive agents were tested for their effect on the development of reovirus-induced diabetes. As shown in Fig. 1, reo-1 produced abnormal GTTs in SJL mice, but these abnormalities were reduced or prevented by treatment with ALS (Fig. 1*a*). Similarly, ATS and Cy prevented the development of reovirus-induced hyperglycaemia (Fig. 1*b*). Reo-1 also produced some glucose abnormalities in NFS mice and these abnormalities were suppressed by ALS (Fig. 1*c*). All eight experiments performed with reo-1 and immunosuppressive agents revealed similar trends, although in some experiments the reovirus-induced abnormal GTTs were much less marked than those observed in Fig. 1*a* and *b*.

Immunosuppression prevented not only the development of hyperglycaemia but also growth retardation. Table 1 shows that

virus-infected immunosuppressed mice gained weight at almost the same rate as uninfected controls, and that oily hair and steatorrhoea were greatly decreased by ALS. Mortality was also markedly reduced. Moreover, the infected mice with retarded growth had considerably lower plasma GH levels than the infected and immunosuppressed mice.

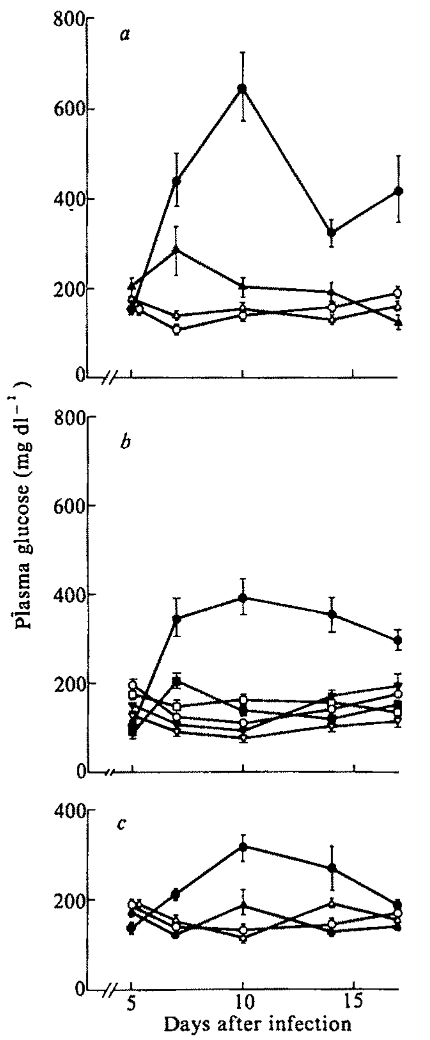

Fig. 1 Effect of immunosuppressive agents on glucose tolerance tests in reo-1-infected mice. Mice were infected with 5×10^5 plaque-forming units (PFU) of virus and single-point glucose tolerance tests were performed at different times thereafter. Immunosuppressive treatment consisted of three 0.1-ml i.p. injections of ALS or ATS on days 0, 4 and 7 after infection or a single i.p. dose of Cy 1 day after infection. 10 to 35 mice were tested at each time point in each group. The mean ± s.e.m. is represented by symbols and vertical lines. *a*, SJL mice: ●, reovirus-infected; ○, uninfected; ▲, infected and treated with ALS; △, uninfected and treated with ALS. *b*, SJL mice: ●, reovirus-infected; ○, uninfected; ■, infected and treated with ATS; □, uninfected and treated with ATS; ▼, infected and treated with Cy; ▽, uninfected and treated with Cy. *c*, NFS mice: ●, reovirus-infected; ○, uninfected; ▲, infected and treated with ALS; △, uninfected and treated with ALS.

To see whether the immunosuppressive agents might be preventing clinical symptoms by inhibiting the autoimmune response, we measured the titre of autoantibodies in the sera of infected mice reacting with tissue sections from uninfected normal mice[10]. As shown in Table 2, autoantibodies to the anterior pituitary, islet cells and GH_3 cells (a rat cell line which produces both GH and prolactin)[15] were greatly reduced, or not detected, in sera from reovirus-infected immunosuppressed mice. Immunosuppression also reduced the percentage of mice with autoantibodies to GH and insulin.

In addition to autoantibodies reacting with cytoplasmic antigens, autoantibodies to surface antigens on viable islet cells, GH_3 cells and thymocytes, but not mouse fibroblasts, were found by avidin-biotin immunofluorescence[16]. In our hands, this method is more sensitive than standard indirect immunofluorescence. Nonetheless, the titre of these antibodies was quite low and they reacted with only a small number (10–15%) of islet cells, GH_3 cells and thymocytes. In reovirus-infected immunosuppressed mice, these autoantibodies could not be detected. Immunosuppression also reduced, but did not eliminate, the antibody response to reo-1 (Table 2); this may account for the ability of the immunosuppressed animal to cope with the viral infection.

As previously reported, reovirus infection produced mild β-cell damage and insulitis, with infiltration of mononuclear and plasma cells[10]. In the present experiments, immunosuppression with ALS greatly reduced the degree of insulitis and β-cell damage (data not shown). Precisely how the viral infection triggers the autoimmune and inflammatory responses[10] and what role, if any, autoantibodies to thymocytes have in this process are unclear.

The possibility that the immunosuppressive agents were preventing the polyendocrine diseases by inhibiting virus replication (such as by antiviral antibody in the immunosuppressive sera or induction of interferon), rather than by suppressing the autoimmune response, was evaluated by measuring virus growth *in vivo*. Figure 2 shows that the former possibility is unlikely as virus titres in homogenates of liver, heart and pancreas were approximately the same in untreated and ALS-treated mice at various times after infection.

Viral infections cause tissue damage by two principal mechanisms: they can directly lyse cells as a result of virus replication, and they can trigger in the host an immunopathological response[17–19]. In the case of reovirus, both mechanisms may operate; infected cells are certainly destroyed as a result of virus replication and a recent study suggests that some cells may also be destroyed by cytolytic T lymphocytes specific for reovirus antigens on the surface of cells[20].

The present experiments suggest another possible mechanism by which reovirus might cause disease: the infection triggers the production of autoantibodies that react with antigens on the surface of normal uninfected cells or with cell products (for example hormones). These interactions could act pathologically by directly destroying hormone- producing cells or by binding to and reducing the concentration of hormones in the circulation.

In experimental animals, we previously showed that neither

Table 1 Reversal of reovirus-induced growth retardation, clinical symptoms and mortality by immunosuppression

Groups		Weight (g)		% Oily hair and steatorrhoea		% Mortality		GH (ng ml^{-1})
Infection	ALS	SJL	NFS	SJL	NFS	SJL	NFS	SJL
+	–	7.6±2.3*	8.3±2.5*	63	50	43	40	16±8
+	+	12.3±3.5†	13.7±1.8†	0	0	25	13	48±4
–	+	11.4±1.0†	13.6±1.0†	0	0	0	0	ND
–	–	14.1±2.4	14.9±2.2	0	0	0	0	41±6

SJL and NFS mice were infected and treated with ALS as in Fig. 1. Each group consisted of 10–20 mice. Body weights given were for 17 days after infection (mean±s.d.), the incidence of oily hair and steatorrhoea was determined 10 days after infection, cumulative mortality was assessed at 17 days after infection, and plasma GH 14 days after infection (mean±s.e.m.). ND, not done.

* $P < 0.001$ compared with uninfected and untreated controls.

† Not statistically significant compared with uninfected and untreated controls.

Table 2 Effect of immunosuppression on autoantibody titres in reovirus-infected mice

Groups		Autoantibodies to: Cytoplasmic antigens*			Surface antigens†			Hormones‡		
Infection	ALS	Anterior pituitary	Islets	GH_3	Islets	GH_3	Thymocytes	Insulin	GH	Antibody to reovirus
+	−	32	8	16	4	2	8	56	89	256
+	+	2	2	<2	<2	<2	<2	16	20	16
−	+	<2	<2	<2	<2	<2	<2	0	0	<8
−	−	<2	<2	<2	<2	<2	<2	0	0	<8

Reo-1 infection and ALS treatment were as in Fig. 1. Autoantibodies were measured in pooled sera from 10 mice. Similar results were obtained with pooled sera from two other experiments. Titres for reovirus antibody are given as reciprocal antibody titres by haemagglutination-inhibition tests to reo-1 in pooled sera 17 days after infection.

* Bouin's-fixed sections of anterior pituitary and pancreas from uninfected mice, or acetone-fixed rat GH_3 cells were incubated with serial dilutions of mouse sera (obtained 14 days after infection) and stained with fluorescein-labelled anti-mouse IgG. Titres represent the reciprocal of the highest dilution of sera giving positive fluorescence[10].

† Suspensions of cultured mouse SJL pancreatic islet cells, or rat GH_3 cells, or freshly prepared thymocytes from weanling SJL mice were incubated with pooled mouse sera obtained 14 days after infection and stained with biotin-conjugated anti-mouse immunoglobulin followed by fluorescein-labelled avidin[16]. Titres represent the reciprocal of the highest dilution of sera giving positive fluorescence.

‡ Individual sera from 10–20 mice per group (obtained 17 days after infection) were tested for antibodies to insulin and GH by an enzyme-linked immunosorbent assay[10]. Sera with titres >10 were considered positive and numbers represent per cent positive.

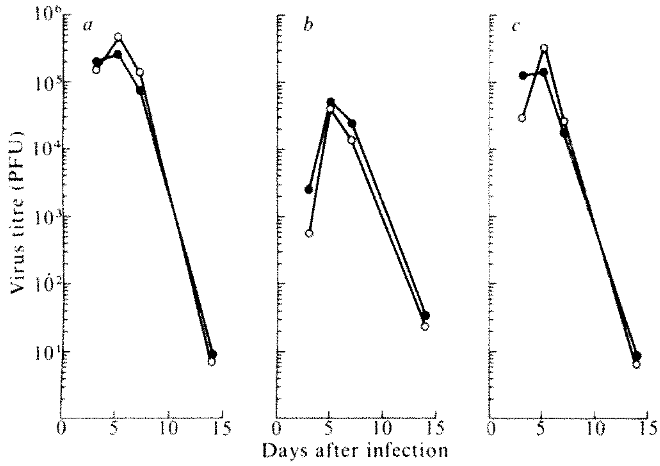

Fig. 2 Reovirus titre in ALS treated mice. SJL mice were infected with 5×10^5 PFU and treated with ALS as in Fig. 1. Virus titres in homogenates of liver (*a*), heart (*b*) and pancreas (*c*) were measured at different times after infection. Titrations were performed on L929 cells by a standard plaque assay[10] and expressed as PFU per organ. Each point represents the mean titre of two to four individual mice. ○, Infected mice given ALS; ●, infected mice not ALS.

virus alone nor sub-diabetogenic doses of streptozotocin alone could produce hyperglycaemia, whereas treatment with both agents resulted in overt diabetes[21]. Our interpretation was that neither virus nor streptozotocin alone depleted the β-cell reserve sufficiently to result in diabetes. Reovirus-induced polyendocrine disease may also be the result of cumulative injury. Both the direct lytic effect of the virus and autoimmune pathology may be required to decrease the hormone reserve sufficiently to make the disease overt. The possibility that virus-induced autoimmunity contributes to the pathogenesis of other diseases merits investigation.

Attenuated reovirus type 3 strains generated by selection of haemagglutinin antigenic variants

Dale R. Spriggs* & Bernard N. Fields*†

Infection of suckling mice with mammalian reovirus type 3 results in fatal encephalitis associated with marked destruction of neurones[1–4]. The viral tropism specific to neural cells is determined by the reovirus haemagglutinin[3,4]. This haemagglutinin (HA), the $\sigma 1$ polypeptide, is encoded in the S1 dsRNA segment[5,6]. In addition to determining cell and tissue tropism, the viral haemagglutinin determines humoral and cellular immune specificity[7–10], binding to cellular microtubules[11] and inhibition of cellular DNA synthesis[12]. To elucidate the structural basis for the functions of the reovirus type 3 HA, we have recently isolated and characterized several anti-HA monoclonal antibodies, which we have used to show that there are distinct functional domains on the reovirus type 3 HA[13]. One group of monoclonal antibodies neutralizes viruses while a second inhibits haemagglutination. Thus there are distinct HA functional domains involving haemagglutination and neutralization. One of the neutralizing monoclonal antibodies was used to select reovirus antigenic variants that were no longer neutralized by the monoclonal antibodies. These 'variant' viruses were tested for their neurovirulence by determining their capacity to replicate in mouse brains, leading to fatal encephalitis. We report here that all variants are markedly less virulent then the parental type 3 virus from which they were selected. These findings demonstrate directly the critical role of the viral haemagglutinin in neurovirulence and show that variant viruses that are altered at a site recognized by neutralizing antibody cannot grow efficiently in neural tissue.

0028–0836/82/180068—03$01.00

Reovirus serotype 3 viruses with antigenically altered HA proteins were selected by incubating the neurovirulent virus stock (Dearing strain) with excess neutralizing monoclonal antibody (designated G5). Viral plaques that appeared on the plates were isolated and passaged a second time in the presence of G5 antibody to eliminate clones that were not resistant to the antibody. Resistant viruses (variants) were then grown in mouse L cells to give virus stocks. Three variant viruses (A, F and K) isolated in this manner were tested for their relative ability to resist neutralization by the G5 monoclonal antibody (Table 1). As reported previously, the parental reovirus type 3 (Dearing) strain was neutralized efficiently by G5 (ref. 13). All three variants showed an altered response to G5 antibody: the F and K variants were totally resistant to the antibody while the A variant was neutralized to a level intermediate between that of the Dearing parent and the F and K variants. For example, the A variant was neutralized at 1:20 and 1:100 dilutions of G5, but the plaque reduction at 1:500 was of borderline significance. The Dearing strain was neutralized at all the dilutions tested. Previous studies have shown that the G5 antibody neutralizes the Dearing strain at dilutions up to 1:12,500 (ref. 13). In contrast to the results with the G5 monoclonal antibody, the three variants were indistinguishable from the parental reovirus type 3 Dearing virus in neutralization tests using a type-specific hyperimmune antiserum (Table 1). These data indicate that all three variants encode an haemagglutinin having antigenic alterations that are readily detected with monoclonal antibodies but not with a standard hyperimmune antiserum.

To determine if the variants were altered in terms of virulence, we compared them with regard to their relative ability to cause fatal neurological disease in suckling mice. The type 3 Dearing parent is highly neurovirulent; as few as 10 plaque-forming units (PFU) inoculated intracerebrally (i.c.) in suckling mice kill 50% of mice by 14 days while higher doses kill 100% (ref. 3; Table 2). To compare the neurovirulence of type 3 Dearing with the variant viruses, we injected varying doses of virus into suckling mice and determined the survival pattern for each infected group of animals (Table 2). The F and K variants had LD_{50}s (lethal dose for 50% of the population) values of 3×10^7 and $>3\times10^7$ PFU, respectively, while the A variant had an intermediate LD_{50} of 1.8×10^5 PFU. These results indicate that all the variants are at least 10,000 times less neurovirulent than the Dearing strain from which they were derived. Interestingly, the A variant that was intermediate in antigenic reactivity, also exhibited an intermediate LD_{50} (1.8×10^5) whereas the F and K variants, which were not neutralized by G5, showed the greatest reduction in virulence. These data suggest that the loss of antigenic reactivity with the G5 antibody is directly related to the neurovirulence.

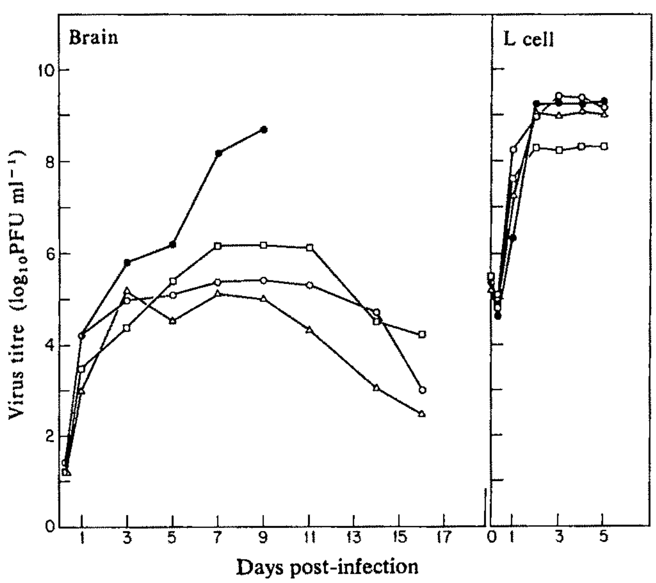

Fig. 1 Growth patterns of reovirus type 3 (Dearing, ●) and antigenic variants A (□), F(○) and K (△) in mouse brains (left) and mouse L cells in tissue culture (right). Virus growth in mouse brains was determined by injecting all mice i.c. with 1×10^3 PFU of virus. Three mice were killed at each time point and the virus titres in the individual brains were determined by titration of brain homogenates on mouse L cells at 37 °C as described previously[4]. Each value represents the average of three titrations. Virus growth in mouse L cells was determined by infecting monolayers of 2×10^5 cells at a multiplicity of infection of 5 PFU per cell. Triplicate samples were taken for titration at each indicated time point[16].

Table 1 Neutralization of reovirus serotype 3 (Dearing) and HA antigenic variants by monoclonal antibody and hyperimmune antiserum

Antibody	Dilution of antibody	% Inoculum resistant to antibody: Dearing strain	Variant strains: A	F	K
G5	1:20	0	21	100	88
	1:100	0	18	100	100
	1:500	5	48	100	100
Hyperimmune	1:200	6	7	4	3
	1:400	5	4	2	4
	1:800	14	4	5	9

Neutralization tests were performed as described previously[13]. Briefly, dilutions of antibody were incubated with 100 PFU of virus at 34 °C for 1 h. These mixtures were then inoculated on to mouse L cells. The G5 antibody was used to select the variants and was used in these experiments as a purified IgG fraction[13]. Values represent the percentage of plaques observed in the presence of antibody relative to a phosphate-buffered saline control. The hyperimmune antiserum is a reference goose anti-reovirus type 3 antiserum obtained from the National Institute of Allergy and Infectious Diseases (V703-501-570).

Because neurovirulence is correlated with the ability of reovirus type 3 to replicate in suckling mouse brains, we analysed the growth of type 3 reovirus and the three variants in mouse brains (Fig. 1). The reovirus type 3 (Dearing) virus grows to high titres in the brain before death of the infected mice[3,4]. The virus yield in these experiments was $\sim1\times10^9$ PFU ml^{-1}, but titres were often $\geq1\times10^{10}$ PFU ml^{-1}. The three variants differed significantly from the Dearing strain in their ability to grow in mouse brains during the acute infection, particularly after the fifth day post-inoculation (Fig. 1). The F and K variants showed most reduction in growth while the A variant was again intermediate between the F and K variants and the Dearing virus.

To determine whether the inability of the three variants to grow in brains was due to a general defect of growth or was

Table 2 Neurovirulence of reovirus serotype 3 (Dearing) and HA antigenic variants A, F and K

Inoculum (PFU)	% Mice alive on day 14 post-infection: Dearing strain	Variant strains: A	F	K
1×10^1	50	100	100	100
1×10^2	0	100	100	100
1×10^3	0	100	100	100
1×10^4	NT	100	100	100
1×10^5	NT	90	100	100
3×10^5	NT	0	100	100
3×10^6	NT	0	90	100
3×10^7	NT	0	50	90
LD_{50}	10^1	1.8×10^5	3×10^7	$>3\times10^7$

Groups of CD mice (24–48 h old) were injected i.c. with varying doses of virus and observed for 14 days[3,4]. Animals began to die between days 8 and 10 in most cases. Values represent the percentage of mice alive at day 14 post-infection. NT, not tested. The LD_{50} is the dose of virus required to kill 50% of the animals in each group by day 14. LD_{50} values were calculated by the Reed and Muench method[15].

specific to growth in the brain, we examined the replication cycle of the variants and Dearing virus in mouse L cells (Fig. 1). Both reovirus type 3 Dearing and the three variants grew to a high titre. The variants were also not temperature-sensitive for growth in L cells (data not shown). Examination of brains infected with variants A, F and K showed a marked localization of tissue destruction in parts of the hippocampus. In contrast, infection with the Dearing strain caused tissue destruction not only in the hippocampus but also diffusely in the cortex and brain stem (unpublished data). Thus the pattern of restricted growth in the brain was not due simply to a general defect in the ability of the three variants to replicate, but to growth in restricted sites in the brain.

Thus, antigenic variants of reovirus type 3 selected by monoclonal antibodies directed against the major neutralization site, have markedly different levels of neurovirulence and capacity to grow *in vivo*. These experiments directly indicate that the reovirus type 3 haemagglutinin is a major determinant of neurovirulence, and imply that particular regions of the HA have critical roles in virulence. The site chosen for selection of the variants, the major neutralization determinant on the HA molecule, is probably the polypeptide region involved in binding to neurone receptors[14]. Other studies have shown that this region is also the site on HA that is recognized by cytotoxic T lymphocytes (unpublished data), and is involved in binding to cell receptors[14]. Furthermore, we have recently demonstrated that these variants induce cytolytic T lymphocytes as well as neutralizing antibody (unpublished data). Further data on the nature of the alterations in the haemagglutinin polypeptide of these variants should enable us to define the role of haemagglutinin in viral virulence more precisely. In addition, the use of monoclonal antibodies to generate attenuated viral strains may serve as a rapid and simple step for developing viral vaccines.

Non-neutralizing monoclonal antibodies can prevent lethal alphavirus encephalitis

A. L. Schmaljohn*, E. D. Johnson†, J. M. Dalrymple† & G. A. Cole*

* Department of Microbiology, University of Maryland School of Medicine, Baltimore, Maryland 21201, USA

Among the heterogeneous population of antibodies specifically induced during many acute viral infections, those having virus-neutralizing activity *in vitro* are generally considered to be most important for recovery and immunity to reinfection. Similarly, the ability to stimulate production of circulating neutralizing (NT) antibodies is a major criterion for evaluating the immunoprophylactic potential of many antiviral vaccines[1]. Although there is obviously an association between NT antibody induction and host resistance, we present here data which indicate that other virus-specific antibodies lacking NT function may be equally important in conferring protective immunity to alphaviruses. We used monoclonal antibodies against Sindbis virus (SV) to demonstrate that passive protection of SV-infected mice from fatal paralytic central nervous system (CNS) disease may be mediated not only by antibodies which neutralize the infectivity of extracellular virus particles but also by those lacking this capacity, which react preferentially with virus-infected cells.

Sindbis virus, the prototype of the alphaviruses, contains two distinct envelope glycoproteins, E1 and E2, which exist as a complex, and a nucleocapsid protein, NC. It has been shown that antibodies raised in rabbits against each of the individually isolated and purified glycoproteins of SV possess distinctly separable activities *in vitro*[2]. Antibodies to E1 (the viral haemagglutinin) inhibit haemagglutination by SV, whereas only antibodies to E2 significantly neutralize viral infectivity. Antibodies specific for the internal NC do not react with intact virions. Both haemagglutination-inhibiting (HI) and NT antibodies are induced during productive infections with SV as well as with other alphaviruses[3], but their respective roles in mediating host recovery are not clear.

Recently[4], we described the preparation of a large panel of monoclonal antibodies against the parental AR339 strain of SV (SV_p), some of which were used to define serological and biochemical relationships between SV and certain other alphaviruses. In the present study, six anti-E1, six anti-E2, and one anti-NC monoclonal antibodies were selected for further characterization and each was assessed for its protective capacity *in vivo*. Because, by any route of inoculation, SV_p produces an abortive immunizing infection in adult mice, a neuroadapted (na) variant[5] of SV_p was used to intracerebrally (i.c.) challenge C57BL/6J (B6) mice previously given monoclonal antibodies. When given i.c. to non-immune adult B6 mice, SV_{na} produces paralysis and fatal encephalitis.

To prepare monoclonal antibodies, spleen cells from BALB/cJ mice immunized with infectious SV_p were fused with P3X63-Ag8 myeloma cells, and hybrid cells were cloned by limiting dilution in hypoxanthine–aminopterin–thymidine medium[6]. Clones producing antibodies to SV_p were selected by solid-phase radioimmunoassay[7] of supernatants. Positive cultures were subcloned in soft agar and tested again by radioimmunoassay for anti-SV activity. Individual hybrid clones were expanded *in vitro*, and then inoculated into groups of pristane-primed BALB/cJ mice[8]. The resulting ascitic fluids derived from each hybrid clone were pooled, frozen in aliquots, and used in subsequent experiments. The specificity of each monoclonal antibody was determined by radioimmunoassay reactivity with individual SV_p structural proteins which had been separated by isoelectric focusing as previously described[2]. Specificity was confirmed by immunoprecipitation of radiolabelled virus, followed by polyacrylamide gel electrophoresis.

The isotypes of the monoclonal antibodies were determined by an indirect immunofluorescence procedure in which glass slides bearing acetone-fixed, SV_p-infected BHK-21 cells were exposed sequentially to predetermined concentrations of monoclonal antibody, rabbit antiserum (Litton Bionetics) specific for individual mouse immunoglobulin heavy-chain isotypes (IgM, IgG1, IgG2a, IgG2b or IgG3), and fluorescein-conjugated goat

Table 1 Properties of anti-SV_p monoclonal antibodies

No.	Monoclonal antibody Specificity	Isotype	Reactivity with SV_{na} IF	NT titre	% C′-dependent cytolysis
		Protective *in vivo*			
12	E2	IgG2b	+	3,200	55.3
43	E2	IgG2a	+	800	21.1
49	E2	IgG2a	+	1,000	47.7
1	E1	IgG2a	+	<10	29.4
2	E1	IgG2a	+	<10	16.8
7	E1	IgG2a	+	<10	29.1
38	E1	IgG2a	+	<10	32.6
31	E1	IgG2b	+	<10	28.5
		Non-protective *in vivo*			
23	E2	IgG3	+	<10	2.1
8	E2	IgG2a	−	<10	ND
10	E2	IgG2a	−	<10	ND
13	E1	IgG1	+	<10	−1.3
3	NC	IgG3	+	<10	0.3

Specific binding by monoclonal antibody to SV_{na}-infected BHK-21 cells was determined by immunofluorescence (IF). Acetone-fixed cells on glass slides were overlaid with monoclonal antibody for 30 min, washed and then overlaid with fluorescein-labelled goat anti-mouse immunoglobulins (Cappel) for 30 min, then washed again. Each reagent was used at a 1:20 dilution in buffered saline, *p*H 7.4. All positive monoclonal antibodies exhibited bright perinuclear and cytoplasmic IF; antibodies 8 and 10 were completely negative. No IF was observed for uninfected control cells. Using the same procedure, all monoclonal antibodies including 8 and 10, were positive on SV_p-infected cells. To demonstrate C′-dependent antibody-mediated cytolysis, BHK-21 cells were infected (or mock-infected) in suspension with virus at a multiplicity of 6 PFU per cell, labelled with ^{51}Cr, washed and seeded into flat-bottomed 96-well tissue culture plates (Costar). Each well received an aliquot (100 μl) containing 2×10^4 cells in RPMI-1640 supplemented with 10% fetal bovine serum. To triplicate wells were added monoclonal antibody (previously heated at 56 °C for 30 min) and guinea pig C′ at final concentrations (v/v) of 2.5% and 5.0%, respectively, in a total volume of 200 μl per well. After 6 h incubation at 37 °C in air containing 5% CO_2 (9 h post-infection) supernatants from each well (100 μl) were counted individually for radioactivity, and the mean % virus-specific cytolysis was calculated as described previously[15]; s.e.m. never exceeded 3%. Monoclonal antibody-mediated release of label from cells in control wells (uninfected cells + C′, and infected cells + heat-inactivated C′) did not exceed 2.8%. In medium alone, 17.9% and 16.7% of total incorporated label were released by infected and uninfected cells, respectively.

anti-rabbit immunoglobulins (Cappel). Slides were washed exhaustively after the application of each reagent.

Each monoclonal antibody was tested, in the presence of 5% (v/v) guinea pig complement (C′), for its ability to neutralize SV infectivity and to mediate C′-dependent lysis of SV-infected BHK-21 cells. We measured neutralizing activity against 100 plaque-forming units (PFU) of each virus preparation (SV_p and SV_{na}), using a conventional 'constant virus–varying antibody' assay[8]. The reciprocal of the highest dilution of a monoclonal antibody which produced a ≥80% reduction in PFU was designated its NT titre. SV-specific antibody-mediated cytolysis was determined in a 6-h ^{51}Cr-release assay (Table 1).

To initially screen monoclonal antibodies for their protective capacity, each was given intraperitoneally (0.1 ml per mouse) to five female B6 mice, 6–8 weeks old, 24 h before challenge i.c. with 1,000 PFU of SV_{na}. All, or most mice in eight such groups resisted challenge, whereas all of a control group of infected non-immune mice, died. As shown in Table 1 (upper panel), passive protection by three anti-E2 monoclonal antibodies correlated with their having measurable NT activity against SV_{na}, although all such antibodies were capable of neutralizing SV_p (data not shown). In contrast, although none of the six anti-E1 monoclonal antibodies had NT activity against either SV_p or SV_{na}, five were protective. Sindbis virions acquire their envelopes by budding from host-cell plasma membranes which express both E1 and E2 during viral morphogenesis[9,10]. Thus, irrespective of their glycoprotein specificity, all protective monoclonal antibodies shared an ability to bind SV_{na}-infected cells as shown by immunofluorescence and, as might be expected from their IgG2a and IgG2b isotypes, by C′-dependent cytolysis (Table 1).

The results of these initial passive protection tests were confirmed using larger numbers of B6 mice; protective monoclonal antibodies either prevented or delayed both paralytic disease and death (Table 2, upper panel). Measurements of infectious SV_{na} in individual brains obtained at intervals after challenge revealed that CNS infections were generally attenuated, rather than prevented, in mice which had received protective monoclonal antibody. On day 3 of infection, when brain virus titres were maximal in mice from groups given either non-protective or no monoclonal antibody, brains of mice from the protected groups contained at least 100-fold less virus (Table 2, lower panel). Furthermore, by day 7 of infection, when all unprotected mice were paralysed and/or moribund, infectious virus was no longer detectable in brains of protected mice (data not shown).

All monoclonal antibodies, whether protective or not, had similar titres ($>10^4$) against SV_p in solid-phase binding assays (data not shown), and the failure of a monoclonal antibody to protect *in vivo* could not be attributed, in any case, to transfer of insufficient antibody. Certain monoclonal antibodies may be nonprotective, however, due to antigenic differences between SV_p and SV_{na} that result in undetectable or low-affinity binding to SV_{na}. Of the three anti-E2 monoclonal antibodies which failed to protect the mice, none neutralized SV_{na} and only one (no. 23) was reactive with SV_{na}-infected cells by immunofluorescence (Table 1, lower panel). The non-C′-fixing isotype (IgG3) of the latter would explain its failure to mediate SV-specific cytolysis *in vitro* but the fact that all three neutralized SV_p infectivity, even in the absence of complement (data not shown), may mean that passive protection conferred by anti-E2 antibodies depended more on their having NT activity against SV_{na} and less on their isotypes. On the other hand, it seems significant that the isotype (IgG1) of the single non-protective anti-E1 monoconal antibody (no. 13) is one which does not mediate immunospecific cytolysis by the classical complement pathway[10]. If, in fact, protection by anti-E1 antibodies, which do not neutralize SV, is effected solely through this C′-dependent cytolytic mechanism, it would be restricted to only those isotypes capable of fixing complement. The importance of the latter in antibody-mediated protection against SV is also suggested by the impaired virus clearance previously noted in mice which are deficient in either the C3 (ref. 11) or C5 (ref. 12) complement components.

The present data suggest two specific but functionally different humoral mechanisms of SV elimination *in vivo*: (1) neutralization of infectivity by antibodies which bind to E2 determinants on extracellular virions, a process which can occur *in vitro* in the absence of C′; and (2) C′-dependent lysis of

Table 2 Prevention of paralysis and death of SV_{na}-infected mice by anti-SV_p monoconal antibodies

Monoclonal antibody No.	Speci-ficity	Paralysis P/T	Mean day of onset	Mortality D/T	Mean day of death	log_{10} PFU per g brain on day 3

None	—	19/20	6	18/20	9	7.7, 7.6

Groups of 6–8-week-old female C57BL/6J mice were given 0.1 ml monoclonal antibody (in 0.5 ml saline) intraperitoneally, challenged i.c. 24 h later with 1,000 PFU of SV_{na} and then observed for at least 21 days. Results are expressed as the proportion of mice that developed hind limb paralysis (paralysed/total, P/T) and died (dead/total, D/T). Brains of mice in selected groups were frozen 1, 3, 5 and 7 days after infection and assayed individually for SV PFU on BHK-21 cells; results are shown for day 3, when maximum brain titres occurred in non-immune control mice.

SV-infected cells mediated by either neutralizing or non-neutralizing antibodies (of restricted isotypes) which bind, respectively, to E2 and E1 determinants on the cell surfaces. It is likely that one or both of these mechanisms involve(s) the recognition of more than one viral glycoprotein determinant. For example, all six anti-E1 monoclonal antibody were capable of binding to SV-infected cells (Table 1) but only two (1 and 31) had significant HI activity (data not shown).

The ability of five anti-E1 monoclonal antibodies to effect cytolysis, but not neutralization, in the presence of C′ suggests that one or more E1 determinants expressed on the plasma membrane of infected cells are not similarly expressed on infectious SV particles. That non-NT anti-E1 antibodies did not recognize infectious SV was indicated further by their failure to neutralize virus in the presence of polyvalent anti-mouse-immunoglobulin antiserum which, in parallel assays, augmented the activity of NT antibodies (data not shown).

During viral morphogenesis, glycoproteins of SV and other alphaviruses undergo configurational changes associated with the cleavage of PE2 (the precursor of E2) and the subsequent formation of the virion E1/E2 complex[9,13]. These changes may cause certain E1 and/or E2 determinants expressed initially on infected cells to become modified or cryptic on mature virions. Therefore, it would follow that the determinant specificities of antibodies induced by a given alphavirus glycoprotein would depend, in part, on the protein being either cell- or virion-associated when presented to the immune system. In this context, our finding that the protective non-neutralizing anti-E1 monoclonal antibody was functionally specific for SV-infected cells suggests that the induction of such antibodies might be enhanced by immunization with infectious rather than inactivated virus.

Our results also bear on the long-standing phenomenon of cross-protective immunity between heterologous alphaviruses in the absence of antibodies having corresponding cross-reactive NT activity (for review see ref. 3). Although the basis of this phenomenon has been ascribed to cross-reactive virus-specific effector T cells[14], the participation of a humoral mechanism is suggested by the fact that monoclonal antibodies to the E1, but not the E2 glycoprotein, of SV exhibit serological cross-reactivity with other alphaviruses[4]. Whether these same non-neutralizing, monoclonal antibodies also mediate heterologous protection *in vivo* is a subject for future investigation.

We thank M. K. Gentry for preparing anti-SV monoclonal antibodies, Celia Jarvis for help in preparing the manuscript, and Dr J. F. Smith for his critical comments. This work was supported by the US Army Research and Development Command and USPHS grant NS 17741.

Note added in proof: We have recently found that four anti-SV monoclonal antibodies (including numbers 31 and 38 above), which bind three distinct determinants on E1, cross-react with western equine encephalitis virus and protect mice from lethal intraperitoneal challenge with this alphavirus.

Specific opiate receptors on isolated mammalian gastric smooth muscle cells

K. N. Bitar & G. M. Makhlouf

Division of Gastroenterology and Departments of Medicine and Physiology, Medical College of Virginia, Richmond, Virginia 23298, USA

The predominant opioid peptides of the gut, Met-enkephalin and Leu-enkephalin are confined to neurones of the myenteric plexus[1–4]. Axonal projections from these neurones innervate the circular muscle layer running parallel to the smooth muscle cells[5]. An opioid tridecapeptide (dynorphin), first isolated from the porcine pituitary[6], is found in neurones of the submucosal plexus in the guinea pig; axonal projections from these neurones also innervate the circular muscle layer[7,8]. Dynorphin consists of an N-terminal Leu-enkephalin sequence coupled to a C-terminal octapeptide by an Arg–Arg sequence. Neural receptors for all three opioid peptides and for opiate narcotics have been identified in the myenteric plexus where they cause hyperpolarization of neurones[9,10], inhibition of acetylcholine (ACh) release[11] and blockade of muscle contraction induced by field stimulation[12–16]. Measurements of motor activity in circular muscle where enkephalinergic fibres are most abundant, suggest that opiates also have a direct contractile action[17–20]. We have tested this possibility in isolated gastric smooth muscle cells devoid of neural elements[21,22], and report here the presence of specific high-affinity opiate receptors on such cells of the guinea pig. The receptors mediate contraction as measured by image-splitting micrometry, and exhibit a rank order of potency and absolute values similar to those reported for neural receptors of the myenteric plexus. In view of the distribution of enkephalinergic fibres predominantly to gut smooth muscle, our results strongly support a direct neuro- transmitter role for enkephalins in this region.

Smooth muscle cells were isolated from the stomach of the guinea pig as described in detail elsewhere[23] (see Fig. 1 legend). The morphometric profile of freshly dispersed cells is illustrated in Fig. 1 (mean cell length ± s.e.m. = 109.3 ± 1.2 μm; $n = 52$). Exposure of the cells to maximally effective concentrations of Met-enkephalin, Leu-enkephalin or morphine for 30 s shifted the curve to the left, causing the appearance of a greater proportion of shorter, contracted cells. The contractile response to a given dose of agonist was determined from the fractional (percentage) or absolute decrease in mean cell length compared with controls.

The kinetics of contractile response to Met-enkephalin and other opiates were similar to those reported for other contractile agents such as ACh, COOH-terminal octapeptide of cholecystokinin (CCK-OP) and gastrin-17)[22]. The response was immediate, reached a peak in 30 s and reverted to a sustained plateau for at least 8 min (Fig. 2). Figure 3 shows dose–response curves constructed for opioid peptides and morphine using the values

Table 1 Maximum contractile responses to opiate agonists

	Maximal contractile response (% decrease in cell length)	Potency [D_{50} (M)]
Dynorphin	33.7 ± 1.9 ($n = 7$)	10^{-10}
Met-enkephalin	34.1 ± 1.4 (9)	1.2×10^{-9}
D-ala^2-met-enkephalinamide	30.1 ± 0.9 (5)	6.0×10^{-9}
Morphine	29.7 ± 1.3 (5)	2.0×10^{-8}
Leu-enkephalin	30.0 ± 3.6 (7)	1.2×10^{-7}

0028–0836/82/180072—03$01.00

of the 30-s peak responses. At the highest doses used, all opiate agonists elicited maximal contractile responses similar to those previously reported for 10^{-9} M CCK-OP and 10^{-7} M ACh[21,22] (30–34% decrease in mean cell length) (Table 1). The order of potency as determined from the dose required to produce one-half of the maximal response (D_{50}) was dynorphin > Met-enkephalin > D-Ala^2-Met-enkephalinamide > morphine > Leu-enkephalin. Note that the widest difference in potency (1,200-fold) was between Leu-enkephalin and dynorphin, which includes the sequence of Leu-enkephalin in its NH_2-terminal; this raises the possibility that tryptic cleavage of dynorphin to Leu-enkephalin terminates the action of dynorphin as a putative neurotransmitter. The higher potency of Met-enkephalin relative to its synthetic analogue suggests minimal or no degradation of Met-enkephalin in muscle cell suspensions[23]. If this assumption is correct, the potency as determined in isolated muscle cells should reflect the true

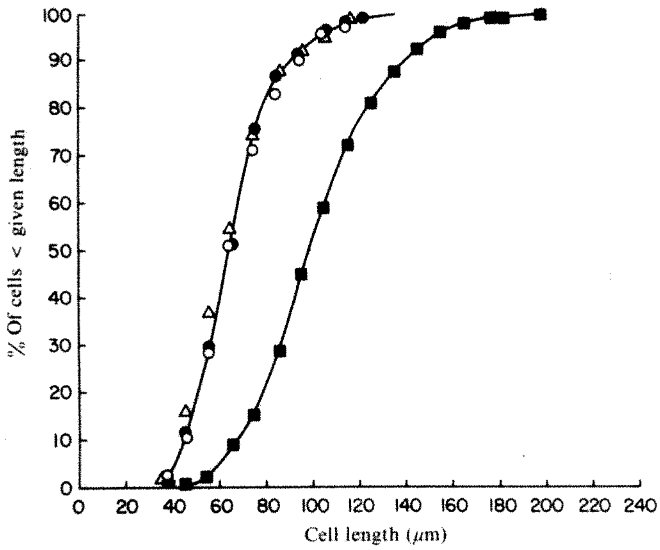

Fig. 1 Distribution of smooth muscle cell lengths in the control state (■) and after 30 s exposure to Met-enkephalin (●), Leu-enkephalin (△) or morphine (○). The shift of the curve to the left indicates the appearance of a greater proportion of shorter, more contracted cells. Cells were obtained from the circular muscle layer of the stomach of guinea pigs by two sequential 45 min incubations of muscle strips in Krebs bicarbonate buffer containing 0.1% collagenase (Worthington CLS, Type II) and 0.01% soybean trypsin inhibitor. The partly digested strips were washed with 50 ml of enzyme-free buffer and re-incubated for 30 min to allow cells to disperse spontaneously. The cells were collected by filtration through 500 μm Nitex then examined within 30 min of dispersion. Aliquots (2.5×10^4 cells in 0.5 ml) were incubated for 30 s with 0.1 ml of a solution containing agonist, and the cells were then fixed rapidly with acrolein. Incubation periods in the range 15 s to 8 min were used to examine the kinetics of contraction. Control cells were treated in the same manner but without added agonist. In the control state and for each test modality, the lengths of 50 cells in sequential microscopic fields were measured by image-splitting micrometry. Contraction was determined from the percentage decrease in mean cell length compared with control.

structure–activity status of Met-enkephalin and other opioid peptides.

Naloxone (3×10^{-10} M) caused a parallel rightward shift of the dose–response curve for Met-enkephalin without affecting maximal response (Fig. 4). A higher dose of naloxone (3×10^{-9} M) caused a further shift of the dose–response curve and 10^{-7} M abolished the response to all doses of Met-enkephalin. We compared the effect of 3×10^{-10} M naloxone against the highest effective doses of opiate agonists (10^{-6} M for dynorphin and Met-enkephalin; 10^{-5} M for morphine and Leu-enkephalin). Naloxone was a more effective inhibitor of the responses to morphine and Leu-enkephalin (83–85% inhibition) than of the responses to dynorphin and Met-enkephalin (34 and 24% inhibition, respectively). Naloxone inhibited

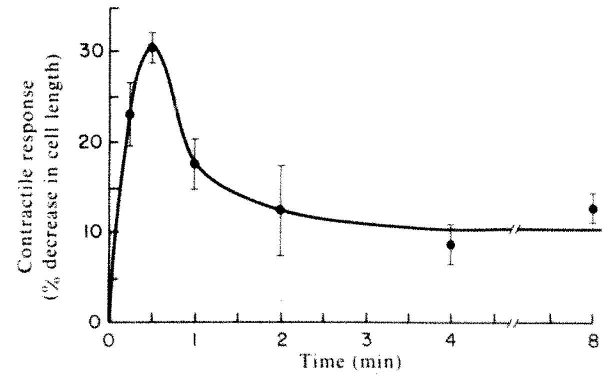

Fig. 2 Kinetics of contraction in response to 10^{-5} M Met-enkephalin. The prompt rise to a peak in 30 s and reversal to a sustained contractile plateau was similar to that previously found for non-opiate agonists[21,22]. Each point is the mean ± s.e.m. of four experiments.

specifically the response to opiate agonists; it affected neither the response to CCK-OP nor the response to ACh. Conversely, dibutyryl cyclic GMP (10^{-3} M), a specific antagonist of the CCK–gastrin receptor in neural, muscular and epithelial tissues[24,25], inhibited the contractile response to CCK-OP but had no effect on the response to the two opiate agonists tested (Met-enkephalin and morphine) or on the response to ACh[22]. Atropine (5×10^{-10}–5×10^{-8} M) also had no effect on the response to 10^{-6} M Met-enkephalin or morphine, although it abolished the response to ACh[22].

There was a remarkable similarity not only in the rank order but also in the absolute potencies of opiate agonists acting on isolated smooth muscle cells and nerve fibres of the guinea pig myenteric plexus[8,13,26,27]. In both tissues, dynorphin exhibited the highest potency ($D_{50} \sim 10^{-10}$ M) and Leu-enkephalin and morphine, the lowest potency ($D_{50} \sim 10^{-7}$ M). The potency of Met-enkephalin in isolated muscle cells was much closer to that of dynorphin than to that of Leu-enkephalin. The high potencies of dynorphin and Met-enkephalin and the relative resistance

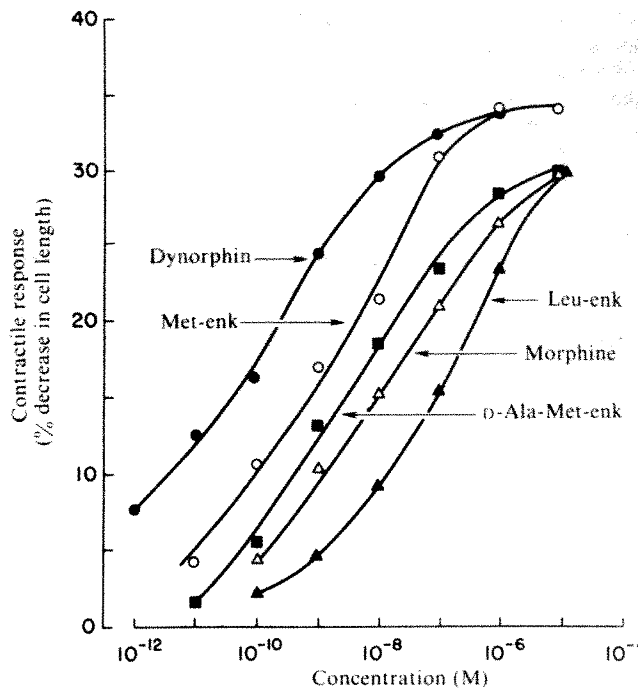

Fig. 3 Dose–response curves for the contractile effects of opioid peptides and morphine on isolated smooth muscle cells. Maximal responses and D_{50}s are given in Table 1. Each point is the mean of 4–9 experiments.

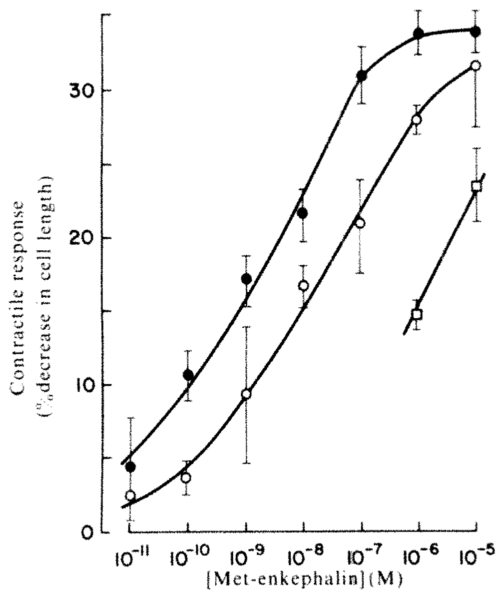

Fig. 4 Dose–response curves for the contractile effects of Met-enkephalin alone (●) or in combination with naloxone (○, 3×10^{-10} M; □, 10^{-9} M naloxone). Each point is the mean ± s.e.m. of four experiments.

of their effects to naloxone in isolated muscle cells suggest that the receptor(s) with which they interact are different from those for morphine (μ receptors). Chavkin and Goldstein[26] applied selective protection against the irreversible antagonist, chlornatrexamine, to show that the receptor for dynorphin in the myenteric plexus of the guinea pig is distinct from that for morphine or Leu-enkephalin. Concurrent desensitization of δ and μ receptors in mouse vas deferens also showed that the dynorphin receptor is distinct from that for other opiates[16,28].

The effectiveness of dynorphin and Met-enkephalin as direct contractile agonists agrees with their relative abundance in the stomach and intestine and their preponderance in the circular muscle layer. Similar results were obtained recently in smooth muscle cells isolated from the human stomach and canine gall bladder (K.N.B. and G.M.M., unpublished observations). The finding of a direct effect favours a role for these peptides as contractile neurotransmitters. However, dynorphin and Met-enkephalin are equally effective neural opiate agonists in the gut. Enkephalinergic fibers ramify with other fibres in the circular muscle layer, forming axonal bundles that could well permit axo-axonal interactions such as presynaptic inhibition of ACh release from cholinergic nerve terminals. It is even possible that enkephalins and ACh co-exist in some nerve terminals of the myenteric plexus as they do in sacral preganglionic fibres in the viscera of the cat[29] and postganglionic cholinergic terminals in the adrenal medulla[30]. Co-release, like adjacent release of enkephalins, could inhibit further presynaptic release of ACh.

Physiologically, the outcome is probably a combination of direct excitatory and indirect neurally-mediated inhibitory effects, the former inducing tonic motor activity in the gut, the latter, phasic or peristaltic activity[31]. The topography of enkephalin fibres in the gut indicates that a myenteric plexus–circular muscle preparation is the more apt physiological model with which to test neurally-mediated effects of enkephalin.

Opiate receptor subclasses differ in their conformational requirements

Peter W. Schiller & John DiMaio

Laboratory of Chemical Biology and Peptide Research, Clinical Research Institute of Montreal, 110 Pine Avenue West, Montreal, Quebec H2W 1R7, Canada

Pharmacological and biochemical studies of classical opiates and opioid peptide analogues have revealed the existence of several subclasses of opiate receptors[1–5], among which the μ-, δ-, κ- and σ-receptors have been most widely discussed. The physiological roles of the different receptor classes and their structural characteristics remain to be elucidated. Recently, a cyclic analogue of enkephalin, H-Tyr-cyclo[-N^{γ}-D-A_2bu-Gly-Phe-Leu-] (Fig. 1, compound I; A_2bu represents α,γ-diaminobutyric acid), showing high potency in μ-receptor-selective bio- and binding assays has been described[6]. To assess the effect of the conformational constraint introduced by cyclization on opiate receptor selectivity, we have compared the cyclic compound I with its corresponding open-chain analogue, [D-Abu^2,Leu^5]enkephalinamide (Fig. 1, compound II; Abu represents α-aminobutyric acid), in bioassays based on inhibition of electrically evoked contractions of the guinea pig ileum and the mouse vas deferens, and in binding assays using μ- and δ-receptor-selective radiolabels. The differences in potency of the two compounds observed in the four assay systems suggest that the various opiate receptor subclasses have different preferences in terms of conformational properties of 'complementary' ligands.

Compared with [Leu^5]enkephalin (H-Tyr-Gly-Gly-Phe-Leu-OH; III in Table 1)[7], the cyclic analogue I shows a 17-fold increase in potency in the guinea-pig ileum (GPI)-assay and is twice as potent as the linear analogue, II (Table 1). The effect of both analogues on GPI was found to be naloxone-reversible. In the case of compound I, the apparent dissociation constant (K_e) obtained with naloxone as antagonist was 12 times lower than that determined for [Leu^5]enkephalin and comparable to that observed for the μ-receptor-selective agonist, levorphanol. These observations indicate that the cyclic analogue exerts its effect on the GPI via interaction with μ-receptors.

In contrast to the results of the GPI assay, however, the cyclic analogue I is seven times less potent than the naturally occurring

0028–0836/82/180074—03$01.00

Table 1 Inhibitory potencies (IC_{50}s) and sensitivities to naloxone (K_e) of peptide analogues, [Leu[5]]enkephalin and levorphanol in the guinea pig ileum and mouse vas deferens assays

No.	Compound	IC_{50}(nM)* GPI	MVD	IC_{50} (MVD)/IC_{50} (GPI)	K_e (nM)* GPI	MVD
I	Tyr-cyclo[-N^{γ}-D-A_2bu-Gly-Phe-Leu-]	14.1±2.9	81.4±5.8	5.77	0.122±0.028	0.576±0.044
II	[D-Abu[2],Leu[5]]enkephalinamide	28.7±1.3	45.6±9.1	1.59	0.181±0.033	1.50±0.19
III	[Leu[5]]enkephalin	246±39	11.4±1.1	0.046	1.53±0.43	5.86±0.90
IV	Levorphanol	17.0±3.0	278±56	16.4	0.064±0.005	0.837±0.182

The assay based on inhibition of electrically induced contractions of the GPI[19] was performed as described elsewhere[20]. The MVD assay was performed as described previously[21]. A log dose–response curve was determined using [Leu[5]]enkephalin as the standard for each ileum or vas deferens preparation and IC_{50}s of the compounds being tested were normalized according to a published procedure[22]. K_e values for naloxone as antagonist were determined from the ratio (DR) of IC_{50} values obtained in the presence and absence of a fixed naloxone concentration (a), using the equation $K_e = a/(DR-1)$[23].

The chemical syntheses of analogues I and II are described elsewhere[6,17].

* Mean of three determinations (±s.e.m.).

peptide and half as potent as its corresponding open-chain analogue (II) in the mouse vas deferens (MVD)-assay. There is evidence that, in addition to the predominant δ-receptor, the MVD also contains μ- and κ-receptors. As indicated by the high naloxone K_e (5.86±0.90 nM), [Leu[5]]enkephalin interacts selectively with δ-receptors in the MVD preparation, whereas levorphanol, with a low K_e value of 0.837±0.182 nM, has high preference for μ-receptors in this tissue. The μ-receptor preference of the cyclic analogue I is revealed by a similarly low K_e (0.576±0.044 nM), whereas analogue II shows a K_e (1.50±0.19 nM) intermediate between those of levorphanol and [Leu[5]]enkephalin, indicating its mixed $\mu+\delta$ character.

The MVD/GPI IC_{50} (50% inhibitory concentration) ratio observed for the cyclic analogue I was 125 times higher than that of [Leu[5]]enkephalin and was comparable to the ratios determined for the μ-type agonists, [D-Ala[2],MePhe[4],Met(O)-ol[5]]enkephalin[8] and [D-Ala[2],MePhe[4],Gly-ol[5]]enkephalin[9]. Interestingly, the cyclic compound I also showed a MVD/GPI IC_{50} ratio about four times higher than the open-chain analogue II. This result, together with the difference in the naloxone K_e values observed in the MVD assay, suggests that the conformationally restricted analogue I has a lower preference for δ-receptor than the more flexible open-chain analogue II.

Affinities for opiate receptors in rat brain membrane preparations were determined in parallel binding assays using ^{3}H-naloxone as a radioligand which preferentially binds to μ-receptors and ^{3}H-[D-Ala[2],D-Leu[5]]enkephalin as a radiolabel with preference for δ-receptors (Table 2). Sodium ratios of 47.0 and 38.9 were determined for analogues I and II, respectively, from ^{3}H-naloxone displacement curves obtained in the absence and presence (100 mM) of sodium chloride. This observation indicates the agonist character of both compounds[10]. In the δ-receptor-selective binding assay, analogue I showed a 28-fold decrease in affinity compared with analogue II, whereas in the μ-receptor-selective binding assay, only a twofold reduction in affinity was observed. The nearly equal affinity of the linear peptide II for μ- and δ-receptors and the low affinity of the cyclic compound I for δ-receptors are reflected in the ratios of the inhibition constants (K_i^{δ}/K_i^{μ}) obtained from the two binding assays. We observed some discrepancies between the binding data and the results of the bioassays; analogue I was twice as potent as its linear counterpart II in the GPI assay, whereas in the ^{3}H-naloxone binding assay, almost the reverse was true. A divergent effect of the conformational constraint in I on 'efficacy' and affinity represents one possible explanation for this observation. Cyclization would reduce affinity for μ-receptors but lead to a more productive peptide–receptor complex. On the basis of the well-known correlation between sodium ratio and 'efficacy'[10], the higher sodium ratio observed for analogue I compared with II seems to support this hypothesis. Alternatively, a third type of receptor may be involved and the simple μ/δ-receptor concept may be insufficient to explain the present data. That the situation in rat brain may indeed be more complicated is indicated by the recent demonstration[5] of three major types of morphine and enkephalin receptors (μ_1, μ_2 and δ). Finally, it is interesting to note that cyclization produces only a twofold potency decrease in the MVD assay but a 28-fold affinity decrease in the δ-receptor-selective binding assay. This apparent discrepancy can be explained by the fact that the greatly reduced affinity of the cyclic analogue for δ-receptors is partly compensated by its ability to act as a highly productive μ-agonist in the MVD, as indicated by its low naloxone K_e.

Thus, comparison of analogues I and II in bioassays and binding assays reveals that introduction of the conformational constraint by ring closure in analogue I is directly and uniquely responsible for its decreased δ-character compared with the linear peptide II. Obviously, the semi-rigid 14-membered ring structure of I is highly compatible with the topography of the μ-receptor, but causes a decrease in affinity for δ-receptors compared with the open-chain analogue II. Analysis of the conformational possibilities of I revealed that several conformations proposed for native enkephalin in solution or when bound to its receptor cannot be adopted by the cyclic analogue[6].

II

Fig. 1 Structural formulas of the cyclic enkephalin analogue, Tyr-cyclo[-N^{γ}-D-A_2bu-Gly-Phe-Leu-] (I), and its corresponding open-chain analogue, [D-Abu[2],Leu[5]]enkephalinamide (II).

Table 2 Inhibitory effects of peptide analogues and [Leu^5]enkephalin on the binding of ^{3}H-naloxone and ^{3}H-[D-Ala^2, D-Leu^5]enkephalin in rat brain homogenates

No.	Compound	^{3}H-naloxone binding, K_i^{μ} (nM)	^{3}H-[D-Ala^2,D-Leu^5]enkephalin binding, K_i^{δ} (nM)	K_i^{δ}/K_i^{μ}
I	Tyr-cyclo[-N^{γ}-D-A_2bu-Gly-Phe-Leu-]	13.8 ± 3.4	115 ± 16	8.33
II	[D-Abu^2,Leu^5]enkephalinamide	5.60 ± 0.11	4.06 ± 1.46	0.725
III	[Leu^5]enkephalin	27.7 ± 5.7	8.05 ± 0.96	0.291

Binding studies using rat brain membrane preparations were carried out as described elsewhere[20]. ^{3}H-naloxone and ^{3}H-[D-Ala^2,D-Leu^5]-enkephalin at concentrations of 0.40 and 0.96 nM, respectively, were used as radioligands and incubations were performed at 0 °C for 1 h. K_i values were calculated based on Cheng and Prusoff's equation[24] using values of 0.5 and 0.8 nM for the dissociation of ^{3}H-naloxone and ^{3}H-[D-Ala^2,D-Leu^5)enkephalin, respectively. Values shown are the mean of three determinations (±s.e.m.).

As the open-chain analogue is distinguished from the cyclic compound merely by the opening of a single carbon–nitrogen bond (Fig. 1), these results permit the unambiguous conclusion that different opiate receptor subclasses have different conformational requirements. The difference in receptor topography could be due to the existence of different conformational forms of a single opiate receptor protein, the distribution of which might be regulated by allosteric effectors[11]. Alternatively, heterogeneity in opiate receptor topography could be due to minor changes in receptor protein sequence[12].

The results described here represent the first direct demonstration of a difference in conformational requirements between receptor subclasses in a situation of peptide receptor heterogeneity. In the case of somatostatin[13,14] and bradykinin[15], differences in receptor topography between receptor types mediating different biological effects have been suspected but could not be demonstrated unambiguously, because in these studies, based on pharmacological profiles of peptide analogues, the effect of amino acid substitutions could not be dissociated from a possible conformational effect. Evidence for a difference in conformational requirements between different receptor subclasses has been obtained in the case of γ-aminobutyric acid[16].

Most linear peptides occurring in nature are very flexible and therefore able to adapt to different receptor surfaces without showing much selectivity. The demonstrated existence of receptor subclasses with topographically distinct features opens up an avenue for the design of receptor-selective peptide ligands by incorporation of appropriate conformational constraints. Subtle variation of the conformational restriction by modification of the ring size in analogue I[17] or by means of a different type of cyclization[18] has resulted in cyclic enkephalin analogues displaying various degrees of receptor selectivity.

We thank C. Lemieux and T. M.-D. Nguyen for technical assistance. This research was supported by an operating grant from the MRC of Canada (MT-5655).

Dopamine modulates a Ca^{2+}-activated potassium conductance in mammalian hippocampal pyramidal cells

Larry S. Benardo* & David A. Prince

Department of Neurology, Stanford University School of Medicine, Stanford, California 94305, USA

Dopamine (DA) is a neurotransmitter in the mammalian central nervous system which has proven or potential importance in such neurological disorders as parkinsonism, Huntington's chorea and epilepsy. Most of the electrophysiological data concerning the actions of DA in the brain have been obtained from studies in the caudate nucleus where DA produces neuronal depolarization and increased spike discharge[1], slow depolarization with decreased spike discharge[2,3] and an increase in apparent input resistance[3] and hyperpolarization with reduced firing rate[3]. The mechanisms underlying these effects have not been examined. The evidence suggests that the hippocampus receives a dopaminergic projection[4–6] and that DA inhibits most hippocampal neurones[7,8]. We have studied the effects of DA on CA1 hippocampal pyramidal cells (HPCs) *in vitro* and report here that DA causes prolonged inhibition associated with hyperpolarization and increased conductance. These effects seem to derive from induction of a Ca^{2+}-activated K^+ conductance, and would make DA effective in modulating the high frequency firing and burst generation which occurs normally in some neurones[9,10], and pathologically in HPCs during epileptogenesis[11].

Hippocampal slices were prepared and maintained as previously described[12]. Intracellular recordings were obtained with K-acetate (4 M)-filled microelectrodes having resistances of 25–60 MΩ. Freshly prepared DA (10^{-6}–10^{-4} M) in standard Ringer's solution (*p*H 7.4)[12] was applied either by pressure ejection of droplets from a broken micropipette on to dendritic areas of CA1 HPCs[13] or via superfusion (10^{-5} M); these two methods produced identical results. Neurones having stable resting membrane potentials > -55 mV for longer than 5 min, and action potential amplitudes >70 mV were selected for study. Current was delivered through an active bridge circuit and bridge balance which was constantly monitored and adjusted. Control data were obtained with electrodes in the extracellular position so that records from micropipettes which showed polarization artefacts or rectification could be disregarded. Membrane potential (V_m) was determined by assuming the bath potential to be 0 mV.

Changes due to DA application were observed in 16 of 21 CA1 HPCs; in 13 of these, membrane properties were characterized in detail before and after drug application. The initial mean input resistance (R_N) of this group of cells was 38.9 ± 10.7

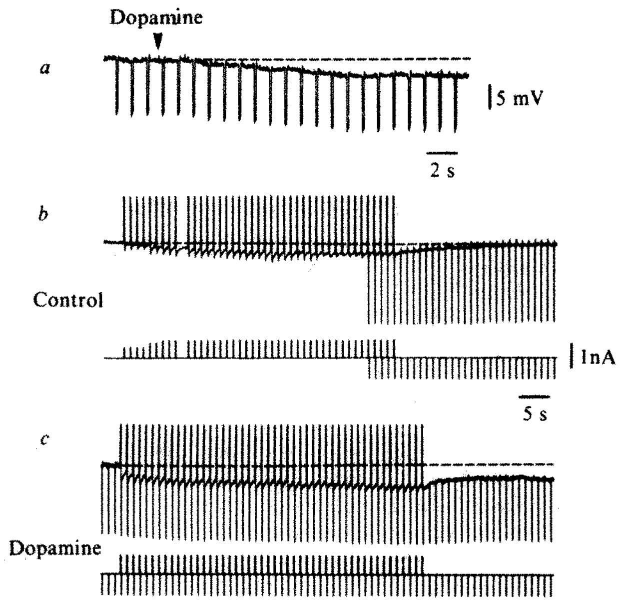

Fig. 1 Examples of DA-induced hyperpolarizations. *a*, Chart recording showing the hyperpolarizing response of a cell to application of 10 μM DA. The voltage response to constant-current hyperpolarizing pulses shows that no detectable change of input resistance (R_N) accompanies this hyperpolarization. Resting potential, −60 mV. *b*, In another neurone in normal conditions, a 1-Hz train of 120-ms depolarizing current pulses, of sufficient intensity to elicit 2–10 spikes, results in membrane hyperpolarization associated with a decrease in R_N. When depolarizing pulses are discontinued the membrane repolarizes and resistance recovers to the control level. *c*, After DA application to the cell in *b*, the membrane hyperpolarized by a few millivolts (data not shown). The membrane potential was then depolarized to the control level with d.c. current and a train of depolarizing pulses was delivered comparable to that in *b*. R_N decreased during the train. Membrane potential and resistance at the end of the train of depolarizing pulses did not recover to pre-stimulus levels. Control resting potential for the neurone in *b* and *c* was −56 mV. Time and current calibrations in *b* apply to *c* also. Voltage calibration in *a* applies to *b* and *c*. Spikes were amputated by inkwriter. Lower traces in *b*, *c*: current monitor, depolarizing current up. Broken lines represent baseline resting potentials.

(±s.d.) MΩ at a mean resting potential of -59.7 ± 5.7 mV. These values are similar to those previously reported[13]. DA application caused a small initial hyperpolarization (mean amplitude 4.9 ± 3.6 mV) in 10 of 13 cells within 3–40 s of delivery (Fig. 1*a*). Often this was not associated with a prominent change in R_N, although decreases in R_N were seen in cells which showed the largest hyperpolarizing responses, or when additional doses of DA were applied to produce further hyperpolarization. The shift in V_m was often sufficient to decrease firing frequency or silence active discharge. Further hyperpolarization was triggered by 120-ms depolarizing current pulses which evoked spike trains. It is known that slow after-hyperpolarizations (AHPs) lasting up to 1–2 s normally follow repetitive spike discharges in HPCs[9,10,14,15]. We found that, in control conditions, when depolarizing current pulses were delivered at frequencies of ~1 Hz, and at sufficient intensity to elicit 2–10 action potentials, these slow AHPs summated until steady membrane potential was reached (Fig. 1*b*). In the control state, V_m consistently recovered to the baseline level within seconds after such stimulation was discontinued. Following DA application, however, the slow AHPs evoked by the same depolarizing current pulses were larger and there was no recovery of V_m to the baseline potential after cessation of the pulses (Fig. 1*c*). In addition, slow AHPs following a single evoked spike train (tested at control V_m maintained with d.c. current) were also augmented (Fig. 2*a*–*c*). Such AHPs were of larger amplitude than those in control neurones and lasted for as long as 18 s (13 s in the case of Fig. 2*d*). Augmented AHPs were also found in neurones impaled after DA application (see below). The prolonged duration was not dependent on the passage of intracellular d.c. current. The DA effect on AHPs was detectable in seconds and reached a maximum after several minutes. In addition it appeared that the actions on the AHP were due to some cumulative process initiated by spike trains, as a sequence of conditioning trains evoked at 1 Hz by 120-ms depolarizing pulses increased the duration of an AHP triggered seconds later.

The maximum total hyperpolarization, that is, that which occurred after DA delivery (Fig. 1*a*) plus that which could be further evoked during summated AHPs (Fig. 1*c*), was 7.7 ± 6.0 mV ($n=13$). These peak increases in V_m were associated with decreases in R_N of 19–42% (compare amplitude of responses to hyperpolarizing pulses in Fig. 2*a*, *b*, before and after DA). The changes in R_N which accompanied the DA-induced hyperpolarization were not related to membrane rectification: for

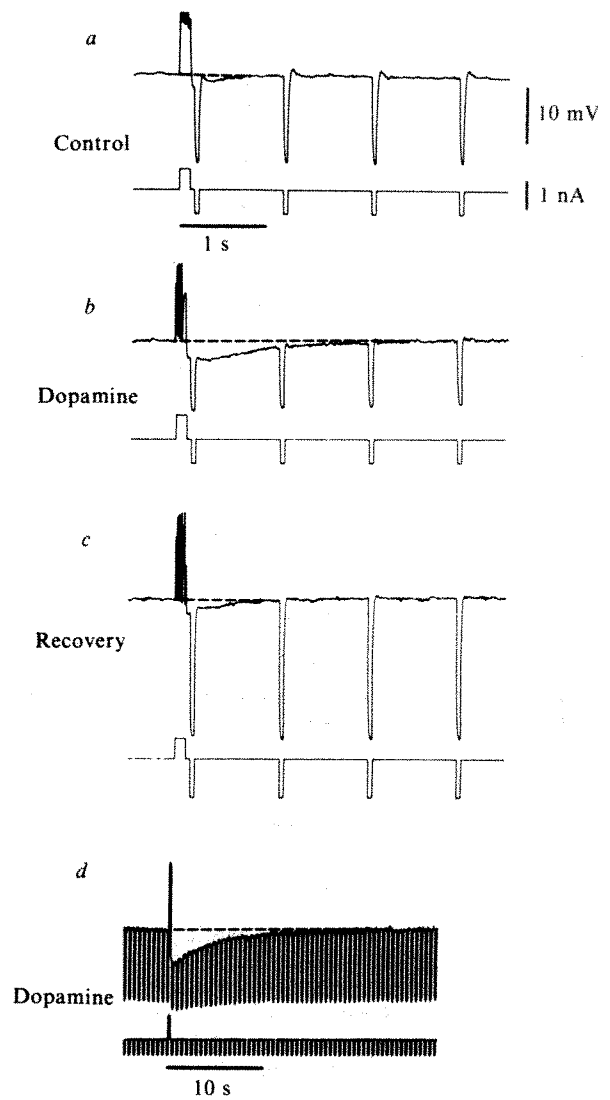

Fig. 2 Slow AHPs induced by depolarizing current pulses. *a*, Chart recording of control response to a depolarizing pulse. The AHP lasts 600 ms, reaches 2 mV in amplitude, and is associated with a peak decrease in resistance of ~11% (ref. 14). *b*, Following DA application (10 μM) this cell hyperpolarized (not shown) and input resistance decreased. The membrane was depolarized to the resting potential of *a* and the amplitude of the depolarizing current pulse adjusted to elicit a number of spikes comparable to those of the stimulus in *a*. This was necessary because of a decrease in baseline R_N of ~35% compared with the control. In these conditions AHPs lasted for 2.5 s, reached 4 mV in amplitude, and were associated with proportionately larger decreases in resistance (peak decrease of ~20%). The apparent difference in responses to initial depolarizing pulses in *a* compared with *b* is due to distortion produced by the low frequency response of the chart recorder, and the effect of DA in decreasing R_N. *c*, Recovery of AHPs to control duration and amplitude was seen in this same neurone 45–60 min after DA application. *d*, Much longer duration AHPs (>10 s) and associated resistance changes were evoked in several cells. In this neurone, impaled 1 h after DA application near the cell of *a*–*c*, the AHP lasted for 13 s. No d.c. current was passed through the electrode during this recording. Voltage and current calibrations in *a* apply to *b*–*d* also. Time calibration in *a* applies to *b* and *c*.

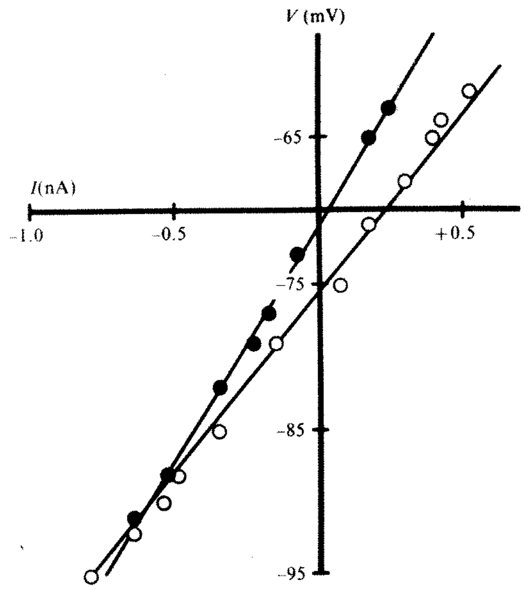

Fig. 3 Representative current–voltage relationship in one cell before (●) and after (○) DA application (10 μM). Curves were obtained by plotting steady-state applied pipette current against the membrane potential. Current (I)–voltage (V) lines were drawn using linear regression to obtain a least-squares fit of the data. The reversal potential for DA hyperpolarization in this neurone, determined from the point of intersection of these curves, was −91 mV.

example, the mean R_N before DA application was 37.3 ± 10.2 MΩ at the original resting V_m of -60.1 ± 6.0 mV ($n = 11$). After peak DA-induced hyperpolarization was attained, sufficient d.c. current was delivered to depolarize HPCs back to the original resting V_m. The mean R_N measured at this voltage level was 29.0 ± 8.8 MΩ, which was a significant ($P < 0.005$) decrease of 22.2% from control values.

A reversal potential for the DA hyperpolarization was obtained from plots of voltage against applied current before and after DA application. Figure 3 shows a representative plot from one neurone. The mean reversal potential obtained from intersection of voltage–current lines was -86.8 ± 11.1 mV ($n = 8$), a value consistent with DA increasing K^+ conductance (g_K)[15], and more negative than the expected Cl^- equilibrium potential of ~ -70 mV (ref. 16). This conclusion was supported by the observation that DA-induced increases in V_m were equally prominent in neurones impaled with KCl-containing microelectrodes, even when inhibitory postsynaptic potentials (i.p.s.ps), known to be primarily Cl^--mediated[17,18], were reversed.

In most cases, recovery from DA-induced hyperpolarization or augmentation of AHPs did not occur during a single impalement. However, in one particularly stable recording, it was possible to follow the time course of DA influence over a period of 2 h (Fig. 2). During the control period, AHPs reached a peak amplitude of 2 mV, and lasted ~600 ms (Fig. 2*a*). Following focal application of DA and adjustment of V_m to the control level with d.c. current, the AHP peak amplitude increased to 4 mV and lasted 2.5 s (Fig. 2*b*); recovery occurred in 45 min (Fig. 2*c*). Other neurones in the same area impaled up to 1 h after DA application showed similar or even more pronounced effects (Fig. 2*d*). No d.c. current was passed to manipulate V_m in cells impaled after DA application since resting V_m before DA application was unknown. The AHP durations and amplitudes, however, were significantly larger and longer than those found in control neurones in these and previous experiments[14]. These data suggest that the DA-induced alterations are reversible, but long-lasting.

Our results are similar in some respects to those reported by Herrling[8] for anaesthetized cats. In both cases cell discharges were decreased or blocked, and in most cells a hyperpolarization developed. However, Herrling found an increase in resistance in four neurones tested, in contrast to our results. The reasons for this discrepancy are not clear, but could relate to the action of anaesthetic or the technical difficulties in studying partially depolarized neurones *in vivo*.

The most reasonable explanation for the DA-induced hyperpolarization and the augmentation of AHPs is that they both derive from increases in K^+ permeability. As noted above, the equilibrium potential for DA hyperpolarization is in the range expected for this ion (Fig. 3). Effects on AHPs could be due to enhancement of the Ca^{2+}-activated g_K which underlies these events in HPCs[14,15]. DA-enhanced and normal AHPs are associated with conductance increases, have reversal potentials at very negative levels, and may both be blocked by Mn^{2+}, a Ca^{2+} antagonist[14,26]. If the DA-enhanced slow AHP were due in part to Na^+–K^+ pump activation[19], we would have expected persistence of at least a component of this potential when trains of spikes were evoked in Mn^{2+} solutions. Although all slow AHPs were blocked in 3 mM Mn^{2+} solutions, hyperpolarizations associated with conductance increases similar to that shown in Fig. 1*a* were still observed after DA application to some neurones. These effects must be postsynaptic as this concentration of Mn^{2+} blocks synaptic transmission in hippocampal slices[14].

Effects of DA in inducing or enhancing a Ca^{2+}-dependent K^+ conductance could result from effects on processes which increase intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) as proposed for neocortical neurones following dinitrophenol injection[20] and for cockroach neurones after DA application[21]. For example, the DA-induced initial hyperpolarization could result from release of Ca^{2+} from intracellular stores, or decreased Ca^{2+} buffering. These actions, combined with tonic Ca^{2+} entry[22], would prolong and increase K^+ conductance. Alternatively, DA may enhance calcium entry into neurones—this is suggested by its reported effects in cardiac muscle fibres[23]; however the persistence of DA-induced hyperpolarization in Mn^{2+} solutions that block Ca^{2+} entry[26] is more consistent with a DA-mediated release of Ca^{2+} from intracellular stores. The cumulative hyperpolarization which follows repetitive stimulus-induced spike trains (for example, Fig. 1*c*) would thus derive from prolonged increases in $[Ca^{2+}]_i$ following Ca^{2+} influx, which in turn would activate a sustained change in K^+ conductance. Recent experiments showing that EGTA injection into neurones blocks DA-induced hyperpolarization and DA-enhanced AHPs further substantiate the involvement of Ca^{2+} in DA effects[26]

DA is a potent inhibitory agent which modulates the relationship between cell activity and the development of intrinsic inhibitory membrane properties in HPCs through effects on the Ca^{2+}-activated K^+ conductance. Its inhibitory action would be most effective during periods of Ca^{2+} entry associated with burst generation[10] and high frequency firing such as occur in CA1 HPCs following exposure to acetylcholine[13], and during epileptogenesis[11,15,24]. The possibility that DA modulates such burst generation and seizure susceptibility *in vivo* is supported by anatomical data demonstrating a more or less direct projection of the hippocampal complex to the cells of origin of the dopaminergic projection[25].

Lipid-soluble toxins thought to be specific for Na^+ channels block Ca^{2+} channels in neuronal cells

Georges Romey & Michel Lazdunski

Centre de Biochimie du CNRS, Université de Nice, Faculté des Sciences, Parc Valrose, 06034 Nice Cedex, France

Many toxic compounds alter specifically the functioning of the fast sodium conductance that is responsible for the generation of action potentials in neuronal and muscle cells. One important class of these compounds consists of the lipid-soluble toxins, such as veratridine and other ceveratrum alkaloids, batrachotoxin, aconitine, and the diterpenoid grayanotoxins. These molecules are thought to bind to a common receptor site on the Na^+ channel[1–5], thus inducing a membrane depolarization which can be suppressed by the addition of tetrodotoxin (TTX) or by the removal of Na^+ from the incubation medium[3]. We show here that this family of molecules is not specific for the Na^+ channel in neuroblastoma cells. Blockade of the voltage-dependent calcium channel is also observed, either in the toxin concentration range in which the molecules act on the Na^+ channel (veratridine, grayanotoxin) or at even lower concentration (batrachotoxin).

Voltage-clamp experiments on differentiated N1E 115 neuroblastoma cells have revealed the existence of two voltage-dependent transient inward currents: a fast Na^+ current that is TTX-inhibitable and a slow Ca^{2+} current showing a voltage- and time-dependent inactivation[6]. Similarly to Ca^{2+} channels described in other preparations, the Ca^{2+} channel of neuroblastoma cells has the following properties: it is permeable to Ba^{2+} and Sr^{2+} cations[6], is inhibited by Mn^{2+}, Co^{2+}, Ni^{2+} or La^{3+} cations[6], is unaffected by TTX[6], and is blocked by the so-called Ca^{2+} channel blockers, verapamil or D_{600}, but only at concentrations as high as 0.1 mM (G.R., unpublished results). Voltage-clamp experiments presented in Fig. 1 show that veratridine and batrachotoxin cause a progressive decrease and ultimately a complete block of the Ca^{2+} current. The following are the main differences between the effects of veratridine and batrachotoxin: (1) batrachotoxin blocks the Ca^{2+} channel at a much lower concentration than veratridine. This difference will be analysed in more detail below. (2) The decrease of Ca^{2+} current due to the action of veratridine (Fig. 1*a*) is accompanied by a slowing of the inactivation step, whereas the kinetics of the Ca^{2+} channel are unchanged in the presence of batrachotoxin (Fig. 1*b*). (3) Veratridine blockage of the Ca^{2+} channel is rapidly reversible on washing for a few minutes (Fig. 2) whereas washing for more than 1 h does not remove the effects of batrachotoxin.

The peak amplitude of transient Ca^{2+} currents before and after applications of 20 and 200 μM veratridine is plotted as a function of membrane potential in Fig. 3*a*. Veratridine blockade of Ca^{2+} channels is partial at 20 μM and essentially complete at 200 μM, and is accompanied by a shift of the current–voltage curve towards more negative membrane potentials. Figure 3*b* shows dose–response curves for the action of veratridine and batrachotoxin in suppressing the transient Ca^{2+} current. The half-maximum effects ($K_{0.5}$) of the toxins are observed at concentrations of 26 μM and 40 nM for veratridine and batrachotoxin, respectively. Cevadine and α-dihydrograyanotoxin II are active in the same concentration range as veratridine.

The concentrations of veratridine and α-dihydrograyanotoxin II required for half-maximal stimulation of $^{22}Na^+$ influx in the same neuroblastoma cells were 44 and 90 μM, respectively[7,8]. Thus, veratridine and α-dihydrograyanotoxin II act on both Ca^{2+} channels and Na^+ channels in the same range of concentration. In contrast, the $K_{0.5}$ value for the action of batrachotoxin on the neuroblastoma Na^+ channel is ~1 μM (ref. 8), which is about an order of magnitude larger than that found for the action of the toxin on Ca^{2+} channels.

Dose–response curves for the action of veratridine, cevadine, α-dihydrograyanotoxin II or batrachotoxin on Na^+ channels in neuroblastoma cells have been obtained in the presence of 1.8 mM external Ca^{2+}. However, higher Ca^{2+} concentrations strongly antagonize this effect of these lipid-soluble toxins[3,5] and it is largely suppressed at 25 mM Ca^{2+}, the concentration at which Ca^{2+} currents were recorded here. Therefore, at high external Ca^{2+} concentrations, veratridine, α-dihydrograyanotoxin II and batrachotoxin seem to be much more specific for Ca^{2+} channels than for Na^+ channels.

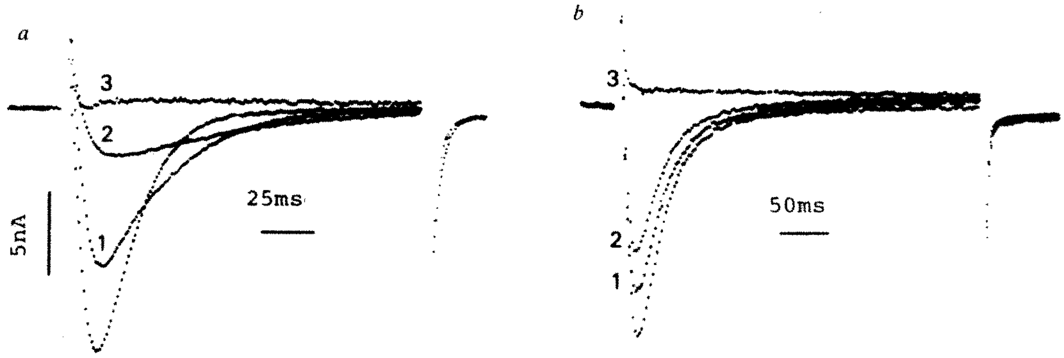

Fig. 1 Voltage-clamp analysis of the effects of veratridine (*a*) and batrachotoxin (*b*) on the Ca^{2+} current of N1E 115 neuroblastoma cells. Depolarizing pulses of 70 mV amplitude and 170 ms duration were applied from a holding potential of −80 mV. *a*, Time course of the effect of 2×10^{-4} M veratridine on the Ca^{2+} current. Successive recordings were taken 1 (1), 2 (2) and 5 (3) min after addition of veratridine. *b*, Time-course of the effect of 2×10^{-7} M batrachotoxin on the Ca^{2+} current. Successive recordings were taken 10 (1), 15 (2) and 30 (3) min after addition of batrachotoxin. Culture dishes containing N1E 115 neuroblastoma cells were used directly after the culture medium had been replaced by a Na^+-free solution containing 25 mM $CaCl_2$, 0.4 mM $MgSO_4$, 5.4 mM KCl, 25 mM HEPES-Tris, 5 mM glucose and 25 mM tetraethylammonium, adjusted to *p*H 7.4 and to an osmotic pressure of 305 mosmol with choline chloride. Tetraethylammonium was used to block the delayed outward K^+ current, which partially masked the Ca^{2+} current[6]. Voltage-clamp experiments were performed with the use of a suction pipette method analogous to that described by Lee *et al.* for snail neurones[10]. The intracellular perfusion solution was 10 mM NaH_2PO_4 and 115 mM glutamic acid, adjusted to *p*H 7.1 with KOH and to an osmotic pressure of 305 mosmol with sucrose.

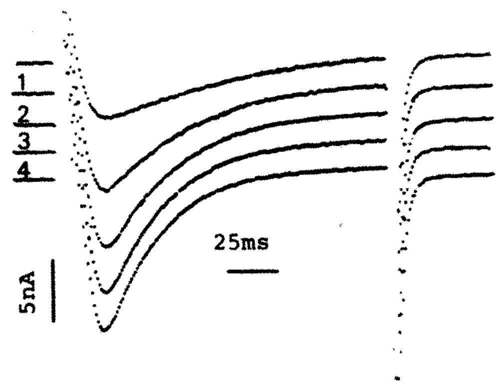

Fig. 2 Reversal by washing of the blocking effect of 10^{-4} M veratridine on the Ca^{2+} current. Successive recordings were taken 1 (1), 2 (2), 3 (3) and 4 (4) min after the beginning of washing. The recovered Ca^{2+} current in (4) was reduced by ~10% from the control Ca^{2+} current measured before the application of veratridine.

Aconitine and ceveratrum alkaloids of the veratridine family such as germitrine, germitridine, germine-3-acetate and protoveratrine A, which cause a persistent activation of Na^+ channels in neuroblastoma cells with an efficiency similar to that of veratridine (P. Honerjäger, C. Frelin and M. Lazdunski, in preparation), are inactive on Ca^{2+} channels, even at high concentrations (0.1 mM). Moreover, none of these molecules antagonizes the action of veratridine on the Ca^{2+} channel, so that they can be considered to be specific for the Na^+ channels.

Other toxins that act on the Na^+ channel include TTX and saxitoxin, and polypeptide toxins extracted from some scorpion venoms or sea anemones. TTX and saxitoxin block the increase of Na^+ permeability produced either by electrical stimulation or by the lipid-soluble toxins. Polypeptide toxins specifically slow the inactivation of the Na^+ channel without changing the properties of the activation step[4]. The polypeptide toxins act in synergy with the lipid-soluble toxins. In neuroblastoma cells they produce an increase in the fraction of Na^+ channels activated at a saturating concentration of the lipid-soluble toxins[7]. We have shown that high concentrations of TTX (10 μM), of *Androctonus australis* Hector scorpion toxin II (0.1 μM) and of *Anemonia sulcata* toxin II (10 μM), are without effect on Ca^{2+} channels in neuroblastoma cells. Moreover, the same high concentrations of these toxins had no effect on the blockade of the Ca^{2+} channels caused by veratridine, regardless of whether they were added before or after the lipid-soluble toxin.

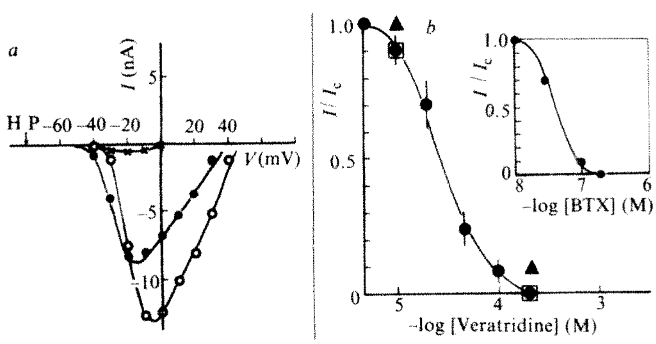

Fig. 3 *a*, Current-voltage relationships for the peak transient Ca^{2+} current obtained from the same cell before (○) and after a 10-min application of 2×10^{-5} M veratridine (●). Veratridine was then added at a final concentration of 2×10^{-4} M for 5 min (×). *b*, Effect of different concentrations of veratridine (●), cevadine (□), α-dihydrograyanotoxin II (▲) and batrachotoxin (inset) on the Ca^{2+} current. For each concentration of toxin, a depolarizing pulse of 70 mV was applied from a holding potential of −80 mV. I_C is the peak value of the Ca^{2+} current in the control, and I is the peak value in the presence of different amounts of toxin. For veratridine, each point represents the mean ratio of I/I_C (±s.d.) from five experiments.

The present observation that veratridine and batrachotoxin block Ca^{2+} channels may lead to a reinterpretation of some of the results obtained by various researchers who used these toxins as tools on the assumption that they were specific for the Na^+ channel.

The fact that veratridine, batrachotoxin, cevadine and α-dihydrograyanotoxin II act on both Na^+ and Ca^{2+} channels suggests that some common structural feature may be necessary for the operation of both types of channel. As tritiated batrachotoxin has now been synthesized[9] and as batrachotoxin is a very potent Ca^{2+} blocker, one of the most interesting possibilities for the future is that this toxin might become the first tool available for the biochemical titration of the Ca^{2+} channel.

Batrachotoxin was kindly provided by Dr J. Daly, α-dihydrograyanotoxin II by Drs M. Nakajima and Ryozo Irize and ceveratrum alkaloids by Dr P. Honerjäger. We thank Dr C. Frelin and M. T. Ravier for providing neuroblastoma cells and Dr Y. Tourneur for his collaboration. This work was supported by CNRS, DGRST and INSERM (CRL, 80.30.10).

Expression of eukaryotic coding sequences in *Methylophilus methylotrophus*

John F. Hennam*, Angela E. Cunningham*, Geoffrey S. Sharpe† & Keith T. Atherton*

* Corporate Research Laboratory, ICI Ltd, Runcorn Heath, Cheshire WA7 4QE, UK
† ICI/University Joint Laboratory, Department of Biochemistry, University of Leicester, Leicester LE1 7RH, UK

Although there have been many reports of the expression of eukaryotic genes in *Escherichia coli* K-12 (refs 1–4), very little attention has focused on the expression of these sequences in other bacteria. The use of other organisms may prove advantageous, especially with regard to industrial processes. For example, work is in progress to develop alternative host/vector systems based on *Bacillus subtilis*[5] and *Saccharomyces cerevisiae*[6]. The obligate methylotroph, *Methylophilus methylotrophus*, is a fermentation organism which grows very well on cheap substrates, methanol and ammonia. Moreover, obligate methylotrophs are unlikely to infect man and hence may be considered relatively safe. Here we report the expression of two eukaryotic cDNAs encoding chicken ovalbumin and mouse dihydrofolate reductase in *M. methylotrophus*, hence demonstrating the potential of this organism for the commercial production of mammalian peptides.

Most cloning vectors developed to date are plasmids or phages specific for *E. coli*. Wide host-range cloning vectors based on RP4 and other IncP group plasmids have been developed[7], but these vectors are large, have a low copy number and are therefore not suitable for cloning when increased expression due to copy number is desired. For ease of manipulation and high gene dosage, small, high copy-number, broad

host-range plasmids are needed. IncQ group plasmids, including R300B[8], meet these criteria and although they are themselves non-conjugative, they are mobilized efficiently by conjugative plasmids of various groups[8]. Despite its advantages, however, R300B has relatively few restriction enzyme sites suitable for cloning. The composite plasmid, pGSS15[9], has both the ampicillin (Ap^r) and tetracycline (Tc^r) resistance from pBR322 while retaining the broad host-range characteristics of R300B and hence contains a number of unique restriction enzyme sites for cloning. Moreover, cloning of eukaryotic cDNA into the *Pst*I site of the Ap^r gene by dG.dC tailing has been demonstrated to lead to the expression of either fused[10] or native[11] eukaryotic polypeptides at least in *E. coli*.

It has been reported previously that using broad host-range cloning vectors, the *E. coli gdh* gene has been expressed in *M. methylotrophus*[12]. Here we have used pGSS15 to demonstrate expression of the mouse dihydrofolate reductase and chicken ovalbumin genes in *M. methylotrophus*.

Copy DNA derived from the mRNA for mouse dihydrofolate reductase (DHFR) has been cloned and expressed in *E. coli*[13]; bacteria which synthesize mouse DHFR can be selected because they are resistant to levels of trimethoprim that would ordinarily inhibit growth.

The plasmid pDHFR7 (ref. 13) was constructed by annealing deoxy-C-'tailed' cDNA to pBR322 DNA which had been cleaved in the β-lactamase gene by *Pst*I and 'tailed' with deoxy-G residues. The *Pst*I sites were regenerated on both ends of the insert as a result of such recircularization. The cDNA insert of pDHFR7 was isolated after *Pst*I cleavage of the plasmid and 1 μg of this DNA was mixed with 0.5 μg of pGSS15 DNA which had been linearized by *Pst*I digestion. The mixture was ligated and used to transform *E. coli* ED8654 (*met*B, *rk*$^-$*mk*$^+$, *sup*F). Out of 221 of the trimethoprim-resistant (Tp^r) clones, 216 were ampicillin-sensitive, showing that the DHFR fragment had been inserted into the *bla* gene. Gel electrophoretic analysis showed that all the plasmids in the Tp^{r}Ap^s clones were the same size and were larger than pGSS15. The DHFR cDNA has a single *Bgl*II restriction site which allows orientation of the fragment. *Eco*RI/*Bgl*II digests of plasmids from Tc^{r}Ap^{s}Tp^s and Tc^{r}Ap^{s}Tp^r clones established that only one orientation led to functional expression of the DHFR sequence, indicating that productive transcription was from the β-lactamase promoter.

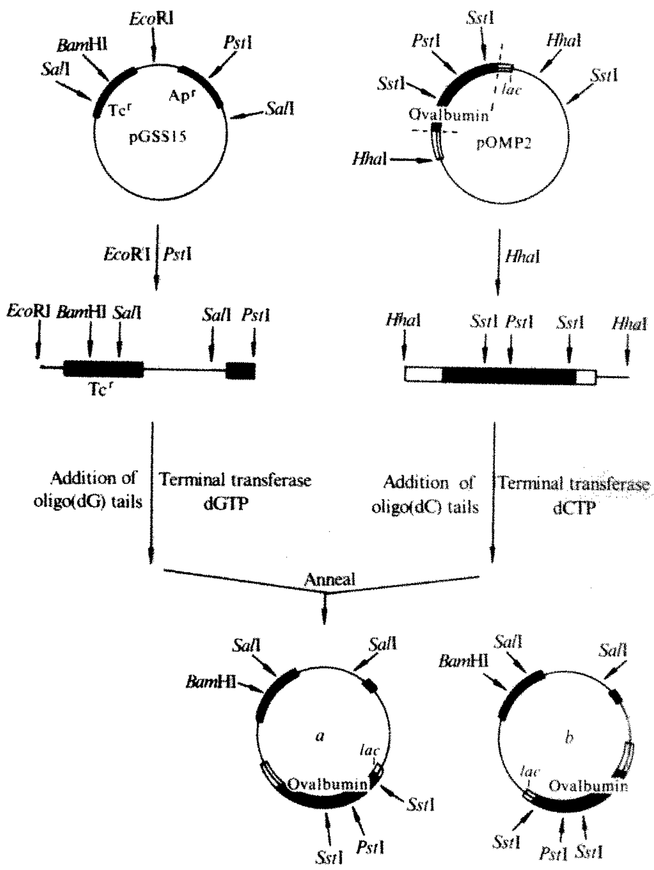

Fig. 1 Outline of the construction of pGSS15 derivatives carrying ovalbumin cDNA sequences fused to the *lac* UV5 promoter. pGSS15 DNA (1 μg) was digested with *Eco*RI and *Pst*I and the larger fragment isolated from an agarose gel using hydroxyapatite[25]. A *Hha*I DNA fragment containing the ovalbumin sequence and *lac* UV5 promoter from pOMP2 was isolated using the same technique. In the case of pOMP2, several other *Hha*I sites are present outside the *lac*–ovalbumin region (not shown). Oligo (dC) or (dG) tails were added using calf thymus terminal transferase, in the presence of 1 mM $CaCl_2$, and the two DNAs were mixed in equimolar amounts, at a total concentration of 1 μg ml^{-1}, for annealing[26]. Aliquots were used to transform $CaCl_2$-treated strain CL499 and transformants selected on nutrient plates containing (10 μg ml^{-1}) tetracycline. Colonies were tested for the presence of ovalbumin DNA sequence by hybridization to the *Taq*I ovalbumin fragment labelled with ^{32}P, and finally for the production of immunoreactive ovalbumin.

Table 1 Dihydrofolate reductase activities of pDHFR 2.43 in extracts of *E. coli* ED 8654 and *M. methylotrophus*

Strain	Substrate	Addition	Activity
E. coli ED 8654	Dihydrofolate	—	0.70±0.14 (4)
E. coli ED 8654 (pDHFR 2.43)	Dihydrofolate	—	1.58±0.26 (5)
M. methylotrophus	Dihydrofolate	—	2.34±0.68 (5)
M. methylotrophus	Dihydrofolate	Trimethoprim*	0 (2)
M. methylotrophus	Folate†	—	0 (2)
M. methylotrophus (pDHFR 2.43)	Dihydrofolate	—	12.6±1.7 (4)
M. methylotrophus (pDHFR 2.43)	Dihydrofolate	Trimethoprim*	2.57±0.53 (4)
M. methylotrophus (pDHFR 2.43)	Folate†	—	0.50 (1)

E. coli strains used were grown on medium containing (per l): $(NH_4)_2SO_4$, 2 g; K_2HPO_4, 14 g; KH_2PO_4, 6 g; trisodium citrate, 1 g; $MgSO_4.7H_2O$, 0.2 g (*p*H 7.2) supplemented with methionine (50 μg ml^{-1}) and glucose added to a final concentration of 0.2%. *M. methylotrophus* strains were grown on methanol minimal medium as described previously[12]. Cultures were grown with shaking at 37 °C overnight, collected by centrifugation and the pellets resuspended in 3 vol 50 mM potassium phosphate buffer (*p*H 7). The cells were disrupted by sonication on ice in the presence of 10 μM phenylmethylsulphonyl fluoride (PMSF) and 10 μM benzamidine and cell debris removed by centrifugation at 10,000*g* for 15 min and 100,000*g* for 60 min. Enzyme assays were performed at 37 °C. The standard assay mixture contained 50 μM dihydrofolate, 60 μM NADPH, 12 mM 2-mercaptoethanol, 50 mM potassium phosphate buffer *p*H 7 and enzyme (normally 100 μl of bacterial extract) in a final volume of 1.0 ml. The oxidation of NADPH was followed at 340 nm for ~10 min. Enzyme activity is expressed as nmol of NADPH oxidized per min per mg protein (mean ± s.e.m.). Numbers in parentheses are the number of separate experiments. Protein concentration was determined by the method of Lowry *et al.*[27].

* Trimethoprim (100 μg ml^{-1}) was added to the enzyme assays.

† Folate (70 μM) was included in the assay mixture instead of dihydrofolate.

The plasmid R64drd11 (ref. 14) was introduced into one Tp^r clone, pDHFR 2.43, and used to mobilize this hybrid plasmid into *M. methylotrophus*. Table 1 shows the levels of dihydrofolate reductase activity in extracts of *E. coli* (pDHFR 2.43) and *M. methylotrophus* (pDHFR 2.43). When trimethoprim (100 μg ml^{-1}) was added to the *M. methylotrophus* extracts, complete inhibition of the bacterial enzyme activity was observed, but the activity in the pDHFR 2.43 extract was reduced to only ~25%, consistent with observations that the mammalian enzyme is less prone to inhibition by trimethoprim[15]. Furthermore, changing the substrate to folate instead of dihydrofolate abolished the activity of the bacterial enzyme but the mammalian enzyme retained a low level of activity (Table 1 and ref. 16). These two observations confirm that the trimethoprim resistance of *M. methylotrophus* carrying pDHFR 2.43 is a consequence of the expression of the mouse dihydrofolate reductase gene.

As pGSS15 retains the broad host-range characteristics of R300B[8], we have been able to transfer pDHFR 2.43 into another methylotroph, *Methylomonas methylovora*, and into an autotrophic bacterium, *Alcaligenes eutrophus*, and have

Table 2 Synthesis of ovalbumin-like protein in bacterial extracts

Strain	Plasmid	Immunoreactive ovalbumin (molecules per cell)
E. coli CL499	pOV230	ND
E. coli CL499	pGSS15 : *Taq*-ov	2.8
M. methylotrophus	pGSS15 : *Taq*-ov	3.6
E. coli CL499	pOMP2	740
E. coli CL499	pGSS15 : *lac*-ov	760
M. methylotrophus	pGSS15 : *lac*-ov	150

Cultures (5 ml) of *E. coli* and *M. methylotrophus* were grown with shaking at 37 °C overnight. *E. coli* cultures were grown in Luria broth containing 10 μg ml^{-1} tetracycline and *M. methylotrophus* in methanol minimal medium[12] containing 1 μg ml^{-1} tetracycline. Cells were collected by centrifugation and washed in 5 ml of phosphate-buffered saline (PBS). The cells were resuspended in 5 ml of ice-cold PBS and disrupted by sonication. Cell debris was removed by centrifugation at 3,000*g* for 10 min and the cell-free supernatant was used for the assay. Antibodies against ovalbumin were raised in rabbits by injecting into multiple sites 1 mg of ovalbumin (99%; Sigma) emulsified in Freund's complete adjuvant. Injections were repeated once a week for 4 weeks and blood was collected 10–14 days after the last injection. Antibodies were purified by $(NH_4)_2SO_4$ precipitation (15–40% saturation fraction) and dialysis. Polystyrene wells (7 mm diameter × 12 mm deep) were coated with anti-ovalbumin immunoglobin; 300 μl of antibody (10 μg ml^{-1}) in 0.2M $NaHCO_3$ (*p*H 9.2) was pipetted into each well and incubated at 37 °C for 5 h. Wells were washed three times with wash buffer (PBS containing 0.5% normal rabbit serum and 0.1% bovine serum albumin). In triplicate, cell extract (300 μl) was pipetted into wells and the released antigen was allowed to bind overnight at 4 °C. After incubation, wells were washed three times with wash buffer and 300 μl of ^{125}I-anti-ovalbumin immunoglobulin in wash buffer was added (25 ng ml^{-1} ^{125}I-anti-ovalbumin, specific activity 18 μCi μg^{-1}). Wells were incubated at 37 °C for 3 h, washed three times and individual wells counted in a gamma counter. A standard curve was constructed using ovalbumin diluted in PBS or *E. coli* cell extract. As a measure of the immunoreactive ovalbumin-like material produced in *E. coli* and *M. methylotrophus*, the dilution of each strain giving 50% of the maximum binding was taken to be equivalent to the mass of authentic material giving the same counts. The viable cell count per ml of culture and the mass of ovalbumin detected were used to calculate the number of molecules of ovalbumin-like protein produced per cell. ND, not detected.

demonstrated that these strains are also rendered trimethoprim-resistant (our unpublished results).

Chicken ovalbumin, the major egg white protein, is a polypeptide consisting of 386 amino acids. The DNA sequence corresponding to the entire ovalbumin structural gene has been cloned[17,18] and ovalbumin-like protein has been detected in bacterial extracts by immunological methods[19,20].

A *Taq*I fragment of ~2,200 base pairs, containing the entire ovalbumin structural gene, can be excised from the plasmid pOV230 (ref. 19). The *Taq*I ovalbumin fragment was extended with oligo(dC) tails and annealed to pGSS15 DNA to which oligo(dG) sequences had been added after cleavage with *Pst*I. The annealed DNA was used to transform *E. coli* CL499 (*E. coli* CB100 P1 transduced to rk^-mk^+). Ap^{s}Tc^r transformants were screened for the presence of ovalbumin cDNA using a ^{32}P-labelled probe generated by nick-translation[21] of the *Taq*I ovalbumin fragment. Several positive clones from the hybridization were screened for the production of ovalbumin using an immunoradiometric assay. The plasmid, R751 (ref. 22), was then used to mobilize the hybrid plasmids from ovalbumin-producing *E. coli* strains into *M. methylotrophus*. Table 2 shows the levels of ovalbumin expressed in *E. coli* and *M. methylotrophus*. Restriction enzyme mapping of the inserts of clones which did or did not express ovalbumin confirmed that expression was in one orientation only and was probably initiated at the β-lactamase promoter.

In the plasmid pOMP2 (ref. 20), ovalbumin sequences have been fused to part of the *E. coli* β-galactosidase gene. Expression of this hybrid plasmid yields a product in which the first four amino acids of ovalbumin are replaced by the first eight of β-galactosidase and the system is under the control of the strong *lac* UV5 (ref. 23) promoter. This system leads to high levels of expression in *E. coli* and it was of interest to determine whether similar high levels of expression could be achieved in *M. methylotrophus*. The fused β-galactosidase–ovalbumin sequence was isolated from pOMP2 as a single *Hha*I fragment of 2.7 kilobases. pGSS15 was cleaved with *Eco*RI and *Pst*I and the large fragment isolated. The *Hha*I *lac*–ovalbumin and *Eco*RI–*Pst*I pGSS15 fragments were then joined by oligo (dG.dC) tailing. (The construction of these hybrid plasmids is outlined in Fig. 1.) The annealed plasmids were used to transform *E. coli* CL499 and transformants were isolated and analysed in a similar manner to that used for the *Taq*I ovalbumin fragment. Table 2 shows the levels of expression of the *lac*–ovalbumin hybrid sequence in both *E. coli* and *M. methylotrophus*. Restriction enzyme analysis of the plasmid DNA from the hybrids expressing ovalbumin-like protein show that the inserted sequence is expressed in both orientations. However, one orientation (shown in Fig. 1*a*) is favoured (evident in 9 out of 10 isolates); the significance of this unknown. Expression in both orientations, together with the comparable levels of expression of the *lac*–ovalbumin fragment in pGSS15 and in the parental plasmid is evidence that the expression remains under control of the *lac* UV5 promoter.

The levels of immunoreactive ovalbumin detected in *E. coli* from both the β-lactamase and *lac* promoters are ~50-fold lower than expected. The expression of a penicillinase–proinsulin fused protein produced in similar conditions[24] was ~100 molecules per cell and expression of ovalbumin-like protein under *lac* control has been reported at 30,000 molecules per cell[19,20], compared with 2.8 and 760 from the present study. The most likely explanation of these differences concerns the assay systems and in particular the specificity, affinity and avidity of the antibodies used. We have tested this hypothesis using a published radioimmunoassay[20]. The ovalbumin levels detected were similar to those of the immunoradiometric assay described above, indicating that the differences from other published results are probably due to the antisera used.

Although less than in *E. coli*, the level of expression of the two eukaryotic cDNAs in *M. methylotrophus* is significant, indicating that reasonable levels of expression may be achieved in the latter using promoter sequences previously investigated only in *E. coli*. It remains to be determined how closely related these *E. coli* promoter sequences are to the natural *M. methylotrophus* control sequences.

We thank Dr S. N. Cohen for providing pDHFR7, Dr B. W. O'Malley for pOV230, Dr O. Mercereau-Puijalon for pOMP2, Dr B. J. Bachman for CB100 and E. M. Pioli for CL499. We thank Drs M. S. Rose and E. C. Dart and Professor W. J. Brammar for their interest, support and helpful discussions.

Evidence that a human β-tubulin pseudogene is derived from its corresponding mRNA

C. Deborah Wilde, Carol E. Crowther, T. P. Cripe, Mary Gwo-Shu Lee & N. J. Cowan

Department of Biochemical Sciences, Princeton University, Princeton, New Jersey 08544, USA

Pseudogenes—sequences which are homologous to functional genes but which contain mutational changes precluding the formation of a functional product—seem to be a common feature of eukaryotic genomes. Such sequences were first described in the 5S gene of *Xenopus laevis*[1], and have since been found in several gene families including those of the α- and β-globins of several species[2–10], immunoglobulin V_κ genes[11], the actin genes of *Dictyostelium*[12] and the small nuclear RNA genes of man[13]. Among the globin pseudogenes, there appear to be two kinds of structural organization: genes that have retained their intervening sequences[4–7] and those that have lost them completely[2,3]. A possible explanation for the generation of such intron-lacking genes involves the reverse transcription of a processed mRNA to form cDNA, and the introduction of this cDNA copy into the genome either by recombinant heteroduplex formation[2], insertion into a staggered chromosomal break[3], or via a retrovirus intermediate[14]. Here we report the complete sequence of a human β-tubulin pseudogene. The sequence data reveal the absence of any intervening sequences, and the presence, in the genome, of an uninterrupted 17 base-pair (bp) tract of A residues 14 base-pairs 3′ to a poly(A) signal (AATAAA)[15]. This sequence organization corresponds closely to the sequence organization of the poly(A) signal and poly(A) tract in a β-tubulin mRNA[16].

Screening of two human recombinant bacteriophage libraries with chicken α- and β-tubulin cDNA probes has resulted in the isolation of most of the tubulin-like sequences contained in the human genome[17–19]. Structural analysis of the β-tubulin sequences has revealed genes of varying length, including some that are close to, or apparently less than the size required to encode a functional mRNA[17]. The complete sequence of one of these genes, determined by the stratagem shown in Fig. 1, is given in Fig. 2. There is a striking overall homology between the chicken and human sequences within most of the coding sequence: 90% of the amino acid sequence is unchanged, while 82% of the bases are conserved. Among those bases that differ, 75% are 'silent' substitutions that do not affect the amino acid sequence. Most of these substitutions are from G or C to A or T residues, accounting for the lower (56%) G+C content of the human relative to the chicken (62%) gene within the coding sequence. The human gene (46β) contains no intervening sequences. It has a 3′ untranslated region which is 44 nucleotides shorter than the corresponding chicken sequence, and is largely non-homologous. Immediately upstream from the initiator ATG in 46β, the sequence is markedly A+T rich (63%), in contrast to the chicken 5′ untranslated region (21%).

Two features render the human sequence incapable of yielding a functional mRNA. First, at amino acid position 230, the serine codon TCG appears as a termination codon (TAA); second, at amino acid position 270, the third base of the phenylalanine codon (TTC) is absent, resulting in a frameshift leading to a termination codon (TGA) beginning at the second base of amino acid 299. In addition, an unexpected feature of the human sequence is the presence, 14 bp 3′ to the poly(A) signal (AATAAA)[15], of an uninterrupted tract of 17 A residues. The spacing between the poly(A) signal and the oligo(A) tract corresponds very closely to the spacing between the chicken cDNA poly(A) signal and its poly(A) sequence. Moreover, the human and chicken sequences share a common trinucleotide (CTT) and pentanucleotide (TTTGT) in this region. This sequence organization strongly suggests that the 46β human β-tubulin pseudogene arose by reverse transcription from a processed human β-tubulin gene transcript.

A second remarkable feature of the 46β human pseudogene is the existence of a 11-bp sequence 3′ to the poly(A) tract that is directly repeated 170 bp 5′ to the initiator ATG (Fig. 2). Because the sequence of a human β-tubulin mRNA has not been determined, it is not possible to identify the equivalent of the cap site in 46β. However, the location of the repeat sequences is consistent with their generation by repair of a staggered chromosomal break following insertion of the cDNA into the chromosome.

Sequence analysis of a second human β-tubulin gene reveals the occurrence of an in-phase termination codon at amino acid position 361, and the apparent absence of sequences encompassing the entire 5′ end up to amino acid position 54 (C.E.C., C.D.W., T.P.C., M.G.-S.L. and N.J.C., unpublished results). In contrast to the data reported here, however, this pseudogene contains a short intervening sequence with correct consensus splice signals. Thus, in common with the globin pseudogenes[2–10], human β-tubulin pseudogenes have arisen with and without intervening sequences. This observation, and the existence of pseudogenes with or without abutting direct repeat sequences[13], suggests that they were produced by various independent and probably unrelated mechanisms. Gene duplication, with a subsequent loss of selective pressure on one resulting copy, can satisfactorily explain the origin of intron-containing pseudogenes. These sequences could remain linked to their functional counterpart[4,7–9] or be transferred to a new location by chromosomal translocation, copy insertion or as part of a transposable element. On the other hand, the integration of cDNA copies might occur either directly, or via a retrovirus intermediate, in either case resulting in the random dispersion of intron-lacking pseudogenes throughout the genome.

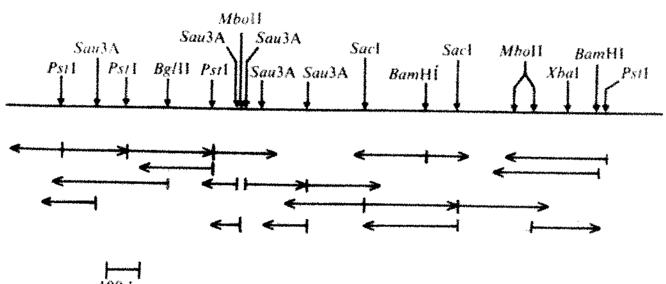

Fig. 1 Sequencing strategem for clone 46β. The sequencing method used was that of Sanger *et al.*[20]. The large *Pst*I fragment was subcloned by digestion of the entire 46β λ clone[17] with *Pst*I, and ligation of the resulting fragments into pBR322. The appropriate subclone was identified by the method of Grunstein and Hogness[21] using a chicken β-tubulin cDNA probe[22] labelled with ^{32}P by nick-translation[23]. This subclone, or the entire 46β λ clone, was used as a substrate for digestion with the restriction enzymes shown. In each case, the resulting fragments were subcloned into the replicative form of M13 mp 8 and/or mp 9. Plaques containing DNA to be sequenced were identified on nitrocellulose replicas[24] by hybridization with the chicken β-tubulin cDNA probe. Sequence analysis revealed two small *Pst*I fragments containing the 5′ end of the 46β-tubulin gene. These fragments were not detected in previous mapping experiments[17] because of their small size and the limitations of blot transfer procedures.

0028–0836/82/180083—02$01.00

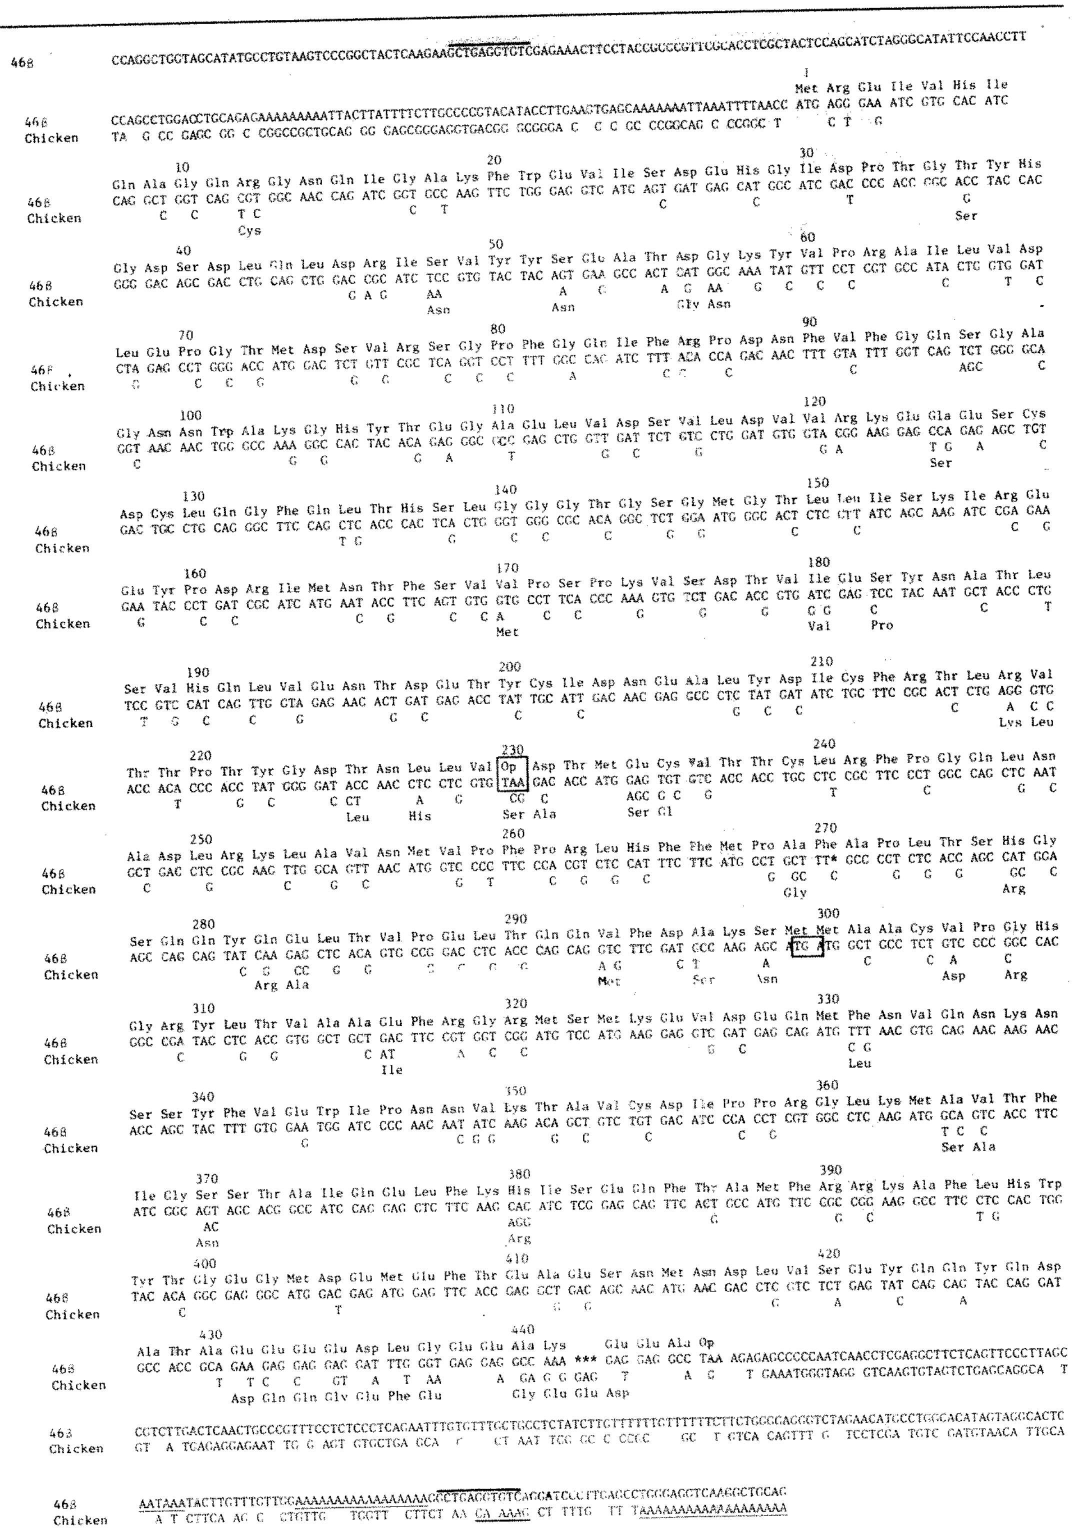

Fig. 2 Sequence of the human β-tubulin pseudogene contained in clone 46β. The chicken β-tubulin cDNA sequence[16] is shown for comparison. Homologies with the chicken cDNA sequence were identified using the computer program of Staden[25]. A termination codon appears at amino acid position 230 (boxed). In addition, a frameshift resulting from a single base deletion at amino acid position 270 has produced an in-phase termination codon (boxed). The poly(A) signals[15] and 3' oligo(A) tracts are underlined. A flanking 11 base-pair direct repeat is overlined. *, Deleted base.

BOOK REVIEWS

The illusory quest for primary colours

J. D. Mollon

Colour Vision in the Nineteenth Century: The Young–Helmholtz–Maxwell Theory. By Paul D. Sherman. Pp.233. ISBN 0-85274-376-9. (Adam Hilger/Heyden: 1981.) £35, $77.

THERE is nothing like colour vision for sorting out the men from the boys. Over the past three centuries the field has attracted the strongest minds — Newton, Thomas Young, Helmholtz, Maxwell — and it is an instructive exercise for the modern student to recapitulate the successive insights of these giants. Equally, however, colour vision has always attracted more than its share of heretics and amateurs, perhaps because colour is so immediate a part of everyone's private experience. In his new book P.D. Sherman traces the sequence of development of the trichromatic theory — and describes too the diversionary actions fought by heretics along the way. Finally, however, his own conceptual development does not keep up and, somewhere around the middle of the nineteenth century, he is himself left behind.

The sub-title is a better guide to the book's contents than is the title: the text is almost exclusively confined to trichromatic aspects of colour vision and it covers the period 1700–1860. There is a quite detailed account of the physical trichromatists of the eighteenth century, whereas there is nothing about the developments of the last four decades of the nineteenth century, such as Helmholtz's line-element, Hering's opponent-process theory and König's derivation of fundamental sensitivities that are very close to those of the photoreceptors.

After discussing the historical position of Thomas Young, Dr Sherman devotes a chapter to one of the most influential heretics in the history of colours, David Brewster, who maintained as late as 1850 that there were only three physical forms of light. Dr Sherman describes the experiments that led Brewster to this position and explains how they were finally answered by Helmholtz. He gives a further chapter to one of the neglected heroes of colour science, Grassmann, who introduced the vector representation of colours. Other chapters are devoted to colour blindness and to geometrical representations of colour, the latter illustrated by several colour plates. This period of colour science is covered in greater detail than in any existing text and useful reference lists are provided.

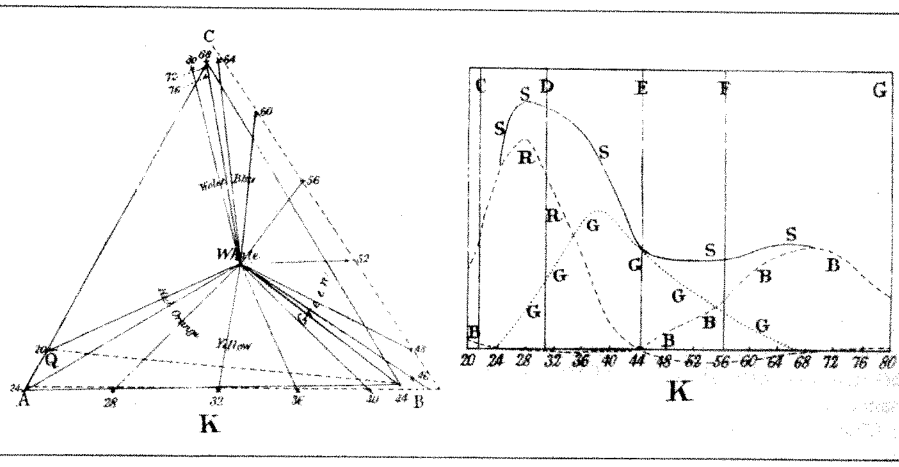
The final two chapters are essentially précis of the great papers on colour vision written by Clerk Maxwell in the period 1855–1860. On the whole the account is admirably accurate and clear (though the student would do as well to read the masterly originals), but when Dr Sherman strays from the path of strict summary he stumbles, and at two crucial points shows that he does not really understand colour vision. The first difficulty centres on the concept of an imaginary primary, a light that has the property of stimulating only a single class of photoreceptors. Since the three classes of receptor have broad and overlapping spectral sensitivities, there do not exist real lights with this property, yet Dr Sherman sometimes suggests that the long-wave fundamental corresponds to an actual wavelength, and he regrets aloud that Maxwell did not measure it. More seriously, he goes on to confuse Maxwell's spectral mixture curves with the actual spectral sensitivities of the receptors. The curves shown by Maxwell represent the proportion of each of his three "standard" wavelengths required to match any other spectral light, but Dr Sherman writes: "Each curve, being an individual physiological response, shows how each primary stimulates a perceived sensation at each point of the spectrum". In fact, Maxwell's curves are very different from the spectral sensitivities of the photoreceptors; but here Dr Sherman leaves us just as the problem is getting interesting.

But was Maxwell himself clear on these two related issues? Certainly on the first question he seems twice to have changed his mind. In his first paper on colour (1855) he writes, unambiguously:

> Though the homogeneous rays of the prismatic spectrum are absolutely pure in themselves, yet they do not give rise to the "pure sensations" of which we are speaking. Every ray of the spectrum gives rise to all three sensations, though in different proportions . . . .

And in his last paper (1871) he writes: ". . . the true primary red is not exactly represented in colour by any part of the spectrum". In 1860, however, Maxwell tabulated the wavelengths of three "primary colours", adding "I have strong reason to believe that these are the three primary colours corresponding to three modes of sensation in the organ of vision . . ." (*Phil. Trans. R. Soc.*, Vol.150). On the interpretation of spectral mixture curves, his words are more guarded than those of Dr Sherman.

So was Maxwell confused? This is a nice historical question, but I think the answer is probably no, for the following reasons. First, he was working with a version of the trichromatic theory which differs from the modern one: he postulated three primary sensations each corresponding to the activity of an independent class of receptor. We now know that the psychophysical transformation is more



Colour mixing results obtained by Clerk Maxwell for his wife, Katherine. In both diagrams, the numbers 20 to 80 represent arbitrary scale readings on Maxwell's apparatus but correspond to various wavelengths, running from red to blue. By applying a centre-of-gravity rule to the chromaticity diagram on the left, one can find what monochromatic light or spectral mixture will match the colour of a given mixture of three standard wavelengths (say, those wavelengths numbered 24, 44, 68). The 'spectral mixture curves' (R,G,B) on the right show directly the intensities of the three standard colours required to match any given wavelength in the spectrum.

complicated: for example, the "red-sensitive" cones are maximally sensitive in the yellow-green and what is maximal at longer wavelengths is the *ratio* of absorptions in the long- and middle-wavelength cones. Second, given his theory and his actual results, Maxwell had empirical reasons for supposing that there existed three real wavelengths each of which produced a nearly pure sensation; for his results, when plotted in his chromaticity space, suggested that the spectrum locus consisted simply of two straight lines that intersected in the green and thus he was led by his data to suppose that a light placed at any apex of the resulting triangle would come close to stimulating only one sensation.

Maxwell's treatment of colour deserves a more careful assessment than is possible here; but much of the problem has escaped Dr Sherman. The one single error that most held back the development of the trichromatic theory was the belief — still to be heard today — that the peak sensitivities of the photoreceptors must correspond to "primaries", either phenomenologically pure "primary hues" or those primaries in a colour-matching experiment that, by direct mixing, allow the matching of the largest gamut of other colours. Only after Maxwell was it realized that the latter primaries should be lights that produce the highest ratio of absorptions in different classes of receptor. Dr Sherman's useful book would have been so much the more valuable if it had identified the essential ambiguity of the term "primary colour" in the literature of the mid-nineteenth century. More generally, his readers would have gained if he had much more clearly set out, in an early chapter, the modern distinction between a chromaticity space (representing physical mixtures that produce matches) and spaces in which colours are so placed as to be uniformly spaced phenomenologically. The mapping of one to the other is now known to be very complex.

The historian of science has a peculiarly difficult trade: he must be master of his period and of at least four languages, and he must be also master of the science. If he is to show us the limits of his subjects' thoughts, he must have a conceptual advantage over them and must share this advantage with his reader. He must be Whig without being presentist: the two are not the same. □

François Jacob on possible worlds

P.B. Medawar

The Possible and the Actual. By François Jacob. Pp.70. Hbk ISBN 0-295-95888-X; pbk ISBN 0-394-70671-4. (University of Washington Press/Pantheon: 1982.) Hbk \$8.95; pbk \$3.95.

THE antithesis embodied in the title of Jacob's short, brilliant and beautifully written little essay can be taken in two ways. In *The Nature of the Physical World*, Sir Arthur Eddington wrote:

> I need scarcely add that the contemplation in natural science of a wider domain than the actual leads to a far better understanding of the actual.

An important fraction of Jacob's essay is indeed an exercise of just this kind. It is an exercise more easily possible in the biological than in the physical sciences because in the latter, as Jacob remarks in a Kantian aside, the right-seemingness and naturalness of the natural world may to some extent reflect "the very way our brains work". In biology, however, it is not a tremendous feat to imagine things otherwise than they really are. Why sex, for example? — and why two sexes and not three? The causal-explanatory answer is not easy but the teleological answer that sexuality is "a diversity-generating device" is satisfying and makes sense of what would otherwise be a puzzle.

The second sense in which we may read Jacob's antithesis is that in which all scientific enquiry is a duologue between the possible and the actual, between what *might* be true and what is in fact the case.

This conception, in which I myself am a firm believer, is sufficiently permissive to make room for myth as an important element in man's attempt to explain his condition, for "whether mythic or scientific, the view of the world that man builds is always largely a product of his imagination". Reflection on this theme allows Jacob to divagate interestingly and amusingly on myths that bear upon sexuality. But of course myths, however effectively they may appease curiosity or dispel the disquiet of ignorance, always fail that difficult exam in which our imaginings are measured up against reality. Yet even in the most "scientific" explanations today there is just a faint hint of the explanatory glibness of the myth — and it is for this reason, I think, that Jacob is a little reserved about natural selection: he does not believe in the universal explanatory value of any one formula.

Needless to say, no one with any understanding of the intellectual tradition to which Jacob belongs and of which he is so able a spokesman could entertain even momentarily the suspicion that Jacob himself is in any serious sense a mystic.

It is an added merit of this book that there is no Message, and that it is altogether too polished and urbane to harangue us at any time. It is a very scientific book which embodies more neatly than I have seen expressed elsewhere the conviction of most scientists that

> . . . there are many possible worlds; but the interesting one is the world that exists and has already shown itself to be at work for a long time. Science attempts to confront the possible with the actual. It is the means devised to build a representation of the world that comes ever closer to what we call reality. □

Sir Peter Medawar is Head of the Transplantation Biology Section at the Medical Research Council's Clinical Research Centre, Harrow, Middlesex.

Marine microfossils

B. M. Funnell

Microfossils from Recent and Fossil Shelf Seas. Edited by J. W. Neale and M. D. Brasier. Pp.380 UK ISBN 0-85312-338-1; US ISBN 0-470-27220-1. (Ellis Horwood/ Halsted:1981.) £35, \$76.65.

A PRINCIPAL merit of this book is the variety of topics it contains. In 28 chapters it covers every geological period from the Silurian to the Recent; a geographical range embracing Spitsbergen and the Barents Sea, East Africa, the equatorial Pacific, the western North Atlantic, Israel, Iran, Pakistan, North-West Europe and the British Isles; and microfossil groups as varied as conodonts, algae, acritarchs, dinoflagellates, ostracods, benthonic and planktonic foraminifers and radiolaria. The organizers of the symposium at Hull University in July 1980, from which this volume derives, were indeed fortunate in having such a wide diversity of contributions on which to draw.

Another successful feature of the book is the high degree of uniformity of contributions, none of which are either too long or too ambitious, and only one of which is reduced to extended abstract dimensions.

The volume as a whole is arranged in stratigraphical order. Approximately 15% is devoted to the Palaeozoic, 35% to the Mesozoic, 20% to the Tertiary, and 30% to the Quaternary and Recent. Most articles apply themselves to stratigraphical or palaeoenvironmental interpretation. No fundamentally new approaches are introduced, and the methodologies used are essentially those developed in the 1960s and early 1970s. A particularly disappointing aspect is the poor understanding of physical and chemical oceanography exhibited by some authors. A few contributions begin to break through this deficiency, for example that dealing with anoxic events in the late Cretaceous and the salutary study of microfossil transport in a modern estuary;

but others, on equatorial Pacific palaeotemperatures and possibly Palaeozoic shelf bathymetries, for instance, tend simply to produce an "acceptable" interpretation that is derivative, and can scarcely be sustained on the microfossil evidence presented.

In spite of these shortcomings the book provides a good review of current research in marine micropalaeontology as practised by members of the British Micropalaeontological Society and their international associates. The inclusion of chapters on the Permian of Iran, the Eocene of Israel and the Recent of East Africa goes a long way towards redressing what would otherwise be a strong emphasis on temperate zone, North Atlantic and North European occurrences.

This collection of papers should serve a useful purpose in stimulating renewed interest in this currently most useful, but sometimes neglected branch of the earth and biological sciences. It can certainly be recommended for reading by both advanced undergraduates and specialist research workers in the field. □

B. M. Funnell is Professor of Environmental Sciences at the University of East Anglia.

Muscle laid bare to the bone

R.M. Simmons

The Structural Basis of Muscular Contraction. By John Squire. Pp.716. ISBN 0-306-40582-2. (Plenum: 1981.) £34.65, $55.

THE publication of an advanced, or even intermediate, text on muscle is a rare event, an obvious disincentive being that the field is now too big and in many areas too technical to be encompassed satisfactorily in a single book or by a single author. The most one can hope for is an expert treatment of a particular area, and that is what John Squire has done for muscle structure.

Progress in understanding the details of the structure of muscle has depended heavily on the use of X-ray diffraction and on optical diffraction from electron micrographs. The author recognizes the difficulty that diffraction theory presents to non-experts and includes in the introductory material a lucid non-mathematical treatment together with examples of common structures found in proteins and polypeptides. There is also a useful description of the methods used in electron microscopy. Thereafter it is a straight slog through the static structure of muscle, the various isolated and assembled preparations from individual molecules through paracrystals, thick and thin filaments, to superlattices, all 300 pages of it. Such an account could easily have ended up as no more than a useful compendium of techniques and results for the expert, but Squire succeeds on the whole in pursuing what is relevant to understanding structure and function in real muscles. Some readers may find that the author's enthusiasm for research on thick filament assembly exceeds their own, and that in the same area he is a little over-protective towards his own models; there is more than a hint of special pleading for smooth muscle myosin ribbons and the boot goes in a bit heavily into the opposition on vertebrate muscle filaments.

The general outlines of most of the static structures emerge with some clarity. But no question is settled until it is settled right, and that does not come easily in muscle research. In spite of years of patient grind we still do not know the precise arrangement of the cross-bridges on the outside of the thick filament in relaxed muscle, let alone the packing of the tail portions in the backbone. Doubts have been raised about the steric blocking mechanism of tropomyosin on the thin filament in the regulation of contraction. There are still arguments about the interpretation of the clearest static picture of the intact lattice — insect fibrillar muscle in rigor. The author gives grounds for believing that many of the static structural problems will be solved and indeed there is some confirmation for this view from results too recent to have been included in the book, such as new reconstructions of decorated actin filaments and improved staining methods for cross-bridges in isolated thick filaments.

When it comes to solving the main problem in muscular contraction, of what are the dynamic structural changes underlying force generation and work production, and of how these are related to biochemical events, the grounds for optimism are fewer (and indeed there are fewer pages on it in the book). The author's profession of faith as a molecular biophysicist is that the more one knows about a structure, the more one grows capable of saying how it works. But it is not at all clear that a detailed knowledge of static structure of the filaments or even of the arrangement of cross-bridges in the relaxed and rigor states is of much help in understanding dynamic changes. Contracting muscle displays a high degree of disorder and although improvements in techniques such as time-resolved X-ray diffraction have led to some suggestions about cross-bridge action, there is not much structural information to go on. One has to conclude that a satisfactory solution lies some way ahead and that new techniques will be needed to find it. □

R.M. Simmons is in the MRC Cell Biophysics Unit, King's College, University of London.

nature

13 May 1982

Will there be war in space?

The sheer scale of the Soviet space programme is awesome. Has the time come when the Soviet government must say what it hopes to achieve?

In June the name of Jean-Loup Chrétien will become a household word in the Soviet Union and France. Chrétien will be the first Western astronaut to be whooshed into space by a Soviet rocket and to ride in a *Soyuz* spacecraft, visit a Soviet space station briefly and, if all goes well, return to Earth. He will join the list of Polish, Czech, East German, even Cuban, cosmonauts whom the Soviet Union has made guests in space, and who have been given a first-hand look at the civilian side of that technology about which the Soviet Union is most sensitive and proud: manned space flight. At about the same time, in Washington, where the Soviet space programme generally draws a big yawn, the President will be in the final stages of a critical decision on whether to proceed with a US manned space station to serve the United States and Western Europe.

The Soviet space programme has received little attention in Europe or the United States. Yet its objectives and momentum will influence East–West relations and the arms race in the 1980s and beyond. True, the Western media are delighted to talk up "Star Wars" fantasies, the US shuttle, Ariane or Soviet space weapons. But they have overlooked the main substance of the Soviet programme, lucidly outlined in a recent book by NASA watcher of the Soviet skies, James E. Oberg*. Since the early 1970s, the Soviet manned space programme, which had been in a shambles after the death of its early architect Sergey Korolev in 1966, has concentrated on a single goal: *Kosmograd*. This is the code word for "Space Colony Number 1, made in the Soviet Union". In an assessment shared by many observers of the Soviet manned space programme, Oberg describes how the Soviet Union is amassing the building blocks of this capability.

First there was *Soyuz*, the free-flying craft in which cosmonauts journey up and down from space and make (brief?) orbital stays for scientific work or military reconnaissance. These flights started in 1967 and numbered 40 by May 1981. Then came the *Salyut* space stations, the first one launched in 1971. These have been orbiting space homes for repeated and successively longer visits by cosmonauts. The world's record of 185 days was reached aboard *Salyut 6* in 1980. One of the astronauts who performed the feat had just spent another 175 days in space, and so has had nearly a year of weightlessness. Finally came *Progress*, the unmanned robot freighter tanker craft described in Moscow as a "reliable cargo barge to ensure year-long operation by orbital stations". *Progress* craft bring lonely cosmonauts fuel, food, fresh water, medicines, horseradish, newspapers, mail and other things. By now there is extensive experience in sending up these vehicles, docking the *Soyuz* and *Progress* craft with the *Salyut*, moving them from one *Salyut* port to another to admit a second visiting craft and making repairs in space, including emergency repairs to the exterior of the craft.

So engineering experience is accumulating, but *Kosmograd* also requires mastery of space biology and medicine as well as experience with prolonged human confinement. The goal of sustaining life in space for a year or more is within sight. Although the large green cucumber that the crew on one *Salyut* showed to astonished mission controllers on television proved to be a joke, with practice the Soviets have managed to get seeds growing in space. Space gardens could provide 20 to 40 per cent of the bulk food consumed in orbit, but it remains a mystery why space-grown plants have not yet grown flowers or seeds. Water aboard the *Salyut* is now 50 per cent recycled, and the addition of a urine still could achieve 90 per cent recycling. Banks of *Chlorella* algae have been used to absorb carbon dioxide and give off fresh oxygen: 80 per cent recycling has been achieved on this front. But things have not always gone well. Cosmonauts set to achieve a new endurance record aboard *Salyut 4* pleaded early on to come home because a green mould was spreading all over the cabin. Mission control ignored these pleas until the endurance record had been broken (61 days).

The objective of all this is a permanent orbiting station. *Salyut*, housing two, will be succeeded soon by a larger spaceship housing twelve. According to Oberg, these craft could even be sent to the Moon with the help of the huge proton booster (whose shadowy cousin, the superbooster, apparently failed so often in the late 1960s that it prevented a photofinish in the race to the Moon against the United States).

But such a feat will, on past experience, require a high price in human life. Cosmonauts may be heroes in the Soviet Union, but few seem to live to enjoy it. Recovery teams have often arrived at a returned capsule dangling by its parachute lines in a tree or sitting in some swamp to find the entire crew dead. There was even an unauthorized space-walk in which the cosmonaut's life support cord was unattached and when his life was saved only by the quick thinking of his colleague. Yuri Gagarin, whose 108-minute flight in 1961 amazed the world, became a national hero but he was fated to eulogize comrade after comrade at one funeral after another. (His own life was thrown away cheaply in an aircraft crash.) Even Korolev's death on an operating table, which cost the Soviet space programme its single most important figure, seems to have been unnecessary. There have also been close shaves with death, as when the cosmonauts who missed their landing area by 2,000 miles had to spend their first night back on Earth in the Siberian snows, hiding in their spacecraft from the wolves that snapped outside.

What is the underlying purpose of all this activity? There are obvious civil benefits, in telecommunications for example. And by now, both the United States and the Soviet Union take for granted the stabilizing effects of each other's use of satellites for surveillance. Even so, there is growing concern in the United States at what seems to be the huge scale of the military part of the Soviet space programme. Oberg says there are two "star cities", one for cosmonauts and their guests and the other for the military. A recent study by Marcia Smith of the Congressional Research Service concludes that as much as 70 per cent of the Soviet effort may be exclusively military, while nobody has yet contradicted the assertion by Richard de Lauer, chief scientist at the Pentagon, that spaceborne Soviet lasers could threaten US spacecraft as early as 1983. Technical considerations make the speculation unconvincing; for the time being conventional rocket-driven explosives are probably a better bet. But as in other aspects of the relationship between the United States and the Soviet Union, policy may be determined by one state's perceptions of what the other is about. The fact that the Soviet Union successfully launched 98 satellites last year, compared with a mere 18 from the United States, is certain to carry weight with the White House.

What will be the outcome? Since the United States and the

*Oberg, J.E. *Red Star in Orbit* (Harrap, London and Random House, New York).

0028-0836/82/190091-02$01.00

Soviet Union ratified the Outer Space Treaty in 1967, they have been bound not to put nuclear weapons or other "weapons of mass destruction" into orbits about the Earth. The treaty also requires them not to establish military bases on celestial bodies. Would that injunction apply to a space station occupied exclusively by the military? Or to a satellite equipped to knock out other people's satellites but which contained no people, only instruments? The Soviet Union should come clean about the objectives of its massive programme. The terrestrial arms race is uncomfortable enough. The prospect of a race to put flesh on the bones of science fiction is alarming. Meanwhile, the odds are shortening that President Ronald Reagan, due to greet the next return of the shuttle *Columbia* at Edwards Air Force Base in California on 2 July, will not merely proclaim that the shuttle is a going concern but that the United States will embark on the next logical step, the building of a space station. As Kennedy did before him, Reagan may find that the Soviet Union's activities justify an expanded programme in the United States.

Academic suicide

The University f London now has a plan for its future; but will it survive that long?

The University of London seems well on the way to making an even greater hash of its affairs than seemed likely a few months ago (see *Nature* 14 January, p.86). For the past year, it has been clear that the consequences of the British government's reduction of support for universities, the limits imposed by the University Grants Committee on the number of students to be allowed at individual universities and the effect on the income of universities of frightening away students from overseas would be especially damaging for the largest British university and, because of its federal constitution, administratively the most complicated. But none of that can excuse the way in which the university has let time slip through its fingers until last week when, with the deadline approaching for deciding how it should finance itself next year, the university's senate was jockeyed into accepting a plan for the future whose analytical foundations are, to say the least of it, shaky and whose academic implications are unknown. The only virtue in the way in which the university has managed its affairs is that this sorry tale may serve as a warning to other academic institutions.

What has happened in the University of London is a kind of pantomime. Two years ago, the then vice-chancellor, seeing the way the wind was blowing, set up a Committee on Academic Organization under an independent chairman. The plan was to recommend a strategy for the university as a whole. Halfway through this undertaking, however, a new vice-chancellor gave the committee narrower terms of reference and set up six other committees, again with independent chairmen, to suggest how the pattern of teaching in different fields of study should be reorganized. (One committee went off on the wrong tack, preferring terms of reference other than those given to it; mercifully, with a different chairman; a set of recommendations has been cobbled together just in time.) Inevitably, these subject committees have produced proposals for moving the teaching of various subjects from one place to another in the federated university which are inevitably in conflict with each other, so yet another committee — called the Joint Planning Committee — was asked to make sense of them and of the volume of comment and special pleading with which the university was deluged. That committee concludes, in its report, that the recommendations of the six subject committees were often based "on inadequate information" (ill-informed) or "cannot be justified in the light of the facts" (or in simple language are wrong). Searching, nevertheless, for some straw at which to clutch, the committee seems to have seized on one of the recurrent themes in the recommendations of the subsidiary committees — physics, or classics, or economics, should be taught at fewer sites. So why not simply concentrate the whole of the university, now spread between a dozen non-medical colleges, on a smaller number of places, say five or six? This is the proposal that the senate of the university found itself having to accept last week.

The most curious feature of the affair is that this radical decision has been reached with hardly any discussion in the university as a whole of the academic implications, let alone the implications for those who work in and for the university. And what is now intended will create further internal contradictions within what is already a sufficiently cumbersome academic machine. The university grew to its present size like Topsy, by the enthusiastic accretion of almost any college, large or small, willing to join the fold. As a result, it now consists of an exceedingly inhomogeneous collection of establishments, some large and some small, some academically excellent, some less so. Two are for practical purposes specialized in the scientific fields. One (Birkbeck College) specializes in part-time students. One small college is not in London at all but in Surrey, while there are agricultural and veterinary colleges in Kent and Hertfordshire respectively. The tidy administration of such a motley collection of establishments is acknowledged to be impossible. Since the late 1960s, the university has chosen to make a virtue out of diversity, letting its separate parts run themselves without much reference to the centre. Now, by a simple show of hands, that policy has been turned on its head. The committee whose recommendations will shape the future of the university pays the usual lip-service to diversity before recommending that it should be done away with.

The university's problem is uniquely difficult — which is all the more reason why it should have been dealt with intelligently. Given that the pressure on the university's finances is likely to continue more or less indefinitely, a measure of concentration is clearly in the long run prudent. Some of the London colleges, seeing the way the wind is blowing, are already making mergers among themselves. The merger (or disappearance) of the rest will now no doubt be forced by the decisions taken centrally by the university on the distribution of funds among its several parts in the years immediately ahead. In the process, it is inevitable that much damage will be done. Many of the shotgun marriages the university is now committed to arranging will be marriages of incompatibles. Undergraduate teaching will become more specialized, and more uniform. The pattern of research will be changed in an arbitrary fashion. And the end result will be a federation of colleges so much more like each other that the advantages of federation will melt away. If the arrangements now agreed are pushed through, it cannot be long before the various parts of the University of London go their separate ways. Is that what is intended?

The peculiar characteristic of the damage that academics repeatedly inflict upon themselves is that it is always done at the eleventh hour (and sometimes the thirteenth). In London, an acceptable solution may already be beyond reach. But that possibility does not mean that it is pointless to look for a better solution. A few clarifying assumptions are obvious starting points. The Imperial College of Science and Technology, in all but name a university in its own right, is rightly acknowledged to be too important to be enmeshed in the financial administration of the University of London (whence the convention that it deals separately with the University Grants committee); it should now be invited to go its own way. The London School of Economics, smaller but equally distinguished and important, should be given some spell of time, say ten years, to grow at the expense of the parts of the university now under threat and then also politely booted out. The rump would be three kinds of colleges — large or largeish place such as University College, smaller colleges concerned principally with the education of undergraduates, and a rag-bag of specialist institutions training veterinarians or assisting with research in outlandish languages. There is ample evidence that each kind of place is valued; what makes their administration impossible is that they are all lumped together. So why not replace them with three (or even more) different universities? When the University of Paris, as now reconstituted, consists of thirteen separate institutions, is it necessary that the largest city in Britain should be condemned to having only one?

Polish university compromise

Buffer between academics and government

Poland's new Higher Education Act, the subject of eighteen months' negotatiations and confrontations — including the threat, last September, of a nationwide university strike — became law last week. The act makes several formal concessions to academics' aspirations for self-governance, but at the same time reserves to the Minister of Science, Higher Education and Technology the last word on a number of key issues.

Students, likewise, get a compromise deal — they have won the right to express their views and form associations but will not be allowed to stage protest actions since, it was explained during the parliamentary debate on the bill, "they do not belong to the community of employees".

The new act gives the minister power to monitor the resolutions adopted by university self-governance bodies and decisions taken by university rectors, and to reverse them should he decide they are inconsistent with the law. Rectors of universities and other higher colleges will be elected by the bodies themselves, the electors being either the university senate or a special collegium. The minister, however, retains the right of veto over elections — providing that he registers his objection within fourteen days.

On these and other questions, there is to be a Main Council for Science and Higher Education to hold the ring, and whose role has been negotiated between the ministry and the Social Drafting Commission — a body representing academics, students, scholars, the trade unions and the Church, which at one stage proposed its own draft bill. The council is in effect a revival under a new name of a moribund body meant to act as an intermediary between academics and the ministry.

The new act gives the council the status of the supreme elective organ of the academic community, with powers to decide on the direction of research and the organization of studies.

The Social Drafting Commission, however, had sought even wider powers for the Main Council. In the event, as Professor Zbigniew Resich, the head of the commission, said last week, "a whole series of important powers" had passed into the minister's hands.

Another major issue has been the dismissal of academic staff. The Social Drafting Commission, said Professor Resich, had considered that a lecturer's contract could be terminated only after disciplinary proceedings. In its final form, the act now contains other possibilities, including the dismissal of junior members of staff (up to and including assistant professors) after two "negative assessment reports". It is not yet clear who would make these assessments, although it seems that the rights of the professorial body will be safeguarded, since any such dismissal must have the consent of the Council of State. But there is some evidence that "assessments" by bodies outside the university are envisaged, another limitation of "self-governance".

Similarly, although the act formally acknowledges the principles of academic freedom, including differences of "world outlook", implementation of these principles, in undergraduate teaching at least, will be constrained by what Professor Resich called "strong emphasis" in the act on the "need to teach and bring up youth in accordance with socialist principles".

These other features of the act are intended to emphasis the state character of higher education in Poland, according to the minister, Dr Benon Miskiewicz. He himself was "following with anxiety" the participation of students and academics in illegal demonstrations, and stressed the role of the universities in ideological and political education.

His concern was timely; in Warsaw alone, six higher education establishments were represented in the arrests following last week's demonstratrations. Students were equally prominent in the demonstrations in Szczecin Gliwice and in the Gdansk-Sopot-Gdynia conurbation.

These demonstrations, which took place in spite of the threat of heavy summary sentences under the emergency regulations, clearly reflect the students' bitterness at the banning of the Independent Students' Association (NZS) and the loss of many of the privileges granted in 1981. The new Higher Education Act is hardly likely to assuage their resentment. **Vera Rich**

Contraction for London university

A proposal by a Joint Planning Committee that the teaching of science in the University of London should be concentrated on five sites was accepted by the senate of the university at its meeting on 29 April. No timetable for the concentration of the university is provided.

This is the university's response to the prospect of an income that will have shrunk by about 15 per cent between 1981-82 and 1983-84, and to earlier reports by the six committees set up to recommend rationalization of teaching in six subject areas. Most committees recommended that teaching should be concentrated at fewer sites.

The planning committee, however, says that these reports reflect "inadequate information" and make comments "that cannot be justified in the light of the facts". In practice, the committee responsible for biological sciences, under its independent chairman Sir James Beament, began last October by assuming that student numbers need not fall as sharply as had been decreed. The committee's second attempt under a second chairman follows the general pattern of recommending concentration on five sites.

The joint planning committee itself is hoping for some relief from the rigours prescribed by the University Grants Committee (UGC). When added together, the recommendations of the six subject committees on student numbers for the year 1983-84 imply that student numbers would then be 1,000 greater than the UGC target. The planning report says that the grants committee has been asked to agree to a larger target number or, alternatively, that the university should have an extra year in which to make the adjustment.

On research support, the planning committee applauds the study now being carried out by the court of the university of the suggestion that financial allocations to the separate London colleges should deal separately with teaching and research. This proposal, put forward last November by Sir James Lighthill, Principal of University College, is regarded as a way of helping to avoid the consequences of the erosion of the dual-support system in the past few years, and also of making explicit the reasons why some colleges in London appear to be dealt with more generously than others. But it seems unlikely that anything will come of this before the court of the university shares out the funds available for the next academic year.

The planning committee's recommendations are that undergraduate science teaching in the university should be concentrated at five sites, where all science subjects would be taught. There are similar proposals for concentration in the arts and the humanities.

The next step in the saga of the University of London will come on 19 May, when the court of the university is to meet for a preliminary assessment of how to divide next year's grant. The exact amount will not be known until the university has heard from UGC at the end of May.

Opinion among senior members of the university is divided about the extent to which the new policy will influence next year's distribution of funds within the university. Some think that the court will be bound to distribute what money there is as the planning committee says it should. Others hold that the university will have to respect the autonomy of its colleges. ●

Paris computer centre

Orsay protests

The *Université de Paris-Sud* at Orsay, one of the principal centres of physics in France, has withdrawn from a plan to assist in the installation and development of the "largest" commercial computer in the world, a Cray-1. The computer is to be installed on the new site of the *Ecole Polytechnique* just a mile or two from the university, but Paris-Sud will have nothing to do with it (except to make a little use of it, once it is running). Orsay physicists have demonstrated over the matter and, at the same time, the scientific director of Paris-Sud's own computer laboratory, *Paris-Sud Informatique* (PSI), has threatened to resign on 20 June unless the government agrees to keep his own laboratory going.

The underlying issue is tangled, and the tangle goes right to the top. *Paris-Sud's* president, physicist Roland Omnès, is going to see the minister of education, Alain Savary, about the matter. But a remark that funding for PSI might not be renewed came from the ministry of research and technology, which is attempting to establish a computer policy for universities and research centres; and the two ministers, Savary and the research minister Jean-Pierre Chevènement, are not the best of friends.

The ministry of defence is also involved, both through its control of the *Ecole Polytechnique* and through the long-expressed wish of the military to purchase a Cray-1 (reportedly vetoed by Washington). So is the ministry of industry, which is trying to revitalize the French computer industry. Given the ever-present IBM lobby and the traditional hostility between the *grandes écoles* (such as the *Ecole Polytechnique*) and the universities, the result is a highly political problem.

At root, however, the dispute is technical. Cray-1 is a "vectorial" computer, whose great power depends on the parallel processing of a series of numbers. It is thus stretched for linear algebra (matrices and so on) only where the sizes of arrays are very large. Physicists generally do not need such arrays (except for modelling large systems such as the atmosphere) and for them the Cray-1 is far from being the most cost-effective machine. So when PSI computer engineers went to the *Ecole Polytechnique* to collaborate over Cray-1 development, they found themselves in conflict with *polytechnique* interests — which were, largely, in engineering and systems modelling. This led to personal conflict and ultimately Omnès withdrew the PSI team from the collaboration.

Since then the atmosphere has become even more heated, with PSI staff claiming, in effect, that the *Ecole Polytechnique* staff are in the hands of IBM; and indeed, the *polytechnique* has scrapped plans to link the Cray-1 to a French-built CII-Honeywell-Bull EBS-8 (a link PSI was to work on) and will go for an IBM instead. The final crunch was a comment made at a meeting by a ministry of research and technology official, who said that Chevènement would probably not sanction the renewal of PSI equipment (a ten-year-old UNIVAC), and that Orsay physicists should use the Cray-1 "only three kilometres away".

Omnès, however, is calm. He believes official thinking is moving his university's way, and that this is not the time for a big public campaign. Nevertheless, some of his more vocal staff disagree with him. Nor does time seem to be on his side. A ministry of research spokesman said this week that it did not want to replace university computers in response to "piecemeal" pressure, and that it would take "several months" to establish a coherent policy. In the meantime the (part-time) scientific director of the Orsay computer centre may have resigned and some of his full-time technical staff, uncertain about their future, may have begun to look for other jobs. That — ultimately — would leave one of France's leading laboratories without a computer.

Schering-Plough take $30 million plunge

Palo Alto

DNAX Ltd, a small Californian company best known for having some pioneers in genetic engineering on its scientific advisory board, seems likely to be acquired by the New Jersey pharmaceutical company Schering-Plough for $29.4 million. Schering-Plough already owns 13 per cent of another leading biotechnology company, Biogen SA.

Schering-Plough is to pay $19 million in cash and is offering 340,000 shares of its common stock valued at approximately $10.5 million. The common stock is to be distributed over 5 years under an incentive plan to the 18-member advisory board and staff of 40 scientists. Preferred shares of DNAX are at present owned by a Swiss group and a US venture capital unit of Elf Aquitaine, the French oil company.

Founded in 1980, DNAX has not so far launched any products or filed any patents. Its scientific advisory board boasts three Nobel laureates: Paul Berg and Arthur Kornberg, both of Stanford University, and George Palade of Yale University.

Alejandro Zaffaroni, DNAX's founder, hopes that the company will eventually manufacture the protein antibodies made by the human body when it is combating infections and inflammatory diseases and allergies, and hopes to have specific macromolecules ready for testing in four to five years.

Zaffaroni is also founder and president of Alza, a company specializing in the delivery of drugs to target organs within the body. Alza's common shares in DNAX, valued at $5.3 million, will be bought by Schering-Plough in its acquisition of DNAX.

In his search for a suitable buyer for DNAX, Zaffaroni says he approached more than 20 companies in Europe, Japan and the United States. Schering-Plough's purchase of DNAX will be the first instance of a major pharmaceuticals company acquiring an entire biotechnology firm.

Charlotte K. Beyers

Law of the Sea

Soviet enterprise

In advance of the inconclusive end to the UN conference on the law of the sea, the Soviet Union last month passed enabling legislation to cover the granting of prospecting and exploitation licences to Soviet enterprises wishing to engage in undersea mining beyond the continental shelf.

The decree of the Supreme Soviet now published describes the measures as "temporary" and stresses that the Soviet Union "is and will continue to be in favour of the settlement of urgent problems of the legal regime of the world ocean on an international basis . . . taking into account the legitimate interests of all states". In the absence of any such legislation, however, the Soviet Union has been "compelled" to protect its interests by granting off-shelf licences to Soviet mineralogical concerns.

The decree was clearly an answer to Western proposals on off-shelf mining. In particular, the head of the Soviet delegation to the law of the sea conference, deputy foreign minister S. P. Kozyrev, categorically rejected Western proposals to grant licences on a "first-come first served" basis. This, he said, was a principle "widely employed during the colonial enslavement of countries and peoples".

Commenting on the new decree, the daily *Socialisticheskaya Industriya* stressed the interest of US companies in off-shelf strategic minerals which, it alleged, had pressurized President Reagan to renege on earlier understandings. The new decree has therefore been interpreted by some commentators as simply a tactical move to strengthen the Soviet position at the bargaining table.

The provisions of the decree, however, are considerably more detailed than would be necessary for such a purpose. It goes into considerable detail about safety zones around deep drilling installations, the notification of temporary navigation hazards, disputes over rights with the "agencies of foreign states" and the setting up of a special fund under the Council of Ministers to which Soviet licence-holders must pay part of their profits.

0028-0836/82/190094-02$01.00

Moreover, a time-lag has been built into the decree, presumably to allow the Soviet Union to acquire the necessary technology. No off-shelf operations, it states, can begin before 1 January 1988.

Several clauses deal with possible non-Soviet participation in off-shelf operations. This would presumably be of two types — with developed and with developing countries. One likely partner in the first category is East Germany, with which the Soviet Union (together with Poland) is already linked in the Baltic drilling consortium *Petrobaltyk* to which the Germans have made a considerable technological contribution. The decree, however, stresses the Soviet Union's role in "assisting" its future partner in the development of technology and the training of personnel, suggesting participation by developing countries. (This would fit in with Kozyrev's rejection of the "colonial" overtones of the Western proposals.)

The developing country would in the first instance presumably provide a shore base and other facilities. Any minerals recovered, according to the decree, would become Soviet property, though in some cases, some or all of them could revert to the partner state. The concept of the Soviet Union building up Third-World off-shelf technology would, however, become particulary relevant if an international agreement were drawn up dividing the off-shelf zone between the interested countries. In that case, the "temporary measures" now announced would automatically lapse. But existing collaboration agreements between the Soviet Union and developing countries on mining activities normally provide for the Soviet Union's initial investment in the technology being repaid over several decades in appropriate minerals. **Vera Rich**

Conference all at sea

Washington

The largest ever diplomatic conference of the United Nations, with 160 governments represented, ended on 30 April in New York with a huge majority for a draft treaty on the Law of the Sea. But the participants in this eight-year-long conference have not gone home in triumph. Instead, they hope to limit the damage that has been done.

What went wrong? In the end, the United States voted against the treaty, as did Israel, Turkey and Venezuela. Britain, West Germany, the Netherlands, Belgium, Spain and the entire Eastern bloc abstained. Ironically, even the dissenters think the draft is a splendid basis for a treaty. It resolves several complex issues, such as navigation through narrow straits.

The stumbling block turned out to be the issue well advertised in the past few years: the rights of private companies to minerals from the deep sea bed. Both the United States and the Soviet Union were affronted. The new Administration in Washington had spent a year trying to decide how to amend the clauses on international access to oceanic minerals that the Carter Administration had negotiated. The Soviet Union, by contrast, objected to a form of words seeming to cast doubt on its freedom from free enterprise.

What happens now is anybody's guess. The procedure requires that governments wishing to sign the treaty must do so by December. Thereafter, the treaty will become international law when a specified quota of signatories has formally ratified it. The flaw is that because the draft of the treaty was not approved without dissent, it is open to any member of the conference to insist that the text cannot be a basis for international law because it was disputed.

So who shoulders the blame? The outcome of the conference was a failure for the diplomats. The bizarre handling of the United States negotiating team may have been crucial.

The Law of the Sea session just ended lasted just eight weeks, and brought to an end the year-long spell during which the United States Administraiton had put the negotiations on ice.

Private seabed mining has been the only stumbling block. Ideologically, the Administration objected to those parts of the text that would give developing countries a say over the private development of seabed minerals. But among the six objections listed by the United States when it returned to the negotiations in January were the provision that the treaty could be amended by three-quarters of its signatories without the US Senate's agreement, and the inclusion of the Palestine Liberation Organization among the members of the conference.

After the event, US negotiators claim that they were not given enough time to negotiate the real issues. The conference chairman, Tommy Koh of Singapore, made them stick to a prearranged timetable. The deadline of 29 March had early on been fixed for the filing of committee reports on which a final draft would be drawn up. By then, however, the mining committee had not agreed a resolution on seabed mining, while the constitutional objection to changing the treaty without consent of the US Congress had not been discussed.

Part of the difficulty seems to rest with the makeup of the US negotiating team. Its leader was James L. Malone, an assistant secretary at the State Department whom the Administration was stripping of his responsibility for nuclear non-proliferation. Malone's chief aide was Leigh Ratiner, a former government seabed mining expert working for the mining industry.

Ratiner was a free-wheeling negotiator and a veteran of earlier sessions at the law of the sea conference. Malone was by comparison a novice. Observers say that Malone would often say one thing and Ratiner another. The result would be either brilliant or confusing, depending on the observer. The delegation was under constant pressure from the mining lobby, which insisted that any sell-out to the conference would be denounced when the treaty came up for ratification in Congress.

The United States' demands for revisions of the treaty, circulated before the beginning of the last session in March, were quickly followed up by detailed textual proposals — and as quickly rejected as too sweeping. A compromise proposal, put forward by 11 states including Australia, Canada, Denmark, Finland, Iceland, Ireland, New Zealand, Norway, Sweden and Switzerland, was quickly rejected by the United States as inadequate but later recognized to be a basis for discussion. By then, however, it was too late.

What will happen now is far from clear. The ceremony at which the treaty will be opened for signature has been arranged for Caracas in December, but the host country, Venezuela, voted against the draft last month because if fails to resolve the dispute with neighbouring Colombia.

No state is bound by the vote it cast on 30 April. Abstaining states or no-voting states could still attend the signing ceremony. But Israel's no is unlikely to change, as the PLO no seems likely to stay in the final text. The Reagan Administration could not change the US vote without an ideological turnabout, which seems unlikely.

Ironically, the Administration's adamant defence of rights to ocean mining may have brought about a situation in which no mining is possible. Tommy Koh has threatened to sue any country that proceeds unilaterally to mine outside the framework of the Law of the Sea. So, if the United States, and other mining states such as the United Kingdom, remain out of the fold, they may see their mining ventures flee to other countries such as Japan.

Meanwhile Elliot L. Richardson, Law of the Sea negotiator for the Carter Administration, believes that the outcome of the conference is "sad". Richardson said that "ideologues" in and outside the Reagan Administration prevented the US negotiating team from being flexible.

The Administration, he said, "wasted" a year deciding whether to continue negotiating, and so spent too little time preparing for the talks themselves. At the meeting at which the US team agreed to produce specific draft articles, it had run out of time and had to include many items that it knew were unacceptable. Similarly, Richardson believes the US team should not have responded so negatively to efforts by a group of eleven countries to negotiate compromises. **Deborah Shapley**

UK nuclear power

Bye British

At last the British nuclear power show is on the road. Advanced gas cooling is an also-ran in the UK Central Electricity Generating Board (CEGB)'s "statement of case" for the construction of a pressurized water reactor at Sizewell in Suffolk, published with due ceremony yesterday (Wednesday).

The price of the British 1,110 megawatt-electric power station is now estimated to be £1,147 million, excluding the initial charge of fuel, compared with £1,590 million for an AGR. The ratio is thus 72 per cent, substantially but not embarrassingly more than the 60 per cent Dr Walter Marshall, chairman of the PWR task force, was hoping for.

The task force was set up to control the cost of safety systems on the British PWR, which a year ago were escalating because of CEGB requirements to keep radiation exposure levels for PWR workers down to those expected of the cleaner gas-cooled reactor. Then there were fears that a British PWR might cost as much as an AGR. In the event, CEGB has maintained its safety requirements, adding elements — such as a larger containment building and a double skin — to the task force design; but the task force effort has shown up in the final price.

An equivalent coal-fired station would cost about the same as the PWR (£1,080 million), says CEGB, but fuel costs would be so much higher with coal that a PWR would give a net saving of some £500–£1,100 million over its 35-year life.

But these few lines give no indication of the scale and density of CEGB's argument which in the statement of case, the accompanying pre-construction safety report, the reference design and the supporting documents amounts to 2½ hundredweight (125 kg) of reading matter.

PWR objectors will now have eight months to study the case, before the public planning inquiry which is to be held at the Maltings, Snape, in Suffolk, in January 1983 — and they will need all of that time. Moreover, CEGB promises a supplement in two months' time which will give a sensitivity analysis (or estimate errors) on the economic elements of the report, and in late June or early July the Nuclear Installations Inspectorate is due to publish its reaction to CEGB's design. The opposition could thus find itself flattened by mere weight of words.

The report, and preparation for the inquiry (including fees to counsel), will cost CEGB some £5–10 million, it is estimated. Some copies will be made available to *bona fide* enquirers, 15 will be placed on public display and others will be sold at £250 a time.

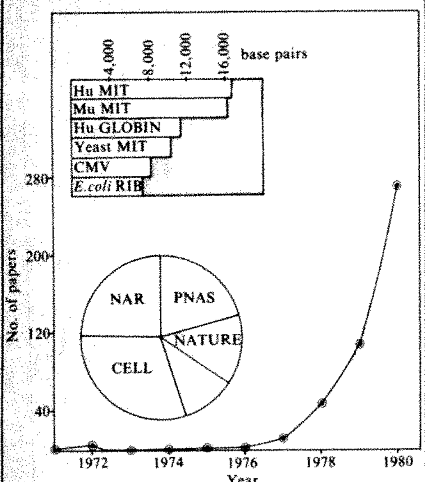
The next crucial task for CEGB is to define the board's procurement policy — where it will buy the components and design work for the reactor. The board estimates that 90 per cent of the PWR cost will pay for work done in Britain — but since the nuclear component (the nuclear steam supply system) amounts to only 10 per cent, CEGB is clearly not ruling out the possibility that the whole of the system might be bought abroad.

The reactor pressure vessel will certainly be bought abroad. Tenders are now out with Combustion Engineering of the United States and Framatome of France. For the rest of the system (such as the steam generators), discussions are beginning with potential British suppliers. Brian George, CEGB's PWR director, said it would be "too strong" to say that the board saw no reason why it should not buy British. In other words, there are good reasons — of price and confidence — why the board should buy foreign, and it will be up to British nuclear industry to convince CEGB otherwise.

Robert Walgate

Sequences add up

The first newsletter of the newly established nucleotide sequence data library of the European Molecular Biology Laboratory (see *Nature* 15 April, p.596) lists 565 entries and is claimed to be fairly complete up until 1980 and perhaps half complete for 1981. Four journals, *Cell, Nucleic Acids Research, Proceedings of the National Academy of Sciences* and *Nature,* dominate the entries. The data base contains nearly



600,000 nucleotides, with 18 continuous sequences of greater than 5,000 nucleotides. The longest of these, at 16,569 nucleotides, is that of the human mitochondrion (HuMIT). Mouse and yeast mitochondria and a human globin gene cluster also provide sequences of greater than 10,000 nucleotides and cauliflower mosaic virus (CMV) and *Escherichia coli* ribosomal genes are not far behind. The mouse provides the biggest number of entries, followed by man. In both cases the sequences are largely of immunoglobulin, globin and interferon genes. The newsletter is available from G. Hamm, EMBL, Postfach 10 22 09, D-6900, Heidelberg, FRG.

Alternative energy

Winding up

Waalre, The Netherlands

The Dutch are again turning to wind as a source of energy. At the end of the last century, more than 9,000 windmills were pumping water or grinding flour in the Netherlands, and if the present emphasis on wind energy continues, by the year 2000 there will be more than 2,000 megawatts of electricity produced from wind power. This is equivalent to about 13 per cent of the country's present requirement for electricity, which is not expected to increase much in the next few decades.

"Looks like the wind's dropped again"

Approximately two-thirds of the wind-derived electricity at the end of this century is expected to come from purpose-built wind-energy parks, with the rest from up to 15,000 smaller individual turbines. There are already 50 small turbines in use, manufactured by 7 Dutch and 14 foreign companies. Until now the growth of the use of wind energy has depended on the enthusiasm of local authorities, but the end of the national five-year research programme and the move into a development programme should see a further boost to wind energy.

The national research programme saw the construction of a 300-kilowatt test turbine, and the new programme will initially involve the building of a wind-energy "farm" with forty 250-kilowatt turbines as a prototype for much larger central electricity generating areas. The cost of this first "farm" is estimated at 40 million guilders (£8 million), half to be paid by the government and half by the public utilities companies.

The government is encouraging the construction of wind turbines by providing a subsidy of up to 40 per cent, which can be paid back over 10 years. The national development programme will also involve the design of a large 60–70 metre commercial wind turbine. Further research is to be done on tip-vanes and a multiple wind turbine is under development, comprising a tower with three cross-bars, each of which will support two rotors, giving a total capacity of 320 kilowatts.

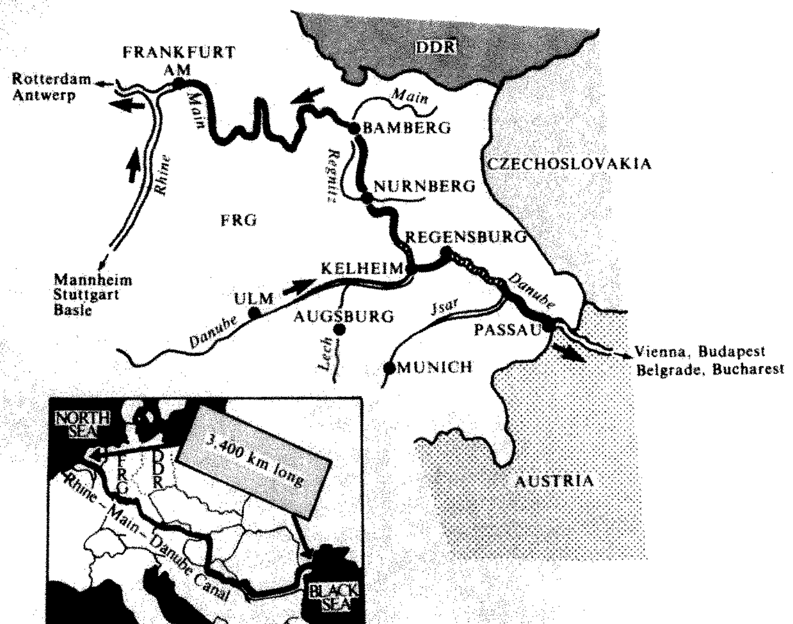
West German waterways

Canal in limbo

Heidelberg

Of the 3,500 km of waterway linking the North Sea to the Black Sea, only 55 km of the Rhine–Main–Danube Canal and 59 km of canalization on the Danube are still incomplete. However, as the work forges on, money is tighter, and controversy about the impact of the canal increases.

The first attempt to conquer the European watershed by joining the Rhine to the Danube dates back to Charlemagne. But it was not until 1855 that, under Bavarian King Ludwig I, a 15-m wide canal with 100 locks was opened. This never competed successfully with the railways and the last 120-ton barge passed through in 1945. Contracts from 1921 and from the 1960s commit the federal government to two-thirds and Bavaria to one-third of the costs of the present canal from Bamberg on the Main to Kelheim on the Danube.



Even by 1976, estimates showed that on each deutschemark invested, the profit would be only 50 pfennig. Total German water freight is in any case falling off: estimates for the canal were 14 million tonnes per year in 1969 and now stand at 3 million tonnes per year. Most of this would otherwise go by the *Bundesbahn*, which is predicted to lose DM60–120 million per year. Worse, German national carriers could face competition from state-subsidized East Europeans not only on the new waterway, but also in the crucial Rhine system. Furthermore, north German seaports could suffer when the canal links Austria, Hungary, Bulgaria and Romania directly to the Rhine delta.

Bavaria considers the project essential to combat local unemployment and underdevelopment and that the DM 3,150 million already invested should not be jeopardized. However, the DM 1,750 million for completing construction and the DM 12 million per year for running the canal might benefit the area more if spent differently. More jobs could be lost in farming and tourism than are created by the canal.

The plans also involve pumping water at 15 m^3 per second up from the Danube to flush out the severely polluted Regnitz and Main and provide cooling water for the four new power plants planned for the Main valley. Without the canal, a DM 500 million pipeline would be needed. But, integrated energy planning and improved waste treatment could meet these needs.

To the 55-m width of the canal will be added a huge parallel service area which in places will carpet the valleys of the Altmuhl and Sulz from wall to wall. After canalization the Danube will deepen its bed, lower the water table and drain surrounding wetlands. These vast landscape changes are the target of mounting environmentalist attack. The Altmuhl valley and the wetlands north of the Sulz and east of Regensburg are not only exceptionally beautiful, but also contain internationally significant biotopes. The destruction of the migrant wintering and resting grounds, the habitats of 46 endangered bird species and 13 endangered fish species, is contrary to the spirit of both Bavarian and federal laws framed in the 1970s to protect fast dwindling wildlife resources.

These serious environmental objections apart, the hard core of the current controversy is economic. In September 1981, while West German Chancellor Helmut Schmidt reassured Kreisky that work on the canal would continue, federal transport minister Hauff, on the strength of his latest reviews, was talking about "the dumbest project since the Tower of Babel". In January the cabinet instructed Hauff to ask the Bavarian Administration for talks about halting or reducing the scheme. Bavaria is holding firmly to its contracts, but Hauff and Strauss will meet this month. Meanwhile, there is nothing in the federal kitty for next year. **Sarah Tooze**

Kew Gardens

Changes ahead

In the cold climate of recession, the Royal Botanic Gardens at Kew in Surrey continue to flourish. Today (13 May) the Queen will re-open the Temperate House after a 5-year renovation programme costing £1.6 million. Building of this vast glasshouse, designed by Decimus Burton for the 3,000 different types of plant from the warm, temperate regions of the world, began in 1860.

The Royal Botanical Gardens may themselves soon undergo a historic restructuring. Since 1903, the institution has been part of the UK Ministry of Agriculture, Fisheries and Food (MAFF) but now talks are being held between officials from the ministry and Kew Gardens to transfer management to a body of trustees. Organizations with an interest in the gardens have been asked to submit their views by 21 May.

The change to trustee status would be largely managerial — the gardens would continue to be sponsored by MAFF. But this arrangement would permit a degree of adminstrative autonomy the lack of which has irritated past directors of Kew. The new board of trustees, many of whom would be scientists, would take decisions on the direction and development of policy. In April, Mr Peter Walker, Minister of Agriculture, Fisheries and Food, told the House of Commons that the present arrangements "are not ideally suited to the management of an institution which combines the functions of curation, research, advice and instruction and public amenity". At present the director, Professor Arthur Bell, is advised by a 12-strong Scientific Advisory Committee drawn mainly from university botany departments. Members of the Forestry Commission and the National Trust sit on a consultative panel at Wakehurst Place, the satellite garden in Sussex.

Kew Gardens have not experienced cuts as such but staff has been reduced through natural wastage from 480 in 1979 to the present level of 440 — a rate which compares with cutbacks at the ministry itself. Total running costs are £6 million, of which £3 million is accounted for by salaries.

Like London Zoo, Kew is a blend of scientific institution and tourist attraction. With an entrance fee of only 10 pence, and over 1 million visitors a year, however, the gardens could not survive without exchequer support. Some 3,100 genera of 340 families are represented in the living collections at Kew, and there are 5 million dried specimens in the herbarium. The physiology section at Wakehurst Place now incorporates a seed bank. But the aesthetic way of displaying plants of scientific and economic interest may obscure the extensive scientific work that the institution performs. **Jane Wynn**

0028-0836/82/190097-02$01.00

CORRESPONDENCE

The Johns Hopkins and India

SIR — In the news section of your 11 March issue, K. S. Jayaraman from New Delhi makes several serious and erroneous allegations regarding the Johns Hopkins University and its participation in research projects in India. I believe it to be important that the record be corrected.

For many years, scientists from the Johns Hopkins University collaborated with Indian colleges in two major projects. One was the pioneering research conducted from 1961 to 1974 at the Narangwal Rural Health Research Centre in the Punjab. The purpose was to design and evaluate practical approaches for the delivery of primary health care. A series of projects under the Indian Council of Medical Research involved a large group of Indian scientists and a few foreign scientists under the direction of Professor Carl Taylor. These studies served as a prototype for other similar health services research subsequently conducted in many countries throughout the world. Professor Taylor, a member of the Institute of Medicine of the National Academy of Sciences and a frequent consultant to the World Health Organization, the World Bank and many other national and international organizations, is universally recognized as an authority in the complex problems of primary health care delivery. He was born in India and has spent half of his life living and working in the villages of the subcontinent. Contrary to Mr Jayaraman's report, the Indian government has officially confirmed that he has never been expelled from India nor has he been forbidden to come to India or any other country in a professional capacity. His visits to India since the Narangwal Project closed have been in response to official invitations. The allegation that the purpose of the Narangwal study was to provide a base for spying on the Halwara airbase is wholly false, indeed preposterous.

The second project, based at several national institutes in Calcutta, was under the direction of the late Professor Frederik Bang. It was one of a group of International Centers for Medical Research and Training which were funded by the National Institutes of Health. With Indian scientific colleagues, a large number of important investigations were conducted dealing with infectious diseases and nutrition. Indeed, many of the fundamental studies which have led to the now universally used methods for treatment of cholera and other severe diarrhoeas with oral fluid therapy were made by the Calcutta group. This laboratory and its scientific staff had no connection whatsoever with the Fort Detrick biological warfare laboratory. There was also no link with the US Navy except for informal, collegial scientific exchanges with the Naval Medical Research Unit, then based in Taipei, which was similarly actively engaged in endeavouring to find more effective and practical methods for the treatment of cholera.

Since its founding in 1916, the Johns Hopkins School of Hygiene and Public Health has been deeply involved in education and research in international health problems in Baltimore and in many countries throughout the world. It continues today as one of the largest institutions so concerned with international health. Its numerous alumni hold eminent positions in national and international organizations around the world. The false aspersions cast on the the institution by Mr Jayaraman are deeply resented.

Ban the billion

SIR — A.J. Southward (*Nature* **294**, 215; 1981) writes: ". . . estimated six billion tons of oil that reaches the sea each year". as he comes from Plymouth, Devon, we have a right to expect that "billion" means 10^{12}: but in context that is surely impossible. We are therefore left to wonder whether he writes in American from an English address. Unfortunately, even "6×10^9 tons" of oil per year flowing into the sea sounds fantastic, given that the world's production of crude oil is about 3×10^9 tons per year. Does that mean that most of the amount talked about is natural seepage? The rest of the article makes that sound implausible. We are left with the uncomfortable feeling that, as the author has introduced one uncertainty of a factor of 1,000, he may just have got the figure wrong.

The confusion is worse confounded by the difficulty of distinguishing spoken "m" and "b", especially on the telephone. As a result, "million" and "billion" are frequently confused, particularly in newspapers. The uncertainty is thus increased to 10^6.

Sir, could I prevail upon you simply to ban the word "billion" from *Nature*? It seems to me unnecessary; given the enormous uncertainty, it would be much better simply replaced by "10^9" or "thousand million".

EDWARD EISNER

Department of Applied Physics, University of Strathclyde, Glasgow, UK

A. J. SOUTHWARD REPLIES — *Mea culpe:* Professor Eisner is quite entitled to his little bit of fun. The word should have been million — 6 million tons of oil per annum into the sea. I agree that the word billion needs replacing.

PhD applications

SIR — The leading article in *Nature* of 15 April (p.592) implies that "promising people from less favoured universities" find it hard to enter PhD courses because the quota system of awards puts graduate student selection into the hands of the luckier university departments.

I expect that supervisors usually want to choose the most productive and biddable graduate students quite independently of their college of origin. If this is so, the main barrier to students moving to a new institution for their graduate studies must be inadequacy of information about projects and places available elsewhere.

For several years this department (which has always had a strict policy of not allowing its own honours students to continue as PhD students here), has organized a scheme for exchanging this information amongst about 80 UK life science departments — mainly in biochemistry, molecular biology, microbiology and cell biology. The scheme also promotes a common application form and loosely coordinated timetable for selection.

This year, for the first time, we have published the *Compendium of Research Topic Outlines*, which forms part of the scheme, as a single volume of over 400 pages, with name and subject indexes. The first indications are that this has proved very useful to students in finding out where they can carry out the kind of research of most interest to them. In the future, the availability of this compendium to libraries and career advisers should make the system of greater use to students in non-participating departments.

I shall be glad to answer enquiries from anyone who thinks that the compendium, or the scheme as a whole, could be useful to their students.

I think that many of the participating departments now find the scheme indispensable, as we do. For this reason I have never understood why physical chemical and social science departments do not cooperate in a similar way.

Man mismeasured

SIR — Scientifically I am certainly no supporter of the main thesis of Stephen Jay Gould concerning punctuated equilibrium. Thus I might be expected to be in favour of (or at least to watch passively) virtually anything that helps to reduce Gould's immense influence and effectiveness, especially if prepared by an outsider to the evolutionary arguments. But in truth, I found the personal attack on Gould by your reviewer of *The Mismeasure of Man* (*Nature* 8 April, p.506) positively nasty, unprofessional, with but slight reference to substantive issues (and then often granting Gould's correctness), and just plain ugly. Who is Mr Blinkhorn to tell us that the book has "the routine flavour of Radio Moscow news broadcasts", as though in and of itself even if it were true (which is not in any way documented), it should damn the book for ever. My reaction is that if Blinkhorn is correct, more of us should join him in listening to those radio waves. Blinkhorn ends by admiring Gould's skill in presentation, and adding "but what a waste of talent". For his part, Blinkhorn has shown us a remarkable lack of skill, unfortunately presumably making full use of *his* talent.

NEWS AND VIEWS

Evolution of bowerbirds' bowers: animal origins of the aesthetic sense

from Jared M. Diamond

IN September 1872 the explorer Odoardo Beccari became the first European to ascend the Vogelkop mountains of New Guinea and to observe there the Arfak tribesmen in their villages. Among the many sights that impressed Beccari were the beautifully decorated little huts scattered in the forest. Each hut was in the form of a cone up to eight feet long and four and a half feet high, so tightly woven of sticks as to be rain-proof. In front of each hut was a little garden, consisting of a mossy lawn decorated with over a hundred red, blue, brown, black, yellow and green objects carefully grouped by colour. The objects that Beccari saw were natural and collected from the forest: fruits, flowers, mushrooms and beetle skeletons. The displayed flowers were fresh and were removed and replaced as they faded. A century later, when Europeans had become regular visitors to the Vogelkop, the decorations included coloured man-made objects, such as shotgun cartridges and yellow cardboard Kodak film cartons.

Was this a quaint native custom of the sort that draws anthropologists to New Guinea? Not at all. What caused a sensation when Beccari[1,2] published his account of these huts was that they were constructed, decorated and used by a bird, the Vogelkop Gardener Bowerbird.

The eighteen species of bowerbirds (family Ptilonorthynchidae) of which fourteen others besides the Vogelkop Gardener build bowers, are confined to New Guinea and Australia[3-5]. Bower structures vary with the species and include, besides the hut of the Vogelkop species, stick towers up to eight feet high, walled avenues, fern mats and moss platforms with parapets. Almost all bowers are decorated with coloured objects such as fruits, flowers, shells and bones, the colour preference varying with the species and with the individual bird. More diverse decorative objects appear in bowers near human habitation, and have included car keys, bottletops, tooth brushes, clothespins, false teeth and spectacles. At least six species use a tool to paint the bower yellow, green, blue, brown, or black with crushed fruit or charcoal, and at least four species orient the bower in a constant compass direction. Bowers are built by adult males and used as the site for wooing and inseminating females, which then fly off and do all the work of building a nest and rearing the young.

Understanding of the function and evolution of the bowers has come slowly, because the areas of New Guinea and Australia where many of the species live are remote and difficult of access. Indeed, the home grounds of a New Guinea species (*Amblyornis flavifrons*), known only from three skins sold to Lord Rothschild by a plume merchant in 1895, remained undiscovered until 1981 (see *Science* 23 April 1982), and the bowers of two other New Guinea populations (*Sericulus bakeri* and *Archboldia p. papuensis*) are still unknown. Two recent papers by Reta Vellenga[6,7] of Castle Hill, Australia, in conjuction with an earlier paper[8], provide the most detailed life history information yet available for a bowerbird.

Vellenga studied the Satin Bowerbird (*Ptilonorhynchus violaceus*) of south-east Australia, following on earlier work by Marshall[3], Chaffer[9] and Green[10]. The bird is about twelve inches long, the adult male glossy bluish-purple, the female and young male green. The bower is a woven platform about 10 feet square, supporting an avenue of woven sticks, with walls a foot high nearly joining in an arch over a floor, and decorated with blue or green natural or man-made objects. Perishable decorations such as flowers are replaced daily. Some bowers are left unpainted, but others are painted daily either blue, black, or green by the male, using a wad of bark as a paint brush and using crushed fruit, charcoal, or (nowadays near civilization) stolen blue laundry powder as paint. The long axis of the bower is generally within 30 degrees of north–south, possibly so that the male and female can face each other during early morning displays without either having to stare into the rising sun. When Marshall picked up a bower and reoriented it, its architect promptly demolished it and rebuilt it in the correct orientation. Between 1965 and 1971 Vellenga banded 940 bowerbirds in her backyard and followed the individual lives of many of them.

Extremely elaborate maypole bower built by a completely unornamented male bowerbird, *Amblyornis inornatus* (mountains of New Guinea's Vogelkop Peninsula). The male lacks a crest. The bower is a hut of interwoven sticks built about one or more saplings, with a lawn in front decorated by over 100 objects of up to seven different colours.

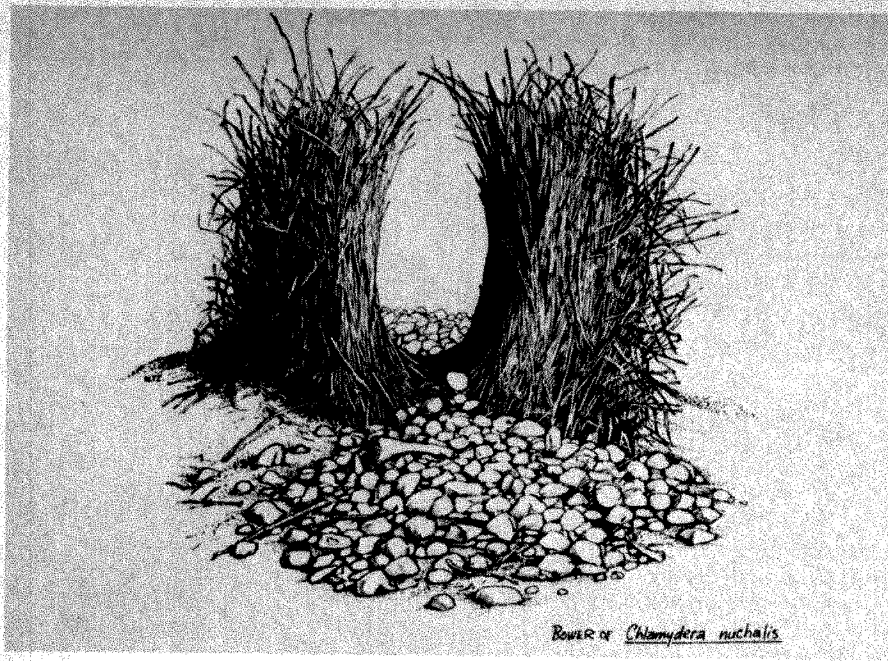
0028-0836/82/190099-04$01.00



Example of an avenue bower, built by the bowerbird *Chlamydera nuchalis* (Australia). An avenue is constructed of a floor and two painted walls of sticks and decorated with many stones and bones. Mating takes place in the avenue.

According to Darwin's theory of sexual selection, intraspecific competition for mates may select for ornaments or behaviours unique to one sex through either of two mechanisms: the value of the ornaments in attracting the opposite sex or in dominating rivals of the same sex. Bowers have traditionally been interpreted in the former sense, as love parlours where males seduce females. Vellenga's observations provide ample evidence for this function. The bower-owning male Satin Bowerbird continually tries to entice females into his bower by picking up in his bill an object such as a flower or snail shell, and posturing, dancing and displaying to the female. Rarely, the female is persuaded to enter the bower and copulation ensues. Far more frequently, the female flees without mating.

Why do courting males have such a low success rate? Perhaps females scrutinize various males and bowers before choosing. Many courtships are interrupted at a crucial stage by the intrusion of other individuals. However, another reason for the low success rate may be the invariant sequel to successful mating: the male bowerbird savagely attacks the female, pecks and claws her, and chases her from the bower. Mating itself is so violent that often the bower is partly wrecked, and the exhausted female can scarcely crawl away. The courtship display can appear little different from the male's aggressive display. When a courted female is won over and starts to solicit copulation, the male often changes his mind and chases her away. Thus, a female may have to make many visits to a bower before she overcomes her fear of the aggressive male. After mating, the female constructs a nest at least 200 yards from the bower and bears sole responsibility for feeding the young. Once the young leave the nest, the young of several females are tended by their mothers in a common nursery area. After the first year, bowerbirds outside the breeding season form separate flocks according to age and sex (females, young males and old males separate). Adult males that leave for the winter apparently dismantle their bowers first.

While Vellenga's studies confirm the traditional view of bowers as love parlours, they provide strong support for a simultaneous role of bowers in male–male interactions. Specifically, bowers, like flags of possession, may serve as symbols of males' property rights in their wars with other males. An adult male spends much time repairing his own bower, protecting it from raids by rivals, and attempting to steal ornaments or destroy rivals' bowers. bowers.

The battles and territorial shifts that Vellenga recorded among her 426 banded adult males make the European Thirty Years' War seem straighforward by comparison. When about 5 years old, male no. 85 won ownership of Vellenga's garden and maintained his bower there against intruders for 15 years. On 15 November 1967 he became ill, and other males demolished his bower, but by 28 November he had recovered and rebuilt the bower. Finally, on the morning of 26 October 1970 he became ill again and disappeared around 10 a.m. By 1:50 p.m. on that day his bower had been destroyed and two other males were in the vicinity. By 3 p.m. male no. 345, who had owned a bower 1.25 km to the west since at least April 1970, was in possession of Vellenga's garden and began constructing a new bower around 4 p.m. Male no. 345 retained Vellenga's garden through constant fighting until defeated on 3 January 1971 by male no. 460, who had until then owned a bower 7 km distant. Male no. 345 thereupon returned to his old bower, expelled a male who had taken it over and was still there when visited three years later, while male 460 still owns Vellenga's garden at latest report. In the meantime male no. 553 took over the bower of male no. 320,0.75 km south-west of male 345, while male no. 429 seized a bower 1 km to the south-east, and male no. 124. . .

What is the significance of all these details of bowerbird military history? As with other bird species, male bowerbirds vary in dominance, and the south-east Australian landscape varies in production of food resources consumed by bowerbirds. Superior locations such as Vellenga's garden are know to have supported active bowers for at least 30 years, though with a sequence of owners. Young males search for good sites to built a bower, and males that already own bowers spend some time searching for better sites. Thus, the old male 85 had long been dominant in Vellenga's neighborhood, and on his disappearance local dominance did not pass to a male at some different site but continued with the new owner of male 85's estate.

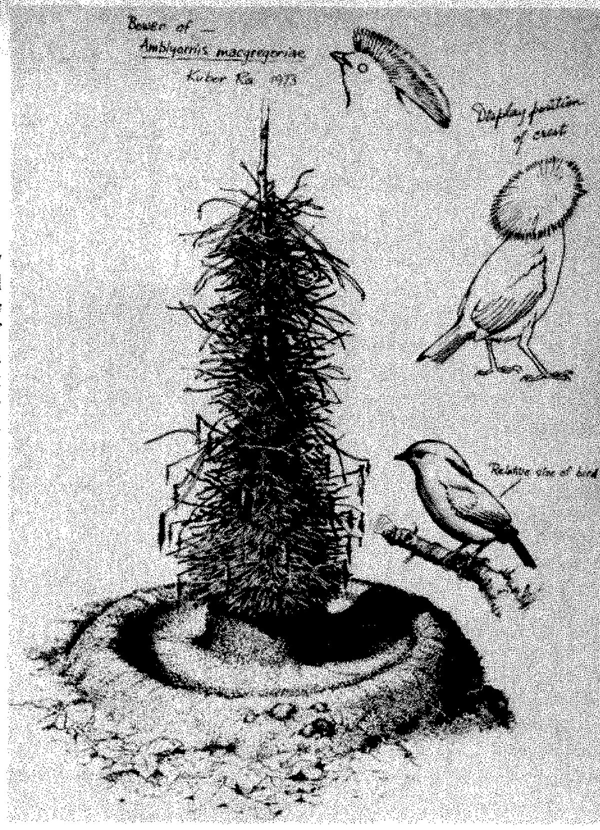
Dominant males directly prevent other males from wooing females by the destruction of their bowers. Young males continually try to erect rudimentary bowers in the territory of an adult male but the latter patrols his property several times a day and wrecks them. When Marshall placed 100 pieces of numbered blue glass into these rudimentary bowers one night, he found 76 of the pieces transferred to the bowers of dominant adult males by noon of the next day. Similarly, Vellenga observed a blue celluloid band to be transfered between bowers several times a day, until one male firmly wove it into his bower.

Dominant males may perhaps even affect their rival's chances through hormonal effects related to dominance and subordinance. The successful male bowerbird needs not only a bower but also blue plumage. Young male bowerbirds have green plumage resembling adult females and only begin to acquire the blue plumage of the adult male in their fifth year. In many animals the acquisition of adult sex-specific colour pattern is controlled by sex hormones, and domination of a male by rivals inhibits production of male sex hormones — it is possible that the acquisition of blue adult plumage by male Satin Bowerbirds is retarded in individuals that are continually harassed and see their bower-building attempts frustrated by dominant males.

How has the evolution of bowers taken place? Gilliard[4,13] argued that the female's attention during the male's courtship display has become 'transferred' from

male ornamental plumage to the bower and its decorations. The transfer is an advantage for the male bowerbird because it enables him to dispense with bright plumage that may attract predators. One line of evidence for this interpretation comes from comparison of courtship displays in the four species of the avenue-builder genus *Chlamydera*. In two species, *C. nuchalis* and *C. maculata*, the male has a lilac crest, which he erects and displays to the female by facing her while twisting his head to the side. In the crestless *C. cerviniventris*, the displaying male still twists his head as if to show the female a crest that his ancestors lost! But the male *C. cerviniventris* compensates by holding a spring of green berries in his bill during the display.

A second line of evidence for the 'transfer theory' is the inverse relationship, among bowerbird species, between elaborateness of male plumage and elaborateness of the bower and its ornaments. For example, among the five species of maypole builders, the male of *Amblyornis macgregoriae* has an erectile orange crest three inches long, builds a simple maypole four feet high and scarcely decorates it; male *A. flavifrons* has a gold crest of the same length, builds a similar maypole and decorates it only with three small piles of fruit of three different colours; male *A. subalaries* has an orange crest only 1.5 inches long but builds a dome over his maypole and decorates it with flowers, fruit, beetles and leaves of at least five different colours; male *Prionodura newtoniana* has a very short yellow crest but builds and decorates two maypoles up to eight feet high and joined by a bridge; and male *Amblyornis inornatus* is entirely crestless like the female but builds the elaborate bower described in the first paragraph of this article. A similar correlation exists among the eight species of avenue builders: from *Sericulus aureus* and *S. chrysocephalus*, of which adult males have golden and black plumage, decorate a two-walled bower only sparsely, and perhaps dispense entirely with a bower on occasion; to *Ptilonorhynchus violaceus* studied by Vellenga, with uniform blue male plumage and a painted two-walled bower with many ornaments; and culminating in *Chlamydera lauterbachi*, in which male and female are similarly dull but the male builds a decorated four-walled bower reinforced with up to 10 lb of stones.



Simple maypole bower built by an elaborately ornamented male bowerbird, *Amblyornis macgregoriae* (mountains of New Guinea). The male has a striking, erectile orange crest three inches long. A circular moss platform with a rim is constructed about the base of a sapling, about which sticks are criss-crossed to form a tower. The bower has few or no decorations.

The construction of bowers out of sticks and moss may have its origins in nest construction. Males of many bird species court females and induce them to ovulate by constructing true nests and offering food. It is possible that bowers began as courtship nests that became free of size constraints as the function of egg incubation was transferred to a separate nest built by the female alone. Decoration of bowers with coloured objects may have stemmed from courtship feeding, since displaying males of at least six species of avenue builder, one maypole builder, and the mat builder *Archbodia papuensis sanfordi* pick up a decorative object in the bill and extend it towards the female. In some cases this decorative object is an edible fruit, although female bowerbirds have never been reported to take and eat the fruit. If courtship feeding was indeed the original meaning of this gesture, the meaning has been lost in the many cases where the display fruit has been replaced by an inedible object, such as a stone, shell, or human artefact like a cloth or marble.

Eight other species build bowers which could less easily have had their origins in nest construction and courtship feeding. The bowerbird *Scenopoeetes dentirostris* rakes an area of ground clean and decorates it with dozens of leaves carefully turned upside-down; the four birds of paradise (family Paradisaeidae, not Ptilonorhynchidae) of the genus *Parotia* rake an area of ground clean without decorating it; and the two birds of paradise of genus *Diphyllodes* rake an area of ground clean and strip the leaves off the trees over this area.

Does bower building imply that bowerbirds are intelligent and have an aesthetic sense? It certainly seems true, as Vellerga concludes, that many skills related to bower building and use have to be learned. Young males in green plumage spend about two years building rudimentary but increasingly complex bowers before acquiring blue adult plumage and building complete bowers. These 'practice bowers' are the joint efforts of several young males, which take turns placing and rearranging sticks, often clumsily and without success, occasionally with the cooperation of more skilled older males. The young males do not paint these bowers and are less discriminating than adult males in choice of colour for bower decorations. The young males spend much time watching the displays, mating and other bower activities of adult males, and are displayed to by adult males.

As for aesthetic sense, colour preference in decorative objects varies with species and with individual, sometimes in a way that can be related to the bird's own colour. Adult males of *Ptilonorhynchus violaceus* prefer blue fruits, flowers, parrot feathers and man-made objects (see photograph on p.867 of ref. 10, depicting nine man-made objects recovered from bowers, all of them blue: a tooth-brush, toy airplane, pen, pencil-sharpener, clothes-pin, marble, shotgun cartridge, button and bottle-top). Blue is also the eye colour in both sexes, and is the colour of the adult male's plumage and bill. *Chlamydera caculata* lives in dry country, has brown plumage and eyes, selects pale ornaments and paints the bower brown. *Amblyornis flavifrons* displays with a blue fruit that affords maximum contrast with its golden crest, and consistently decorates the bower with fruits of three colours: the same blue fruit, green fruit that is the unripe form of the blue fruit, and a yellow fig similar to the colour of the abdomen and male crest. *Amblyornis inornatus* males vary individually: one used ornaments of seven different colours, another preferred brown and black, another favoured red and one specialized in white. The function of bower painting is mysterious, but a possible clue is that Vellenga twice observed a young male visiting a bower in the absence of its owner

and painting the walls with saliva, whereupon the owner returned, expelled the intruder and repainted the walls with green liverwort. Perhaps painting not only has an 'aesthetic' purpose but also provides an olfactory and visual mark of individual ownership, like the marking by urine or anal scent glands in many mammals.

Even if antecedents can be suggested for bower construction, decoration and painting, why have these display activities evolved to such an extreme degree in bowerbirds but in no other birds? One prerequisite is ample leisure time. Male bowerbirds spend most of their time repairing the bower, fighting rivals, raiding rivals' bowers and wooing females. Bowerbirds are among the largest frugivorous songbirds of Australia and New Guinea and are aggressive and dominant over other species because of their size. They may thus have preferential access to trees with concentrated fruit crops of high nutritional quality, enabling them to satisfy food needs in a short time and to devote remaining time to bower activities (see ref. 14). Other large tropical frugivores devote their leisure time to other bizarre social activities, such as the arboreal displays of most birds of paradise and the 'bowers' of the bird-of-paradise genera *Diphyllodes* and *Parotia* and the cotingid *Rupicola rupicola* (Cock-of-the-Rock).

It is apparent that major facets of bowerbird behaviour await further study. Gilliard argued that bowerbirds are lek species (ones with concentrated display grounds); this appears true for *Archboldia papuensis sanfordi* (known population confined to small areas on two New Guinea mountains), untrue for *Amblyornis flavifrons* (bowers spaced one-quarter of a mile apart) and unclear for other species. It is unknown whether simple, erratic, or nonexistent bower construction in the genera *Sericulus, Ailuroedus* and *Scenopoeetes* is a primitive condition or an advanced one: are these genera acquiring or losing the bower-building habit? Have bowerbirds co-evolved with certain tree species on whose fruit they specialize, as seems true for birds of paradise? Vellenga's work only begins to give tantalizing cues to the origin of colour preference, the origin of painting and the relative roles of instinct and learning in bower construction. To many ornithologists, bowerbirds remain the most intriguingly human of birds. □

The missing mass — now it's a gravitino!

from Joseph Silk

COSMOLOGISTS have a dire secret. They have not the slightest clue to the nature of the dominant mass constituent of the Universe — only the inherent implausibility of the idea prevents them from postulating the existence of innumerable copies of *Nature* floating in space. Preference has alternated for many years between two candidates: black holes and degenerate black dwarfs of the substellar variety. The mass density in the invisible form must exceed that in luminous material by one to two orders of magnitude.

The amounts of matter and luminosity in a given region are commonly measured in units relative to the mass and luminosity of the Sun. One finds a mass–luminosity ratio of about 2 in the solar vicinity; this means that the matter around us consists of stars typically of somewhat lower mass (luminosity being very sensitive to mass) than the Sun. In a great cluster of galaxies such as Coma, the ratio is about 300 (if one specifies that blue light is measured and that the Hubble constant is 50 km s^{-1} Mpc^{-1}). Part of this difference can be understood in terms of the type of stars present in the cluster. Most of the cluster galaxies are ellipticals, which lack the young, hot, blue stars that contribute little to the mass of a galaxy such as ours but dominate its light. Thus, the mass–luminosity ratio of the underlying old disk and bulge populations of stars near the Sun that are most comparable with stars in ellipticals is about 6. Indeed, this is confirmed by measurements of the velocities of luminous K giants at a height of 1 kpc or more above the disk, which directly sample the local gravitational field. It follows that the total stellar content of the Coma cluster of galaxies amounts to only about 6/300 or 2 per cent of its dynamical mass.

Further, a substantial fraction (about 10 per cent) of the mass of the Coma Cluster has been discovered to be in the form of hot, X-ray-emitting gas. Thus, the total content of the Coma cluster that is in luminous form is only 12 per cent of its total mass. The remaining 88 per cent of the mass of Coma is invisible, at least hitherto, and its nature is a continuing source of speculation. A similar fraction of non-luminous matter appears to be present in the spiral-dominated groups of galaxies (although data on the intergalactic gas content of groups are very incomplete). These measurements both refer to scales of one or two million light years.

On smaller scales, galaxy rotation curves sample the distribution of dark matter in the outer parts of the galaxies. The predominance of flat rotation curves out to several times the optical radius of the galaxy indicates that the mass-to-light ratio is rising with increasing scale. The group and cluster data suggest that the invisible mass fraction of the Universe continues to rise at least up to scales of millions of light years. Whether there is still more dark matter unclustered on larger scales is unknown. One can say that for the Universe to be of critical density, corresponding to closure, the required amount of dark matter has a mass–blue luminosity ratio of about 1,000. Measurements of the redshift–magnitude (or velocity–distance) relation for distant galaxies suggest that the mean density of the cosmos cannot much exceed this critical value. This ratio is only a factor of 3 larger than the Coma cluster value.

Does this signify that the Universe is near its closure density? Almost certainly not, since rich clusters are rather rare objects. Far more typical is the sparse group which has a characteristic mass–blue luminosity ratio of about 50. The large values of mass to luminosity in clusters are due in part to the older (and dimmer) star populations, and in part to the fact that a substantial amount of matter that would perhaps have formed spiral disks is in the intergalactic medium. The phenomenon that is responsible for the dark matter is a universal one. Even studies of galaxy haloes where little light is seen indicate that the ratio of mass to luminosity must locally be extremely large, amounting to several hundred or more. The evidence that exceedingly dark matter dominates the mean mass density of the Universe seems overwhelming. Such matter exists in galaxy clusters and groups, in the haloes of galaxies, and even in the solar vincinity, where, however, the principal contributor to the density is the old star population.

Particle physicists have joined the quest for dark matter in the cosmos. Experimental indications (still unconfirmed) of a finite rest mass for the neutrino have led to a new candidate for the dark matter. The big bang theory predicts that the number density of neutrinos at present should be comparable with the number of photons, both being relics of the primordial fireball that described the early evolution of the Universe. If the neutrino has a rest mass of 1 eV (or one-millionth of an electron mass), it would presently dominate the mass density of the Universe. With a neutrino rest mass as large as 100 eV, the Universe could even be of closure density. The existence of a massive neutrino has notable implications for the large-scale structure of the Universe. Neutrinos are collisionless particles and cannot sustain density fluctuations. As a consequence, all small-scale structure in the Universe would be suppressed, until

Joseph Silk is Professor of Astronomy at the University of California, Berkeley, California 94720.

0028-0836/82/190102-02$01.00

very late times. This supports a theory of galaxy formation in which the galaxies arise from the fragmentation of large structures that have collapsed anisotropically into pancake-like sheets. Such anisotropies arise naturally in collapse when small-scale structure is suppressed, and lead to the formation of great voids between the clusters and superclusters of galaxies that develop in the high-density regions. One question that remains unanswered in such a theory concerns how the scale of a typical luminous galaxy is determined.

Now a new particle, the gravitino, has emerged from the creative minds of two particle theorists as a new candidate for the dark matter (H. Pagels and J. Primack *Phys. Rev. Lett.* **48**, 223;1982). The gravitino is a child of supersymmetry, associated with the search for a theory that unifies gravity along with the strong, weak and electromagnetic interactions. Supersymmetry unites fermions and bosons on a similar basis, and may help explain relations between certain large mass ratios involving the Planck mass, the mass associated with the grand unified theory symmetry breaking, and the mass associated with the electromagnetic-weak force symmetry breaking. Super-symmetry breaks down below energies of about 100 GeV, and results in the production of long-lived fermion partners of the graviton and the photon, the mediators of the only long-range forces. The new particles are called gravitinos and photinos, and both may have finite rest masses. The number of photinos is comparable with the number of neutrinos, and the implications of a finite photino mass are indistinguishable from those of a neutrino rest mass.

However, the gravitino uncouples sufficiently early that the predicted number of gravitinos is only about 10 per cent of the cosmic neutrino flux. Subsequent decouplings of other particles produce the bulk of the neutrinos. This leads to an interesting consequence: if gravitinos are of sufficient mass to account for the dark matter in the Universe, the gravitino rest mass must be some 10 times greater than the neutrino rest mass, or as large as 1,000 eV if gravitinos are at closure density. As the Universe expands, the more massive gravitinos become non-relativistic at an earlier epoch than do the neutrinos. The horizon scale at this instant provides a measure of the minimum primordial fluctuation scale that can survive the free streaming of particles at the speed of light. For neutrinos of mass 30 eV, the perturbation amplitude peaks at 4×10^{15} $M_{\odot}$, whereas for 1 keV gravitinos the perturbation spectrum peaks at about 10^{12} $M_{\odot}$. This is just the mass-scale associated with the dark haloes of galaxies. If we take the coincidence seriously, then gravitinos of mass 1 keV are the dominant source of matter in the Universe, and may account for the characteristic scale of galaxies.

Indeed, it turns out, according to unpublished calculations by J. R. Bond, A. S. Szalay and M. S. Turner, that gravitinos may lead to the best of all possible scenarios for large-scale evolution. For their mass spectrum extends all the way from scales of supercluster mass down to scales comparable to that of dwarf galaxies. Unlike the neutrinos, gravitinos do not dominate the mass density of the Universe until long after they have become non-relativistic, and this enhances the growth of large-scale gravitino perturbations relative to smaller-scale perturbations, whose growth is inhibited by the inertia of the radiation-dominated mass content of the Universe.

Dark matter may therefore consist of massive neutrinos or gravitinos, or perhaps some more exotic species of elementary particle whose presence arises from unification theories that describe the first 10^{-36} second of the Universe. Such cosminos are the bane of the astronomer's life, for they are likely to be forever invisible, yet they provide a potential solution to some of his greatest problems.

The regulation of contraction in cardiac muscle

from D.A. Eisner and D.G. Allen

One hundred years ago Sydney Ringer, a physician working at University College London, discovered that calcium is required for the heart to contract. Only in the past twenty years, however, have the intracellular mechanisms responsible for this calcium dependence become clear and the central role of intracellular calcium in the control of cellular processes become widely appreciated. In the past five years our understanding of the regulation of cardiac contraction has taken a leap forward with the introduction of techniques for measuring the crucial intracellular ion activities (Ca^{2+}, Na^+, H^+, K^+ and Cl^-) and the development of biochemical methods for assessing the regulation of protein function. The field of cardiac electrophysiology also seems poised for a period of rapid growth with the recent introduction of single cell and patch clamping techniques. Each of these fields was represented at a recent meeting* at University College London which concentrated on two aspects of the regulation of cardiac contraction. The first was that of how the low resting level of calcium is maintained and how the increase of intracellular calcium required for contraction is produced. The second concerned mechanisms other than changes of calcium concentration which may be involved in the regulation of cardiac contraction.

The role of Na^+/Ca^{2+} exchange in the regulation of intracellular calcium dominated the first half of the meeting. L.J. Mullins (University of Baltimore) suggested that the intracellular calcium concentration is controlled by a voltage-dependent Na^+/Ca^{2+} exchange which, at rest, pumps calcium ions out of the cell in exchange for sodium ions that enter by flowing down their electrochemical gradient. A novel aspect of his model is that it attributes much of the calcium entry during the long cardiac action potential to this mechanism. It was suggested, by analogy with experiments on squid axons, that depolarization makes the Na^+/Ca^{2+} exchange bring Ca^{2+} into the cell and extrude Na^+. In contrast, H. Reuter (University of Berne) stressed the importance of conventional Ca^{2+} channels in providing the influx of calcium ions during the action potential. Recent recordings from single channels have removed lingering doubts about the existence of the calcium channel in the heart. It is clear that quantitative measurements are now required to establish the relative contributions of Ca^{2+} channels and Na^+/Ca^{2+} exchange to the rise of Ca^{2+} which produces contraction.

Papers given by D. Eisner (University College London) and by D. Ellis (University of Edinburgh) were concerned with altering the magnitude of Na^+/Ca^{2+} exchange and examining the effects of contraction. It is clear that small changes of internal sodium concentration have enormous effects on contraction. These effects depend on the membrane potential and the external sodium concentration in a way which is, at least, consistent with the predictions of a voltage-dependent Na^+/Ca^{2+} exchange model. However, it was also shown that changes of internal and external sodium concentrations have pronounced effects on intracellular *p*H and these may also affect contraction.

Evidence that the contractility of cardiac muscle can be regulated by mechanisms other than changes in the calcium levels was also presented. Direct evidence was presented by D. Allen (University College London) who, using the bioluminescent protein aequorin as a calcium indicator, showed that as well as increasing the cytoplasmic calcium concentration during contraction, adrenaline reduces the sensitivity

*The Physiological Society Symposium on 'The Regulation of Contraction in Cardiac Muscle' was held on 25-26 March 1982.

D.A. Eisner and D.G. Allen are in the Department of Physiology, University College London, Gower Street, London WC1E 6BT.

of the contractile proteins to calcium. In an examination of the biochemical basis of this phenomenon, P. England (University of Bristol) showed that the application of adrenaline results in a protein kinase-dependent phosphorylation of troponin and other proteins. The phosphorylation allows the troponin to speed up its release of bound calcium and may help heart muscle to relax more quickly — of obvious importance for the high heart beat rates produced by adrenaline. Other proteins which become phosphorylated in the presence of adrenaline include a component of the sarcoplasmic reticulum calcium pump and a surface membrane protein. These phosphorylations may therefore affect movements of calcium between the cytoplasm and the sarcoplasmic reticulum and between the cytoplasm and the extracellular space. It was suggested by F. Flitney (University of St Andrews) that some of these phosphorylations could be controlled by the relative levels of cyclic AMP and cyclic GMP.

A major difficulty inherent in studies of the regulation of contraction is that the intracellular calcium concentration cannot be controlled when the studies are performed on intact cells. Unfortunately, biochemical studies suffer from the disadvantage that cell constituents involved in the regulation of contraction may be lost. To circumvent this problem, S. Winegrad (University of Philadelphia) has attempted to make cells which are 'hyperpermeable' to calcium ions but which retain larger substances within the cell. Using this technique he produced evidence for the control of the calcium sensitivity of contractile proteins by phosphorylation of troponin. This approach came under attack from D. Miller (University of Glasgow) who suggested that such cells are not really permeable to calcium ions. It appears that this problem must be resolved before the results can be unequivocally interpreted. Winegrad also described recent experiments which suggest that a proportion of the myosin molecules are normally inactivated but can be activated by a cyclic AMP-dependent process. If confirmed, this raises the prospect of an additional mechanism whereby force production in cardiac muscle can be varied. □

Recent developments in optical storage technology

from Alan E. Bell

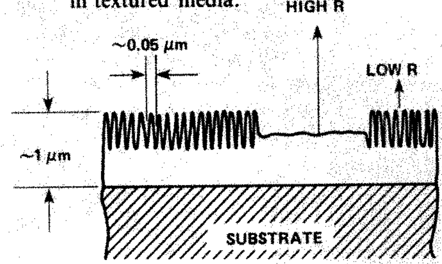
RESEARCH and development in the field of high-density optical data storage media and devices continue to move forward at a brisk pace — in the eighteen months since last reviewed in these columns[1], several companies have committed themselves to development efforts and the introduction of commercial optical disk computer memories can be expected in the next few years. Such devices will offer rapid random access (∼200 ms) to a database of up to 10 gigabytes per disk at a cost of 10^{-6} cents per byte or less and seem likely to leap-frog the projected improvements in the currently ubiquitous magnetic data storage media. The impact in many areas of electronic data processing, ranging from the 'electronic office' to large data-base archives and even to small business and personal computer systems, will be profound[2].

The two most critical components of the optical memory system are the diode laser read/write light source and the optical storage medium itself. The diode laser source is much preferred to the alternative gas laser sources, mainly because of the small size and power requirement, the capability for direct modulation of the optical record beam by the input data signal and the potentially high reliability and lifetime. Recent advances in the design and fabrication[3-8] of high-power (>40 mW output at 10 MHz modulation) diode lasers have made them available as commercial products, albeit at an initially high cost. With manufacturing scale-up and improved process yields, the cost should rapidly decrease to less than $100 (ref.9).

The 'ideal' optical storage medium has yet to be found and the past year has seen reports of many new recording media and configurations. Several new write-once (that is, irreversible) recording mechanisms have been identified and significant gains in the optimization of reusable (that is, reversible) media have been made.

Workers at Bell Telephone Laboratories (BTL) have reported the recording characteristics of irreversible media, microscopically textured low-reflectivity films of vacuum-deposited semiconductors[10]. The textured surface layer (see Fig. 1) is formed

Fig. 1 Recording mechanisms in textured media.



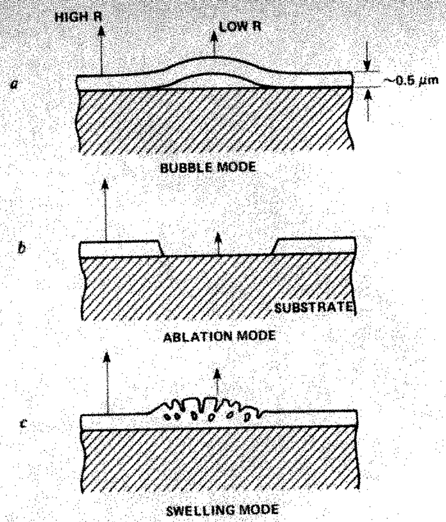


Fig. 2 Recording mechanisms in hydrogenated amorphous semiconductor films. *a*, Bubble formation; *b*, ablation; *c*, sponge formation

by plasma etching the semiconductor (Si or Ge) layer in the presence of aluminium. Atoms are sputtered from the aluminium surface and deposited on the semiconductor film to form a relatively thin and discontinuous layer of aluminium islands with dimensions of 100 nm or less. These act as an etching 'mask' that produces a microscopic needle-like texture on the etched semiconductor surface. The texture has a relatively broad-band antireflection characteristic (previously used in solar thermal collectors[11]) and can be locally melted by an efficiently coupled recording beam. Surface tension promptly restores a more nearly planar geometry to the melted area (see Fig. 1) and the data so recorded may be retrieved by detecting the increased reflectance of the smoothed region. Some critical problems of this approach do remain — it is not yet known how much playback signal-to-noise ratio (SNR) is reduced by the inherent 'graininess' of the textured surface, and whether the plasma etching can be sufficiently well controlled to act uniformly over disk-sized areas (∼0.1 m^2.).

Bösch[12], also of BTL, has investigated the recording characteristics of amorphous hydrogenated semiconductors prepared by reactive sputter deposition of the semiconductor material in a gas mixture containing 25 per cent hydrogen in argon at 10 mtorr. Three distinct recording mechanisms are possible, all of which are activated by the effusion of the hydrogen from the region heated by the laser beam; a process which occurs at a relatively low temperature and is strongly dependent on the choice of semiconductor. At low powers a blister or bubble region (Fig. 2*a*) forms in amorphous hydrogenated silicon semiconductors. At higher powers, ablation of the films occurs, apparently without melting, since no re-solidified residue is observed at the rim of the pit (Fig.2 *b*). In the case of amorphous hydrogenated germanium semicon-

Alan E. Bell is Senior Staff Physicist at Exxon Research and Engineering Company, PO Box 45, Linden, New Jersey 07036.

0028-0836/82/190104-03$01.00

ductors, the effusion of hydrogen produces a micrometre-sized porous region, somewhat resembling a sponge (Fig.2c). The hydrogenated semiconductors provide a very stable storage medium but recording with a diode laser source is difficult because the wavelength of the beam (~820 nm) is in the region of the bandgap energy and absorption is therefore low.

Bubble formation is perhaps the most intriguing recording mechanism reported by Bösch and has previously been described by workers at 3M[13] and Thomson-CSF[14]. In the Thomson-CSF approach, micrometre-sized blisters are formed in a thin layer of a noble metal alloy (for example, Au or Pt alloy) by partial vaporization of an underlying polymer layer. The scattering of the read beam by the blister results in a relatively low effective reflectivity of the blister compared with the undisturbed planar regions (Fig. 3*a*). Workers at 3M and others[15] have combined the bubble mode storage medium with the anti-reflection trilayer structure[1,16] (Fig. 3 *b*). The trilayer increases optical efficiency ($A \leq 0.9$) and thus improves sensitivity. When the blister forms in the uppermost (absorber) layer the interference properties which cause the structure to have low reflectivity are unbalanced and a high-reflectivity blister region forms. One advantage of the blister approach is its potential for extremely high SNR. Irregularly shaped residue at the pit rim, often the limiting factor in the playback SNR of melted pit media, are absent. Furthermore, since the recording sensitivity of bubble mode media is dictated by the thermal vaporization properties of the underlying polymer layer, rather than those of the bubble-forming absorber layer, relatively refractory and stable materials can be used for the latter without sacrificing the recording sensitivity normally associated only with low melting point, often unstable, recording materials[17].

A novel approach to optical storage media has been disclosed by workers at IBM[18]. A layer of amorphous silicon is coated with a noble metal layer, such as Rh or Pt, to a thickness which has a low reflectivity at the recording wavelength. Heat generated by the absorption of the recording beam energy causes the two layers to react and form a microscopic mark consisting of relatively highly reflective noble metal silicide (Fig.4). This approach provides archival stability but appears to be relatively insensitive. Unfortunately, if an attempt to improve sensitivity is made by choosing metals (such as Pd) which form silicides at relatively low temperatures, then the rate of reaction between the layers, even under room temperature storage conditions, leads to an unacceptibly low archival lifetime for the disk.

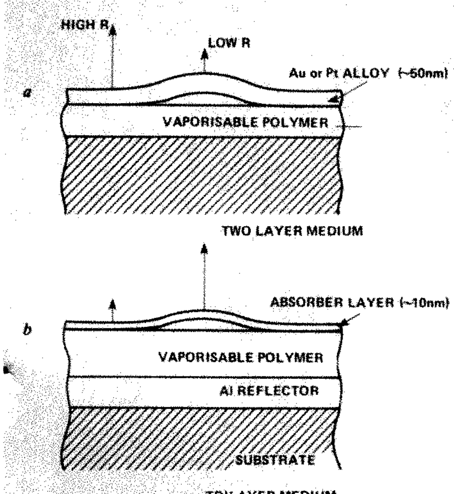

Fig. 3 Bubble mode recording media. *a*, Bubble formation in single layers; *b*, bubble formation in trilayer structures.

For a number of data storage applications, for example the filing of legal, financial and medical records, the write-once storage media discussed above provide a positive guarantee that the records have remained unchanged since input. Nevertheless, computer-operating systems have evolved for a period of 30 years with data storage devices that offer erasure and rewrite capability. Two potential candidates for reversible optical storage media that have been intensively investigated are the chalcogenide alloys such as TeGeAs[19] and magneto-optic alloys such as MnBi[20] and GdCo[21].

The chalcogenide alloys exist at room temperature in either the crystalline or amorphous form, each having different optical properties. An amorphous mark is recorded in a polycrystalline film by briefly melting (~50 ns) the crystalline material, and the subsequent rapid cooling (~10^{10}° s^{-1}) 'freezes' the random atomic structure of the melt to produce an amorphous solid. Recrystallization (that is, erasure) can be accomplished by laser beam heating the amorphous region to a temperature above the glass transition temperature but below the melting point. If the temperature is maintained for longer than about 1 μs, the amorphous dot is annealed and so returned to the original polycrystalline state. Bell and Spong[22] demonstrated reversible optical recording of video signals with an encapsulated tellurium trilayer disk. The encapsulation inhibits the irreversible process of hole formation during the molten phase of the amorphization step. Despite earlier reports[23] indicating limited cyclability of chalcogenide alloys it was found that with pure tellurium up to fifty record and erase cycles were excuted on a single track without significant deterioration of signal quality.

In contrast to the chalcogenide alloy phase-change materials, the number of cycles of magnetization reversal possible in conventional magnetic media appears to be unlimited. In reversible magneto-optic materials, magnetization reversal is accomplished by Curie-point writing or other techniques[24]. In Curie-point writing the magnetization of a micrometre-sized region of the film is reversed by first using the record

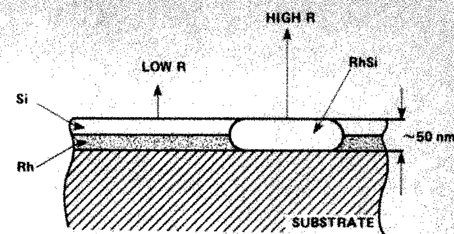

Fig. 4 Alloying bilayer approach.

laser beam to heat temporarily the region above the Curie temperature and then cooling in the presence of an external magnetic field oriented antiparallel to the initial (perpendicular to the substrate) magnetization direction. The presence of the magnetization reversal is detected by the sign of the Kerr or Faraday polarization rotation produced in light respectively reflected from or transmitted by a magnetized layer. In the past, playback SNR has been limited by the low optical signal contrast between oppositely magnetized regions. It has been known for some time[25], however, that the Kerr effect, in particular, can be increased by coating the magneto-optic material within an anti-reflection structure[16]. Mansuripur *et al.*[26] showed that the incorporation of a magneto-optic material into the trilayer structure can lead to a significant increase in signal contrast and thus SNR on playback. The incorporation of recently developed ternary amorphous magneto-optic alloys such as TbGdFe[27] into trilayer structures promises the practical realization of reversible high-density optical data storage. Incidentally, the interference properties of the trilayer structure can also yield significant increases in SNR of both Raman and Kerr spectroscopy used in basic studies[28,29] of the properties of very thin films ($\leq$ 10 nm).

Optical data storage technology is at a particularly exciting phase in its development. Steady improvements in both key areas of semiconductor laser sources as well as the optical storage medium promise the realization of optical storage memory devices within the next few years. Much further research into the microscopic degradation and ageing mechanism in thin films will be required to develop a truly archival (>100 yr) storage medium, and the development of independently addressable semiconductor laser arrays that will permit extremely high (10–100 Mbytes s^{-1}) record and playback data rates. □

Rival transmitters in visual transduction

from Helen Saibil

MANY recent papers suggest that cyclic GMP plays a major role in visual transduction, relaying the light stimulus from the visual pigment, rhodopsin, to the sodium channels of the retinal rod. Until a few years ago it was thought that this role was exclusively played by calcium ions, but the new results suggest that calcium and cyclic GMP interact to regulate the sodium conductance.

Absorption of light by rhodopsin, the visual pigment in the rod outer segment (ROS) disc membranes, changes the concentration of a cytoplasmic transmitter that controls the conductance of sodium channels in the ROS plasma membrane. These channels (or carriers) allow a continual sodium influx, or dark current, which is reduced by the absorbtion of even a single photon of light. It is this reduction (rather than an increase) of 'dark current' that brings about the neural response to a visual stimulus that is transmitted through the retina to the brain. It was originally proposed that bleached rhodopsin released stored Ca^{2+} from the discs because it was known that Ca^{2+} blocks the sodium conductance (see refs in ref 1). The recent discovery of a large and rapid light-induced release of Ca^{2+} from rods supports the idea that light causes the required rise in cytoplasmic free Ca^{2+} (refs 1,2). But recent papers on the sequence and kinetics of a series of enzyme reactions in ROS provide evidence for another mechanism in which rhodopsin bleaching controls the concentration of cGMP.

As reported in these pages about two years ago[3], rhodopsin bleaching can rapidly decrease cGMP concentration in ROS (see refs 4-6). In contrast to Ca^{2+}, injection of cGMP depolarises the rods, and delays the subsequent photoresponse[7]. Ca^{2+} could thus act as a positive transmitter, absent (or bound) in the dark and released by light to block channels[8] and cGMP could act as a negative transmitter keeping channels open in the dark, with light reducing its concentration and allowing channels to close. As well as having opposite effects on the sodium channels, Ca^{2+} and cGMP also have antagonistic effects on some phosphorylation levels in ROS[9]. Various combinations of Ca^{2+} and cGMP have been proposed to function as intracellular transmitter; these are reviewed in a recent collection of articles on the subject[10] which raises the exciting prospect that electrophysiological and biochemical approaches may be brought together from opposite ends of the transduction process.

The central question is how photoexcited rhodopsin controls the sodium conductance. From the outside of the rod, electrophysiologists have sought to characterize the sodium channels and the process controlling their conductance. From the inside, biochemists have looked for reactions activated by photoexcited rhodopsin (R*).

The first approach, using intact, functioning rods, has yielded precise information on the electrical response, showing that the transduction process has four major delay stages and that a single photoisomerization causes many channel closures (summarized in ref 11). Electrical recordings also establish that excitation and light adaptation are both mediated by diffusible transmitter substances in the outer segment[12-14]. They do not, however, provide information on the chemical nature of the controlling process, that is, the link between R* and transmitter concentration. To study this, biochemists have isolated and broken open outer segments to get at the cytoplasm where R* activation of the transduction takes place. This has led to the discovery of an enzyme cascade which links rhodopsin bleaching to cGMP hydrolysis in the ROS cytoplasm, a chain of reactions with close parallels to hormone receptor-adenylate cyclase activation[4,15].

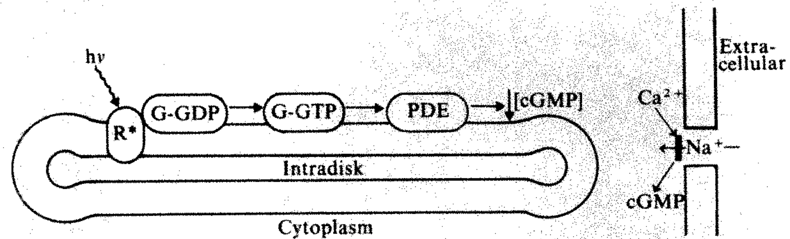
Rhodopsin bleaching stimulates this cascade, as shown in Figure 1. R* interacts with a three-subunit GTP-binding protein (called G-protein, GTPase or even transducin[15]) and catalyses its exchange of bound GDP for GTP. A single R* molecule can catalyse many such exchanges sequentially. Each G-GTP in turn activates many cGMP phosphodiesterases (PDE) which hydrolyse cGMP to 5'GMP. G and PDE, as well as a rhodopsin kinase, are bound to the cytoplasmic surface of discs[16]. G slowly hydrolyses bound GTP back to GDP, an activity which earned its original name GTPase[4], switching off PDE activation. The rhodopsin kinase may deactivate R* by ATP-dependent phosphorylation (ref.6, but see ref.9).

Changes in the far-red light scattering of ROS suspensions that were found to be elicited by a brief bleaching flash[17-19] are now being used to follow the kinetics of the earlier parts of the enzyme cascade. Kühn's key discovery that the binding of G-protein to the disc surface depends on ionic strength, light and GTP has made it possible to separate G from unbleached discs so that light scattering signals can be directly related to the amount of G present in reconstituted disc + G mixtures. Without GTP there is a strong light-induced binding of G to the discs.

Kühn, in collaboration with Bennett, Michel-Villaz and Chabre[20], went on to show that the light-induced drop in transmission (increase in turbidity) of disc suspensions in the absence of GTP reflects the formation of a 1:1 R*-G complex (fig 2). This 'binding signal' saturates when all the available G is bound (10 per cent of rhodopsin in native ROS). If > 20 μm of GTP is present, an increase in transmission, the so-called 'dissociation signal', occurs as the G-GTP dissociates from R*. This signal is seen only when GDP-GTP exchange occurs and it saturates at <0.8 per cent bleaching. Moving on to the next stage in the cascade, PDE activation, Bennett[21] used light-scattering techniques in parallel with the proton release method of Liebman and Pugh[6] to follow cGMP hydrolysis. It begins soon after the onset of the dissociation signal (Fig 2) and has the same dependence on nucleotides and light intensity, showing that PDE activation by G-GTP[15] is rapid.

The rod electrical response has a characteristic s-shaped delay which shortens with

Fig.1 Photoexcited rhodopsin (R*) binds G-protein and catalyses its exchange of bound GDP for GTP. G-GTP dissociates from R* and activates the phosphodiesterase (PDE) which hydrolyses cyclic GMP. The sodium conductance is decreased by Ca^{2+} and increased by cyclic GMP.



Helen Saibil is in the Biophysics Department, University of London King's College, Drury Lane, London WC2R 2LS.

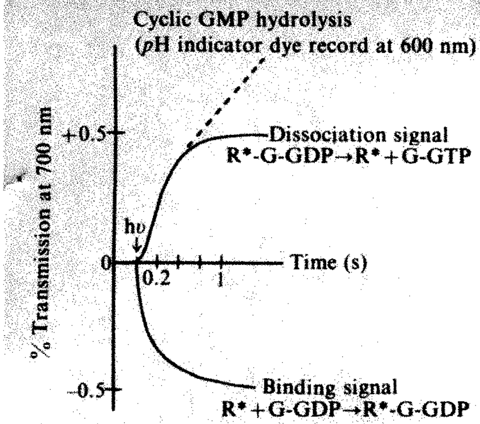

Fig. 2 Far-red light-scattering signals induced by rhodopsin bleaching in a suspension of ROS fragments or from washed discs reconstituted with isolated enzymes. The binding signal indicates the formation of a stable 1:1 complex between R* and G. The dissociation signal results from GDP–GTP exchange on G. Hydrolysis of cyclic GMP to 5′-GMP + H^+ is monitored by a pH-sensitive dye.

increasing light intensity. It is intriguing that the dissociation signal shows very similar behaviour, but it is dangerous to compare experiments on completely intact rods to those on completely disrupted ones. A possible explanation for the delay, advanced by Liebman and Pugh[6], stems from the fact that rhodopsin molecules are more abundant than the proteins with which they interact. As a result, at low bleaches when there are fewer R* created it takes longer for an isolated R* to find its target protein — a process dependent on lateral diffusion. Lateral diffusion seems rate-limiting in the analogous hormone receptor system where chemically increasing the membrane fluidity speeds up cyclase activation[22].

Both Ca^{2+} and cGMP have drawbacks as candidates for the intracellular transmitter. From the biochemical viewpoint, the persistent failure to relate Ca^{2+} uptake or release to changes in rhodopsin or disc membranes[23] and the relative completeness of the R*-cGMP pathway makes cGMP an attractive alternative. From the electrophysiological viewpoint, cGMP hydrolysis has kinetics comparable to the electrical response only if the hydrolysis is triggered by light levels much higher than needed to trigger the corresponding electrical response (see refs in refs 5 & 11), and there are questions about its time course *in vivo*[24]. We have had already had to accept that the minor proteins in ROS cannot be dismissed as irrelevant to visual excitation; now we may have to learn to live with multiple regulation of the sodium conductance by calcium and cGMP. □

Scrapie agent: prions or virinos?

from Richard H. Kimberlin

In the last few weeks considerable publicity has been given to a claim, by Stanley B. Prusiner of the University of California, San Francisco, that the agent causing scrapie — a degenerative disease of the central nervous system in sheep and goats — is a novel kind of proteinaceous infectious particle[1]. The particle, named the 'prion' by Prusiner, is claimed to be either a very small oligonucleotide surrounded by a tightly packed protein or, more remarkably, an infectious protein that contains no nucleic acid at all. This latter possibility is, as Prusiner says, 'clearly heretical' and raises all the problems of how a non-nucleic acid-containing particle can replicate itself. Have we indeed reached the point where the existence of an infectious protein seems likely? To answer this question Prusiner's work needs to be set in the context of 20 years' research in a very difficult area.

In the early 1960s, scrapie was experimentally transmitted from its natural hosts, sheep and goats, to mice and other rodent species, allowing a wide variety of experimental models of scrapie, novel techniques for identifying different strains of agent and a conceptual framework for the genetic control and slow pathogenesis of the disease. Equally important, quantitative studies on the nature of the transmissible agent could begin using titration in mice to measure infectivity (see ref. 2 for a review).

Since then, various classes of microbial agents, such as bacteria, mycoplasmas and viroids, have been excluded as the scrapie agent. The agent has many of the biological properties of a virus but is 'unconventional' in its high degree of physicochemical stability and apparent lack of specific antigenicity. However, we still have very little detailed knowledge of the nature of the scrapie agent.

There are two main reasons for this slow progress. First, the infectious agent is notoriously 'sticky': it seems to aggregate to cell components and has not been sufficiently purified to make biochemical characterization easy. Consequently, its physicochemical properties have been determined only on crude or partially purified extracts. Second, titration in animals is still the only method of measuring the infectious agent. Even with the quickest models of scrapie in mice and hamsters, a complete titration takes 200–300 days. There are also difficulties in interpreting the results: infectivity titres obviously reflect the amount of scrapie agent in an inoculum but they are also influenced by the efficiency of the infection process. This in turn depends on factors which may include varying host constituents and residual reagents in inocula, and the degree of dispersion or aggregation of a 'sticky' agent after treatment. A change in scrapie titre may be particularly difficult to interpret if a given reagent interacts with more than one molecular species, for example, protein and nucleic acid.

Prusiner has worked largely with a short-incubation hamster model of scrapie and has added a sizeable amount of evidence, supporting earlier observations that scrapie infectivity can be reduced by treatments which denature, disaggregate or breakdown proteins[3-6]. The loss of infectivity is generally quite large and it seems reasonable to conclude that the infectivity of scrapie agent involves protein.

However, the unresolved issue is whether such protein is 'contained' in the agent as an integral part of its structure or merely associated with it. This leads to the key question: is there a scrapie-specific protein? Neither Prusiner nor anyone else has any published data showing that there is, but, for the moment, let us assume that one does exist. Conventional thinking would then be that the protein is encoded by a specific nucleic acid which forms the genome of the agent. However, Prusiner has produced two interesting lines of evidence which he regards as indicating the absence of a scrapie nucleic acid.

First, treatments known to inactivate nucleic acids, even though not specific for

0028-0835/82/190107-02$01.00

them, are not found to destroy scrapie infectivity. Infectivity is relatively resistant to heating at 65°C in the presence of zinc ions, to photochemical inactivation after treatment with psoralens and to treatment with 0.5 M hydroxylamine[1]. Failure to inactivate may, however, simply mean that these reagents did not gain access to the putative nucleic acid, perhaps because of protection by protein forming part of the infectious agent or by contaminating host molecules. In any case, as Prusiner points out, not all viruses are inactivated by psoralens or hydroxylamine.

Second, in preliminary studies using detergents and gel filtration, some scrapie infectivity eluted between bovine serum albumin and ovalbumin markers[1]. Assuming a globular structure for the infectious agent, and recognizing the potential problems of determining molecular weights in this way, Prusiner argues that scrapie agent may have a molecular weight of 50,000 or less. He considers that a proteinaceous agent of this size would be too small to contain a nucleic acid of more than just a few nucleotides.

Interesting though they are, these two findings are not by themselves compelling reasons for considering highly unorthodox models of scrapie agent, particularly when faced by some of the problems these pose. Prusiner suggests three such models.

In the first model, the agent contains no nucleic acid and scrapie-specific protein acts as its own template, either directly, or by 'reverse translation'. It is difficult to conceive how proteins could code for their own synthesis although scrapie models of this kind were proposed as long ago as 1967 (ref. 7). But since then the requirements of a scrapie model have become more stringent; the copying process must have a precision compatible with the existence of several different, genetically stable strains of scrapie[8].

In Prusiner's second model, the agent contains no nucleic acid but has protein which induces host genes to code for its own synthesis. The third proposes that there is a very small scrapie oligonucleotide which does not code for protein but acts as a regulatory element promoting the synthesis of agent. In these models, therefore, it is the host nucleic acid that encodes scrapie-specific information. This is certainly conceivable but difficult to reconcile with evidence that scrapie agents behave like pathogens with their own coded information: the natural disease is infectious[9], various strains of agent can be transmitted experimentally to many different species[8], some strains give rise to mutants[10] and strain selection can occur on serial passage of mixtures[11]. To explain these properties in terms of host coding introduces a complexity that seems unnecessary in the absence of data which necessitate it.

A much simpler working hypothesis which fits both established facts and even Prusiner's recent data may be proposed. It makes only two assumptions: first, that there is indeed a scrapie-specific nucleic acid, as indicated by the properties of replication, strain variation and mutation; and second, that, as in viroids, the scrapie nucleic acid is not translated[12].

The hypothesis has some interesting consequences. The scrapie nucleic acid could be very small as all it has to do is be replicated (using host enzymes) and interact in strain-specific ways with the host to produce disease. The latter it could do by acting as, or coding for, some kind of regulatory nucleic acid. Alternatively, disease could be a consequence of the binding of the scrapie-specific nucleic acid to host protein needed to form an infectious agent, especially if the protein normally has an important biological function. Since the protein associated with the agent is host derived we have a very simple explanation for the apparent absence of specific antigenicity.

This hypothesis may also explain our current failure to purify agent or to identify it in the electron microscope: if the scrapie-specific nucleic acid is covered with host protein it may well be 'sticky' and hard to purify from other host proteins and, unless it has a regular, virus-like nucleoprotein structure, it could be hard to recognize. An agent of this kind would be novel but fit nicely into a biological niche lying between viruses, which specify some of their own proteins, and viroids which need no protein at all. The neologism, 'virino', has already been suggested for a novel agent of this kind[13], and may by preferable to Prusiner's term 'prion' because the latter emphasizes a molecular species which may not be the most important one, as did the conclusion in 1935 that tobacco mosaic virus was proteinaceous[14].

However, the main point of these speculations is that we do not yet need to build hypotheses outside the current framework of molecular biology to accommodate the scrapie agent. The real need is to assemble more hard facts and, just as Prusiner[1] says, this means "purification of the scrapie agent to homogeneity and the subsequent identification of its macromolecular components"; undoubtedly a difficult task but not an impossible one. □

NATURE

100 years ago

THAT the French should know better than any other nation how to enlist art in the service of science is just what might be expected. Such a service on the part of art to science is a fair return for the immense resources which scientific research has been able to place at the disposal of art. Nowhere have the discoveries of science been more useful or more utilised than at the celebrated porcelain manufactory of Sèvres, and the illustrations which we give to day will afford some idea of the beautiful results which are thus produced. As a permanent record of successful scientific efforts, nothing could be more satisfactory and appropriate. In the figure the characteristic features of the Arctic regions are rendered with almost perfect success and truthfulness.

REVIEW ARTICLE

Aspects of the electrochemistry of steel in concrete

Information available on mechanisms of corrosion of steel in concrete is reviewed and the need emphasized for a better understanding of the electrochemistry of the subject and aspects of the physical performance of the concerete cover in relation to the diffusion of both chloride and oxygen. The practical influence of data obtained from studies in such areas in relation to longer-term improvements in durability of reinforced concrete is considered.

THE practice of embedding steel bars in a mixture of Portland cement, graded aggregates and water to form reinforced concrete was introduced during the second half of the nineteenth century. Initially the material was employed for projects of modest scale but the scope of its applications grew rapidly as its composite properties were appreciated.

Since the turn of the present century reinforced concrete has been in widespread use in a great variety of building and civil engineering work. It is exposed to many different types of environment and, as for any structural materials, the related characteristics of durability and need for maintenance are of considerable importance as service lives are expected to extend over several decades. In these respects, the performance of reinforced concrete has generally been impressive and there are many examples of its long-term durability (see ref. 1).

There are, however, several degradative processes which affect a minority of reinforced concrete structures leading to loss of serviceability or, in extreme cases, to structural collapse and, amongst these, the most common cause of deterioration is corrosion of reinforcing steel[2]. This gives rise to a familiar sequence of events owing to the volume increase associated with the transformation of steel to rust which generates tensile stress within the surrounding concrete and causes cracking and eventual spalling of the cover to the reinforcement. Some examples of the types of problems and potential safety hazards which reinforcement corrosion can cause in buildings are illustrated in Fig. 1. Similar corrosion problems are also of major importance worldwide in relation to reinforced concrete road bridges and marine structures.

Despite the length of time during which experience has been gained of the corrosion behaviour of steel in concrete, there are still several important aspects that are not fully understood: in particular, the interpretation of information obtained from relatively short-term electrochemical studies, which are frequently used as an aid in predicting long-term performance[3]. Because such investigations often represent the only practicable approach for rapid assessment of the effects on corrosion behaviour of changes in materials specifications, concreting practices and so on, it is important to seek improved fundamental understanding of the electrochemistry of this complex and variable system.

We now survey briefly the commonly encountered causes of reinforcement corrosion and highlight some main areas where basic research is considered necessary.

Mechanisms of corrosion protection in concrete

Any attempt to describe in general terms the nature of concrete, viewed as a potentially corrosive medium, is likely to prove inadequate because many factors can affect both the physical pore structure of the material and the chemical composition of the solution phase within the pores. The most important constituent is the hydraulic binder, Portland cement, which, in its unhydrated form, consists mainly of four minerals of the following approximate compositions: tricalcium silicate ($3CaO\,SiO_2$), dicalcium silicate ($2CaO\,SiO_2$), tricalcium aluminate ($3CaO\,Al_2O_3$), tetracalcium alumino-ferrite ($4CaO\,Al_2O_3\,Fe_2O_3$) (In cement chemistry these minerals are conventionally referred to as C_3S, C_2S, C_3A and C_4AF.) When Portland cement is mixed with water, the constituent minerals undergo a complex sequence of hydration reactions, which gradually transform the paste to a hardened matrix of hydrated products. The most important reactions, insofar as the development of physical structure and mechanical properties are concerned, are those involving C_3S and C_2S which are converted to a gel of calcium silicate hydrates of ill-defined composition and structure (C–S–H gel) and to calcium hydroxide produced mainly in the form of well-developed portlandite crystals[4]. In a mature (fully hydrated) sample, C–S–H gel would be expected to account for ~70% of the weight of solid material and calcium hydroxide for ~20% (ref. 5), the eventual porosity and pore size distribution being determined largely by the water/cement ratio, as illustrated in Fig. 2.

From the point of view of the electrochemical behaviour of steel in concrete, the most significant feature of cement hydration is that the aqueous phase rapidly acquires a high pH value. Initially, the solution in contact with the hydrating cement grains contains hydroxides and sulphates of calcium, sodium and potassium but sulphate ions are rapidly precipitated to form the highly insoluble calcium sulpho-aluminate hydrate ($C_3A\,3CaSO_4\,31H_2O$) (ref. 6). Thereafter, the liquid becomes increasingly concentrated with respect to sodium and potassium hydroxides and, as the pH rises, the concentration of calcium ions decreases in approximate conformity with the solubility product of calcium hydroxide. This state of affairs is reflected in the fact that, after a few weeks of hydration, pH values well in excess of 13 are frequently recorded for Portland cement pastes of water/cement ratios such as are commonly used in practice[7-9].

For iron in an alkaline environment, the Pourbaix diagram indicates that the metal may remain passive over a wide range or potentials[10] and a very limited supply of oxygen is sufficient to provide the necessary degree of anodic polarization to maintain conditions within this range, as shown by rest potential measurement in deaerated limewater[11]. Thus, in all but highly anaerobic environments, the primary mechanism of corrosion protection in concrete involves passivation of embedded steel resulting from the chemically inhibitive influence of hydroxyl ions.

The secondary feature of corrosion protection that is provided by dense concrete depends on the capacity of the material to act as a physical barrier between embedded reinforcement and the external environment, limiting the access of substances which may play a part in corrosion. In this respect, however, it is clear that concrete, with its continuous pore system and tendency to form surface cracks, is a far from perfect barrier. Thus concrete is not generally effective in excluding water but this may not cause corrosion problems unless the pH falls below that required to maintain passivity. Where the pH does fall, however, corrosion problems can arise even when the material is exposed to the air inside buildings provided the appropriate circumstances prevail[12]. It has also been established that dense concrete is normally fairly permeable to oxygen and, although the rate of oxygen diffusion is obviously limited by increase in the degree of saturation of the material, a significant flux can be sustained even through specimens that are fully submerged for long periods in water[13]. The real importance of the physical barrier presented by concrete cover is therefore related mainly to its ability to preserve the conditions of high pH needed to maintain the reinforcement in a passive condition by limiting the rate of ingress of acidic substances from the external environment.

Generally the acidic substances concerned are atmospheric carbon dioxide and, in polluted locations, other gases such as sulphur dioxide. These react with the alkaline constituents of the cement paste to form a carbonated zone which gradually penetrates into exposed concrete, reducing the pH of the affected region to a value below pH9.

Loss of protection by carbonation

The kinetics of carbonation for various types of concrete in different environments have been widely investigated and it has generally been observed[14] that the relationship between carbonation layer thickness (x) and exposure time (t) is approximately parabolic in form:

$$\frac{dx}{dt} = kt^{-1/2}$$

The magnitude of the proportionality constant (k) depends on several variables related to the quality of the concrete (water/cement ratio, type of cement and so on) and to the environment (temperature, relative humidity and so on). By specifying a suitable grade of concrete for a given service situation, it is possible to ensure that the rate of advance of

carbonation dx/dt declines within a fairly short time to a low level (<1 mm yr^{-1}) Provided the depth of concrete cover to the reinforcement is adequate, therefore, carbonation should not penetrate to an extent which endangers the passivity of the steel during the design life of a structure It is this principle that underlies recommendations made in codes of practice regarding minimum depths of cover appropriate for concretes of different quality exposed to environments of varying severity[15]

It is particularly important when concrete is being produced in adverse climatic conditions that adequate precautions be taken to ensure proper curing of the external surfaces because the formation of a weak, permeable surface layer would otherwise tend to promote carbonation[16] In general, however, problems of corrosion arising from carbonation should be avoidable in normal density structural concrete, provided that well-established guidelines for constructional practice are followed The situation that most frequently gives rise to corrosion risks, altogether more serious and difficult to contend with, occurs when reinforced concrete contains a substantial amount of chloride ion as this may cause depassivation of steel even in a medium of high pH such as uncarbonated concrete

Loss of protection by chloride

Chlorides may be introduced into concrete during manufacture or service Within the former category, there is the posibility of deliberate inclusion of admixtures containing calcium chloride to accelerate the early stages of cement hydration, a practice that is now strongly discouraged for reinforced concrete[17] There are also many cases of adventitious introduction of chlorides as contaminants of the aggregates or mixing water, which may be almost unavoidable in certain circumstances where the use of locally available resources is necessary[18,19] During service, chlorides from external sources may penetrate concrete to levels which exceed normal depths of cover to reinforcement within a small fraction of the design life in the case of structures exposed to marine conditions[20,21] or to de-icing salts[22,23]

Several matters arising in relation to the behaviour of steel in chloride-bearing concretes remain incompletely resolved despite long and numerous researches, the corrosive effects of calcium chloride in concrete were, in fact, studied as long ago as 1923 (ref 24) We now consider some of the outstanding difficulties

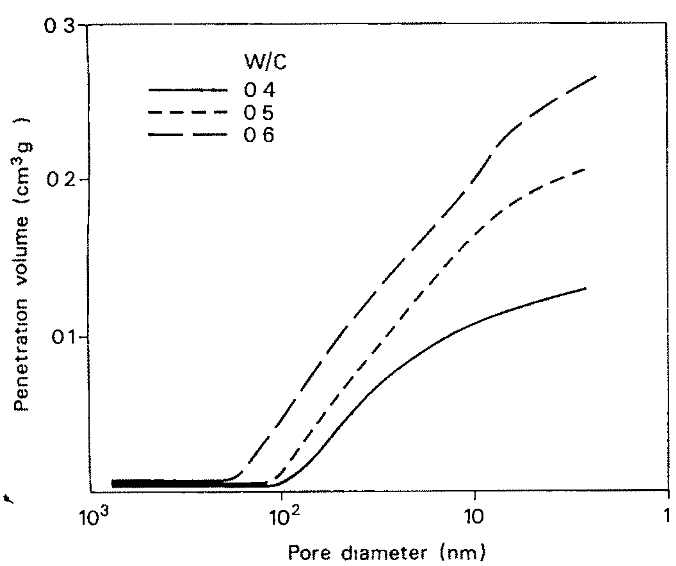

Fig. 2 Pore size distribution curves for mature hydrated ordinary Portland cement pastes determined by mercury intrusion porosimetry (Penetration volume indicates cumulative pore volume intruded by mercury, W/C indicates water cement ratio of pastes)

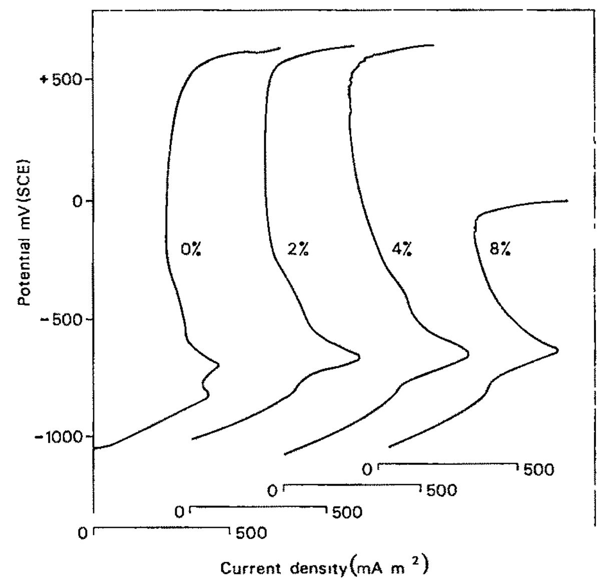

Fig. 3 Potentiodynamic anodic polarization of mild steel in hydrated ordinary Portland cement pastes of water/cement ratio 0 4 containing various percentages of calcium chloride dihydrate by weight of cement (sweep rate = 1 mV s^{-1})

A question of practical importance, that has to be considered when chloride-bearing concreting materials are specified or when investigations of the durability of reinforced concrete structures are made, concerns the threshold level of chloride ion which is liable to stimulate corrosion of steel in concrete As might reasonably be expected, however, bearing in mind the range of possible variations in concrete quality and exposure conditions, there is no simple answer to this question and on the basis of surveys of large numbers of reinforced concrete structures in Britain, the Building Research Establishment has recently proposed a classification for assessing the risk of corrosion[25] Thus for concrete made from ordinary Portland cement (or similar), it is considered that a low risk is associated with chloride contents (by weight of the cement) of <0 4%, an intermediate risk for chloride contents of 0 4–1 0% and a high risk for levels >1 0% The influence of carbonation in this process is also considered, the risk being enhanced when carbonation reaches the reinforcement

Whilst providing sound practical guidelines that are adequate for many purposes, the above classification is not based on any mechanistic interpretations of the factors which determine the risk of corrosion in concrete containing a given quantity of chloride ion It is therefore limiting in the sense that it provides no means for distinguishing *a priori* between the effects of a number of possible sources of variation, for example, the following (1) chlorides associated with different cations, (2) chlorides introduced at or after the time of mixing, (3) chlorides introduced in the presence of other contaminant anions such as sulphates, (4) chlorides in concrete made from cements of different compositions, (5) chlorides in concrete of varying water/cement ratio, (6) chlorides in concrete cured or exposed in different conditions

Because these and other factors are likely to influence the corrosion risk associated with the presence of a given concentration of chloride ions, there is a need to examine their roles and relative importance

Mechanisms of corrosion of steel in concrete

The simplest and most reliable method involves long-term exposure tests on laboratory-prepared specimens of reinforced concrete, a costly and time-consuming procedure but which yields results that can generally be considered as a realistic guide to practical performance The Building Research Establishment have used this approach in studying the influence of

many factors, such as the use of various types of reinforcing steel, and found that differences in performance may take several years to manifest themselves clearly[3]

The alternative methods, that are often used when information has to be obtained within a restricted time, involve the application of various electrochemical techniques They may be applied to steel which is either embedded in concrete, mortar, cement paste and so on, or else immersed in a solution of which the composition is believed to resemble that of the pore electrolyte in the concrete under consideration With all of these methods, there are considerable difficulties in relating the results obtained to the performance of reinforced concrete as recorded from service experience or from exposure tests

In studies involving the use of simulated pore-solutions there are fairly obvious uncertainties regarding the nature and concentrations of solutes that should be present Thus it has commonly been assumed that saturated calcium hydroxide solution, which has a pH value of ~12 6 at 25 °C, may be taken as an approximate electrolyte for electrochemical studies This, however, is apparently at variance with the findings of several investigations of the composition of pore solutions extracted from actual Portland cement pastes or mortars, these have shown that, after a few weeks of curing, the pore liquid has often become essentially a mixed solution of sodium hydroxide and potassium hydroxide with a pH in the range 13–14 (refs 7–9) The latter electrolyte would be expected to maintain the passivity of steel in the presence of chloride concentrations well in excess of the level (~500–700 p p m) which induces depassivation in saturated calcium hydroxide[11 26]

Before concluding that a more alkaline solution would constitute a more realistic model, however, note that the pore-solution in concrete is not buffered at a pH value in excess of ~pH 12 6 and several commonplace processes may tend to reduce the naturally high alkalinities produced by cements rich in sodium and potassium oxides Examples of such processes are (1) use of calcium salts, for example, calcium chloride, as admixtures which would lead to precipitation of hydroxyl ions to form additional calcium hydroxide, (2) ingress of cations which form insoluble hydroxides from certain environments, for example magnesium ion from seawater, (3) leaching of sodium and potassium hydroxide from concrete frequently or continuously exposed to water, (4) diffusion of hydroxyl ion from the interior towards the carbonated surface zone of concrete exposed to the atmosphere, (5) simple dilution of the pore-solution associated with the cement paste by water from continuous pores within the aggregates

It is perhaps reasonable, therefore, to consider that, in service conditions, the pH of uncarbonated concrete at the level of reinforcing bars may often tend towards the buffering range of saturated calcium hydroxide[27] This suggestion would fit in with the otherwise surprising observation that cements with high alkali-contents have not been found to provide significantly enhanced corrosion protection to steel in reinforced concrete exposed for long periods to chloride-bearing environments[28]

Apart from the question of pH, the other principal uncertainty regarding the composition of the liquid phase in concrete concerns the extent of binding of the chloride ions by solid hydration products It is well-known that the aluminate and ferrite constituents of Portland cements can form incongruently soluble calcium chloro-aluminate and chloro-ferrite hydrates the former being the more important from the point of view of their capacity to remove free chloride ions from solution[29 30] There is also considerable evidence that the C_3A content of the cement has an important role in determining the extent to which chlorides included in the mix constituents are complexed and that this influences the degree of protection afforded to embedded steel in the presence of chloride[29,31 32], this is recognized in codes of practice by the imposition of stringent controls over the use of chloride-containing materials in concretes manufactured from cements of specified low C_3A content, such as sulphate resisting Portland cement[17]

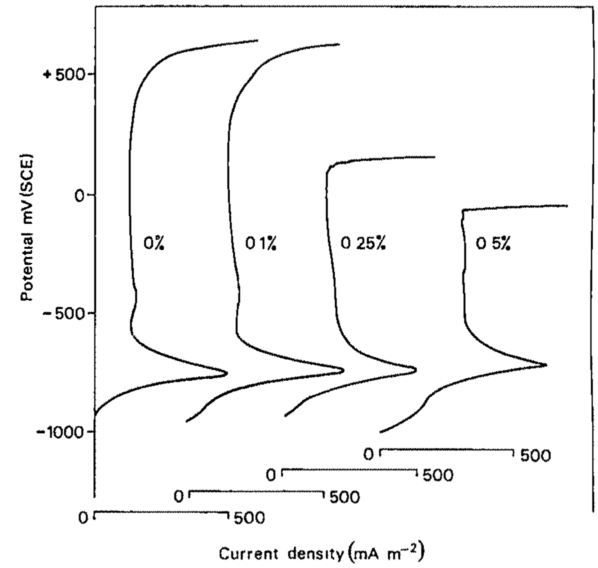

Fig. 4 Potentiodynamic anodic polarization of mild steel in saturated calcium hydroxide containing various percentages of calcium chloride dihydrate (sweep rate = 1 mV s^{-1})

Nevertheless, there is a general lack of information about the levels of chloride likely to remain uncombined for long periods in the solution phase associated with concretes made from various cements in different conditions of natural exposure The source of the chloride ions may be significant and it has been suggested that chlorides which penetrate concrete from the external environment tend to remain uncomplexed to a greater degree than those present at the time of manufacture[21 33] It is also unclear to what extent the presence of various levels of sulphate ions, either as constituents of the mix materials or as contaminants entering from the service environment, may liberate chloride ions owing to preferential formation of calcium sulpho-aluminate hydrates Similarly the extent to which carbonation may cause decomposition of calcium chloro-aluminate hydrates is uncertain

The above considerations highlight the need for further investigations of the solution chemistry of concrete pore electrolytes, aimed particularly at resolving the role of cement compositional variables (such as C_3A content and alkali content) in relation to several of the possible long-term changes that have been identified Examination of solutions extracted from concretes, exposed for long periods to different service environments, is practicable and would appear to be an important field for future work

Whilst improved understanding of the constitution of the aqueous phase within concrete would greatly facilitate attempts to understand the electrochemistry of steel in concrete by means of experiments involving steel electrodes immersed in simulated pore-solutions, the latter can never be an entirely satisfactory model The main objection is that the kinetics of diffusion of the reactants and products of electrode processes cannot be comparable in solutions and in concrete

As has been noted previously[16 27], depassivation as a result of chloride-induced pitting of steel in concrete is likely to be controlled by the rates of diffusion of several substances within the material One significant factor is the rate of oxygen transport to the metal surface as this will influence cathodic polarization and determine whether the potential of the steel is sufficiently noble to support the formation and growth of pits at a given effective concentration of chloride and pH (ref 34) For reinforced concrete, fully submerged in a chloride-bearing aqueous environment, pitting is often likely to be suppressed[27] and the only question that arises is whether the supply of oxygen to the steel will be even sufficient to balance the very low anodic leakage current density required to maintain the passive film[35] or whether a low-potential 'active' condition will result[36 37] It

has also been suggested that the magnitude of this leakage current density is itself controlled by diffusional constraints on the passage of iron ions into the surrounding medium, and may vary in response to change in the surface concentrations of chloride and hydroxyl ions[38]. In conditions other than those of total immersion, the supply of oxygen to embedded steel is unlikely to be a limiting factor and the availability and rates of replenishment of chloride and hydroxyl ions seem liable to govern the anodic behaviour of the metal. Notwithstanding the controversy regarding mechanisms of chloride-induced pit initiation, it is generally accepted that pit growth is accompanied by the development of solution conditions within the pits of locally elevated chloride ion concentration and depressed *p*H (ref 34). Factors which limit the diffusion of chloride ions or enhance the diffusion of hydroxyl ions in the vicinity of incipient pits will therefore tend to promote repassivation. One such factor is associated with the composition and physical barrier-layer characteristics of the lime-rich interfacial zone of segregation which surrounds steel embedded in cement-rich dense concrete[16,27], others are related to the mineralogy and pore structure of the hydrated cement matrix and, in this regard, it is significant that effective diffusivities of chloride ion, measured at fixed temperature for different cement pastes of constant water/cement ratio, have been found to vary widely[39,40]. Activation energies recorded for chloride ion diffusion in hydrated cement pastes indicate that the kinetics are governed by interactions between the diffusing ions and the pore surfaces[39,40]. The nature of these interactions and the effects on them of cement compositional variables represent a potentially useful field of continuing research. This may have practical applications related to the development of hydraulic cements which offer a high degree of corrosion protection to embedded steel by virtue of their capacity to retard the diffusion of chloride ions[41,42].

The foregoing discussion has indicated several major shortcomings of electrochemical investigations performed with electrodes immersed in solutions. To simulate the various dynamic factors which may play a part in controlling the durability of reinforcement in concrete, it is therefore necessary to undertake studies with electrodes embedded in concrete, mortar or cement pastes and several attempts have been made to carry out electrochemical measurements with specimens of these types. As will be discussed, the results obtained must generally be interpreted with considerable caution.

One of the greatest practical problems associated with all such investigations concerns the method of masking the embedded electrode so that it may be connected to external apparatus with a predetermined part of its surface area exposed to the electrolytic medium. The avoidance of crevice effects in the specimens is very difficult and the situation is exacerbated by the fact that many commonly used lacquers, coatings and gasket materials are themselves likely to suffer some degree of degradation during exposure for long periods to a highly alkaline environment such as concrete. When quantitative data are sought from long-term electrochemical studies of this nature, specimen design is therefore crucial if experimental artefacts are to be avoided. In particular, we suggest that, in planning such experiments it is worthwhile to consider using a range of specimens with systematically varied exposed surface area as this may facilitate the subsequent diagnosis of misleading effects of the type mentioned.

In the case of standard methods, such as potentiodynamic or potentiostatic polarization curve determinations, the data obtained will depend on variables such as the rate of change of potential and they have little prospect of yielding information which can be directly related to long-term durability. Their value is purely comparative in the sense that they can be used to provide rapid evidence of trends associated with a particular variable which is altered whilst others are held constant. Thus, for example, using fixed experimental conditions, different types of alloy steel may be graded according to their relative susceptibilities towards pitting in particular chloride-containing mortars[3], or the relative effects of given dosages of chloride may be examined for steel embedded in various types of cement pastes and mortars[43–45].

As the typical data shown in Fig 3 illustrate, however, the levels of chloride that are observed to cause significant effects in short-term experiments of this type are often considerably greater than those which are associated with a high risk of corrosion in long-term exposure tests or service. Note that the concentration of chloride ions in the original mixing water of the paste specimen containing 4% of calcium chloride dihydrate by weight of the cement, which appears to be on the borderline between passivity and pitting (see Fig 3), is almost 1,000 times larger than the concentration required to induce pitting in saturated calcium hydroxide solution (see Fig 4). This scale of disparity cannot be adequately explained in terms of the effects of chloro-aluminate hydrate formation or the excess hydroxyl ions contributed by sodium and potassium oxides in the cement, particularly bearing in mind the *p*H-depressing action of calcium chloride[44]. The main factor is probably the slowness of chloride diffusion towards the embedded steel surfaces, which causes pitting to be 'missed' even at a relatively low rate of potential scan unless very large chloride concentrations are present in the pore solution.

Similar considerations apply, in general, to the use of galvanostatic polarization for examining the response of embedded steel electrodes. The technique has been useful as a means of providing comparative data[3,46–50]. There is little doubt, however, that whilst this approach may be more reliable than potentiostatic or potentiodynamic methods when small current densities are applied, concentration polarization distorts anodic behaviour to an extent which makes accurate prediction of long-term performance impossible. A further disadvantage, common to galvanostatic, potentiodynamic and potentiostatic polarization curve determinations, is that the specimens used may be examined once only because of the likelihood of irreversible changes being brought about by potential attenuation over a range of several hundred millivolts, this effectively eliminates the possibility of following time-dependent changes in the response of individual specimens.

There are various alternative electrochemical methods which have been applied to steel in concrete or similar media in attempts to provide data continuously or at timed intervals over a period of several months or more. The range of techniques used has included rest potential measurements[50,51], current measurement in potentiostatic conditions in deaerated media[35], polarization resistance determination[52,53], and a c impedance measurement[54,55]. In addition to the practical difficulties mentioned regarding electrode design to avoid misleading crevice effects and so on there are other grounds for caution in interpreting data from long-term electrochemical investigations carried out in concrete and, even in straightforward rest-potential studies, ambiguities can exist as other workers have

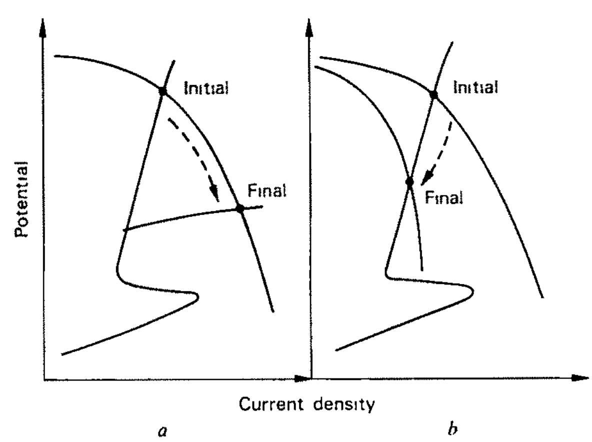

Fig. 5 Movements in rest-potential towards more negative values associated with *a*, passive film breakdown, *b*, restriction of oxygen access

indicated[36 50] Thus, it is well-established that passivity is frequently associated with a noble potential, which tends to increase with time towards a steady value, usually in excess of about −220 mV SCE (ref 51) as the passive film thickens, implying a plentiful supply of oxygen In cases where the rest-potential is observed to decrease with time, depassivation may or may not be implied since the increased cathodic polarization may be associated either with passive film breakdown (Fig 5a) or with progressive restriction in the supply of oxygen to the surface of passive steel (Fig 5b)

Of the other techniques referred to, it would appear that a c impedance studies offer the greatest likelihood of resolving present uncertainties about the fundamental nature of mechanisms of corrosion rate control in chloride-bearing concretes and similar media Their major advantage in this respect lies in the ability to yield information concerning dynamic characteristics of the system, revealing in particular the influence of diffusion-controlled processes on the response of an embedded electrode In view of the importance which has been ascribed to diffusional effects with respect to the mechanism of chloride-induced pit growth, it would be of considerable interest to compare a c impedance data obtained in various concrete or hardened cement paste systems, for which chloride diffusion kinetics have been studied directly

Implications for the practical situation

We have, so far, concentrated on developments of a better basic understanding of the mechanisms of corrosion of steel in concrete However, there is also an important practical need for such better understanding The minority of reinforced concrete structures which deteriorate prematurely as a consequence of reinforcement corrosion do so as a result of poor constructional practices, inadequate design and, on occasions, poor quality of materials While codes of practice lay considerable emphasis on design and general aspects of quality control, in respect to the use of marginal quality concrete materials they give little detailed guidance, it is here therefore where a better knowledge of corrosion protection mechanisms especially in relation to the microstructure of the matrix, interactions of contaminants (particularly chloride and sulphate) and the role of water/cement ratio and curing could well lead to wider usage of poorer quality indigenous materials without adverse effects on durability At the same time, building owners will continue to repair existing deteriorated reinforced concrete structures and better understanding of the performance of repairs is urgently needed[56] This is particularly the case in relation to three factors (1) The diffusion of chloride through concrete (both in marine structures and where contact between chloride contaminated and uncontaminated units occurs) (2) The redistribution of anodic and cathodic sites in the concrete following repair (particularly in the substrate concrete) (3) The electrochemical interaction between repair and substrate materials and its influence on corrosion at the interface

Conclusions

Work should be undertaken in the following areas to improve practical understanding of mechanisms of corrosion and protection of steel in concrete

- Continued examination of the pore liquid in concrete at various stages of hydration and in different environmental conditions of curing and exposure
- Further investigations of the distribution of chloride (at a range of concentrations) between the solid and solution phases of hydrating cements and the relationship of this distribution to cement type
- Fundamental electrochemical studies of the performance of steel electrodes in electrolytes simulating pore solutions and complementary electrochemical studies on steel/concrete systems
- Studies of the diffusion rates of chloride through uncontaminated cement pastes and through those contaminated with chloride and/or sulphate
- Studies of oxygen diffusion through cement pastes and concretes, particularly in underwater exposure
- Development of improved electrochemical monitoring techniques for laboratory experimentation and *in situ* measurement of corrosion rates in structures, which accommodate difficulties arising from the high electrolytic resistance of concrete, and from crevice effects at electrode edges
- Investigation of the mechanisms of macrocell development in chloride contaminated concrete, especially in relation to concrete repairs

Improved understanding in these areas would have wide scope for application to the construction of durable reinforced concrete structures in adverse conditions and to the evolution of successful repair techniques The economic benefits to be gained from solution of the problems outlined above are therefore substantial

Identification of resonance features within the rings of Saturn

J. B. Holberg*, W. T. Forrester* & Jack J. Lissauer†

The Voyager 2 UV spectrometer observed a stellar occultation by the rings of Saturn, which located ring features with an accuracy of 12 km A high-resolution (3 km) optical depth atlas of the rings shows at least nine features, including four density wave patterns, identified with satellite resonances Analysis of these density wave patterns yields the first surface mass densities for the A ring and, together with our optical depth atlas, a total ring mass of 6.4 × 10⁻⁸ Saturn masses

IT has long been customary to link certain gaps and boundaries observed in the rings of Saturn to the locations of resonances with several of Saturn's satellites Most notable in this regard has been the association of the outer edge of the B ring with the location of the Mimas 2 1 resonance The vastly increased spatial resolution of the rings available from Voyagers 1 and 2 has made it possible to pursue this activity with much more confidence, however, the new clearer picture of the rings is complicated by two factors First, the rings contain a vast number of radial features on all scales Second, the newly discovered inner satellites have greatly increased the number of potential resonances with which one has to contend Both of these factors have led to the suggestion of numerous possible associations[1–4] To resolve any ambiguities a further increase in spatial resolution, together with a reliable distance scale for the rings is necessary Both of these criteria are met by the stellar occultation experiment performed by Voyager 2

Some of the first Voyager 1 images of the rings were used by Collins *et al*[1] to produce a list of observed features and possible corresponding resonance locations involving Titan, Iapetus, Hyperion, Mimas and the co-orbital satellites 1980S1 and 1980S3 The uncertainty in the absolute location of ring features, however, was ±500 to ±1,000 km Later Voyager 1 and 2 images showed wave-like patterns associated with several A ring features These features were suggested as being near to areas where two or more resonances coincided[2] A more positive identification was provided by Cuzzi *et al*[5] who analysed Voyager 1 images of the Cassini division showing density waves due to the Iapetus 1 0 resonance Further evidence of density waves associated with the 1980S1 2 1 resonance was provided by the Voyager photopolarimeter experiment[6] which obtained stellar occultation data simultaneously with the UV spectrometer

The ring features which we describe here are located near the inner Lindblad resonances with the external satellites of Saturn Many theoretical consequences of such resonances, including tightly wound spiral density waves propagating radially outward from the resonance location, were first discussed by Goldreich and Tremaine[7] (also see refs 5, 8)

In general these resonances are described by a ratio of two integers of the form $l/(m-1)$, which represents the approximate ratio of the mean orbital motion of a satellite to that of a ring particle Resonances of importance in Saturn's rings can be classified into two types[1] Type I resonances, where $l=m$, are usually the strongest and are independent of satellite orbital eccentricity, while type II resonances, where $l=m+1$, are weaker, being proportional to the first power of satellite orbital eccentricity A special type I resonance case occurs when $l=m=1$ Here the rate of the apsidal advance of a ring particle's orbit equals the mean orbital motion of the satellite We will refer to the three resonances of this variety present in the rings as apsidal resonances An additional class of resonance considered here involves resonances in the rings due to the rotation of Saturn[4] Such resonances depend on an azimuthal asymmetry in the gravitational figure of Saturn

The locations of the resonances used here are those of Lissauer and Cuzzi[8] who have computed the locations and strengths of expected satellite resonances using the zonal harmonics of Saturn's gravitational potential through J_6 These locations differ slightly from those given by Collins *et al*[1] and except for the apsidal resonances are believed to be accurate to within ±10 km Expected resonance locations are shown in Fig 1 together with normal optical depths (τ) of the A, C and portions of the B ring observed by the UV spectrometer

δ Sco occultation

During the Voyager 2 Saturn encounter the UV spectrometer[9] observed an occultation of the bright B0 5 IV star δ Scorpii by the rings of Saturn The occultation began as the star emerged from the atmosphere of Saturn at 23 45 07 UTC 25 August 1981 and continued for 130 min During this time the apparent path of the star traversed the entire ring system from the D ring to beyond the F ring with a mean radial velocity of 10 3 km s^{-1} Throughout the occultation the UV spectrometer obtained a complete 912–1,700 Å spectrum of δ Sco every 0 32 s, yielding a resolution of ~3 3 km in the rings A preliminary discussion of the UV spectrometer ring occultation results is given elsewhere[10] The data from which the normal optical depths of the rings were derived are the result of summing an entire UV spectrum to yield a single intensity measurement at an effective wavelength of 1,125 Å These intensity data were then corrected for instrumental background and the effects of spacecraft limit cycle motion Normal optical depths have been computed from the ratio of the attenuated to the unattenuated signal and corrected for the 28 71° angle between the line of sight to δ Sco and the plane of the rings Details of the data reduction will be presented elsewhere

0028–0836/82/190115—06$01 00

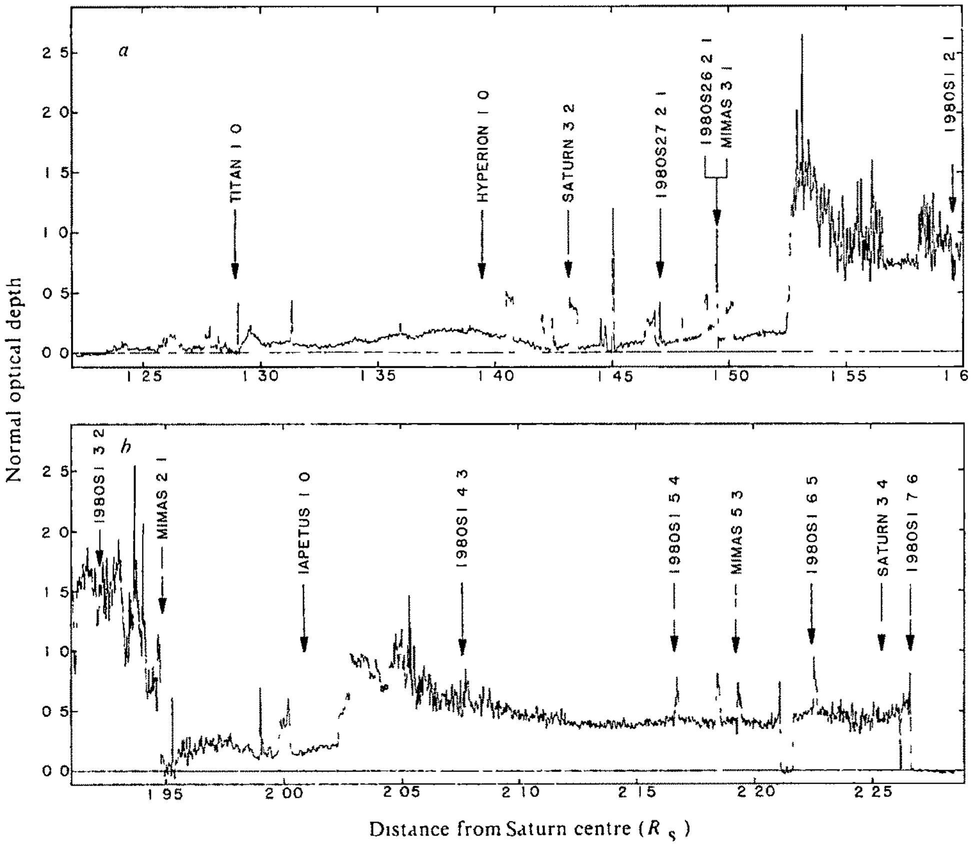

Fig 1 The normal optical depths in the rings observed by the Voyager 2 UV spectrometer These data, which have been plotted at a resolution of ~15 km, span the entire C and A rings and include those portions of the B ring containing resonances discussed in this report The expected locations of these resonances[4 8] are indicated by arrows *a*, The C ring and the inner portion of the B ring *b*, The outer portions of the B ring, Cassini division and the A ring Optical depths between 1 95 and 1 983 R_S are preliminary due to present uncertainty in the spacecraft limit cycle in this region The resulting uncertainty in the Cassini division mass (Table 2) is perhaps as large as 50% Precise ring boundaries observed by the UV spectrometer are given in Table 2

Many of the identifications of ring resonances presented here rest on the absolute radial locations obtained for the associated features A brief discussion of the accuracy of these determinations is therefore appropriate For a star occulted by the rings, the location of observed ring features depends only on the apparent position of the star, the precise trajectory of the spacecraft relative to Saturn coupled with the timing of events, and the location of Saturn's rotational pole The uncertainty in the apparent position of δ Sco, after corrections for proper motion, parallax and aberration of starlight is negligible (<0 1 km in the ring plane) The trajectory uncertainty projected on to the ring plane is of the same order as the uncertainty due to the UV spectrometer time resolution, 2 4 and 3 2 km respectively The dominant uncertainty, at present, is due to the location of Saturn's rotational pole Errors in the location of ring features produced by this factor are difficult to estimate, but use of various pole locations derived from Voyager trajectory analysis as well as pre-Voyager determinations cause location changes of <20 km in the rings

Fortunately, it is possible to compare directly the distance scale used here with the locations of features seen in two additional stellar ring occultations observed with the UV spectrometer from Voyagers 1 and 2 These are a Voyager 1 observation of ι Herculis and the Voyager 2 entrance of δ Sco through the opposite side of the rings Both of these occultations extended out to 1 43 R_S ($1R_S = 60{,}330$ km) The locations of all recognizable features in these three occultations are in mutual agreement to within 12 km except for one ringlet known to be eccentric from imaging data If we make the reasonable assumption that this agreement is not just coincidence but rather a consequence of symmetry in this part of the C ring, then we can be confident of our absolute distances to this level Ultimately it should be possible to reduce the locational uncertainties to 6 km or better

Detected and undetected resonances

The recently discovered small inner satellites of Saturn[2], 1980S1, 1980S3, 1980S26, 1980S27 and 1980S28 all possess numerous resonances within the ring system Because of the small mass of several of these bodies only a fraction of these resonances are important Of these, the type I resonances due to the leading, more massive, co-orbital 1980S1 are trongly evident in the rings Figure 2 shows full resolution data for the six type I 1980S1 resonances seen in Fig 1 Three of these resonances display characteristic density wave structure (2 1, 5 4, 6 5) while the 3 2 and 4 3 resonances are more chaotic These will be discussed more fully together with other resonances in high optical depth regions of the rings, however, one point is unique to 1980S1 resonances The interchange of the orbits of 1980S1 and 1980S3 which occurs every 4 yr [11], changes the resonance locations of 1980S1 by 10–15 km A 'kink' in the wave train of approximately this magnitude will develop (S Tremaine, personal communication) and propagate outward at the wave's group velocity[7] In the ~960 days (ref 11) between the last interchange and our observations, these waves have travelled roughly 60 km from the 2 1 resonance of 1980S1 and over 100 km from the other type I resonances This effect may cause a slight error in our subsequent determination of the surface density at the 2 1 resonance The 7 6 resonance is coincident with the outer edge of the A ring The smaller co-orbital, 1980S3, has resonances which occur 30–45 km inward of the corresponding 1980S1 resonances These resonances are not apparent in our data

Features due to resonances with the two F ring shepherd satellites 1980S26 and 1980S27 are also present in our data (Fig 1) Many of the >50 type I shepherd satellite resonances in the rings are noticeable, particularly in the outer A ring We have included in this discussion only the 2 1 resonances with each of these satellites because they occur in low optical depth regions Because of their number and lower amplitude, discussions of the remaining 1980S26 and 1980S27 resonances will be presented elsewhere There are ~100 1980S28 type I resonances present in the rings, near the outer edge of the A ring they reach a separation of 9 km At present there is no evidence of any features due to resonances with this small satellite

The occultation data show clear evidence (Fig 3) of features corresponding to all three of the strong Mimas resonances present in the ring system The strongest and best known is the 2 1 resonance which has long been believed to be coincident

with the outer edge of the B ring The two additional Mimas resonances are the only known examples of type II resonances seen in the rings Apparently, the 0 02 eccentricity of Mimas is large enough to allow Mimas to exert sufficient torque to create observable features of the 5 3 and 3 1 resonance locations

The only apsidal resonance which we can definitely detect is the Titan 1 0 which occurs in the C ring (Fig 4) Hyperion and Iapetus, being much less massive and more distant than Titan, exert significantly less torque at their apsidal resonances so that our failure to observe features at these resonances is not surprising The density waves described by Cuzzi *et al*[5] near the Iapetus apsidal resonance are of too low an amplitude to be seen in our data The stated location of the wave source[5], however, is seen in Fig 1 as the inner edge of the band of low τ containing the Iapetus resonance The wave source and the resonance location are separated by ~370 km

Finally, we have examined our data for the presence of ring features associated with the predicted location of resonances with Saturn's rotational period The possibility of such resonances has been suggested by Franklin *et al*[4], who tentatively identified the locations of the 3 2 and the 3 4 rotational resonances with two prominent gaps in the rings seen in Voyager 1 images Our data (Fig 1) show the 3 2 resonance to be located at the outer edge, rather than the centre, of the gap suggested by Franklin *et al*[4] The 'gap' itself has a distinct non-zero optical depth and is similar in appearance to several other inter-ringlet regions in this part of the C ring The precise location of the 3 2 resonance falls at the inner edge of the 230 km-wide ringlet located at 1 434 R_S Doubt as to the significance of any link between the resonance and either the gap or ringlet is increased by the failure to observe the presence of the related 3 4 resonance Franklin *et al*[4] associated the 3 4 resonance with the prominent narrow gap between the Encke division and the outer edge of the A ring We find this gap to be located at 2 2627 R_S, 440 km outside the location of the resonance but within the ±700 km uncertainty of the Franklin *et al*[4] observational data At the location of the resonance itself we see no convincing evidence of any associated structure

Resonances in low τ regions

The morphology of ring features associated with the strongest resonances appears to be controlled by the local optical depth

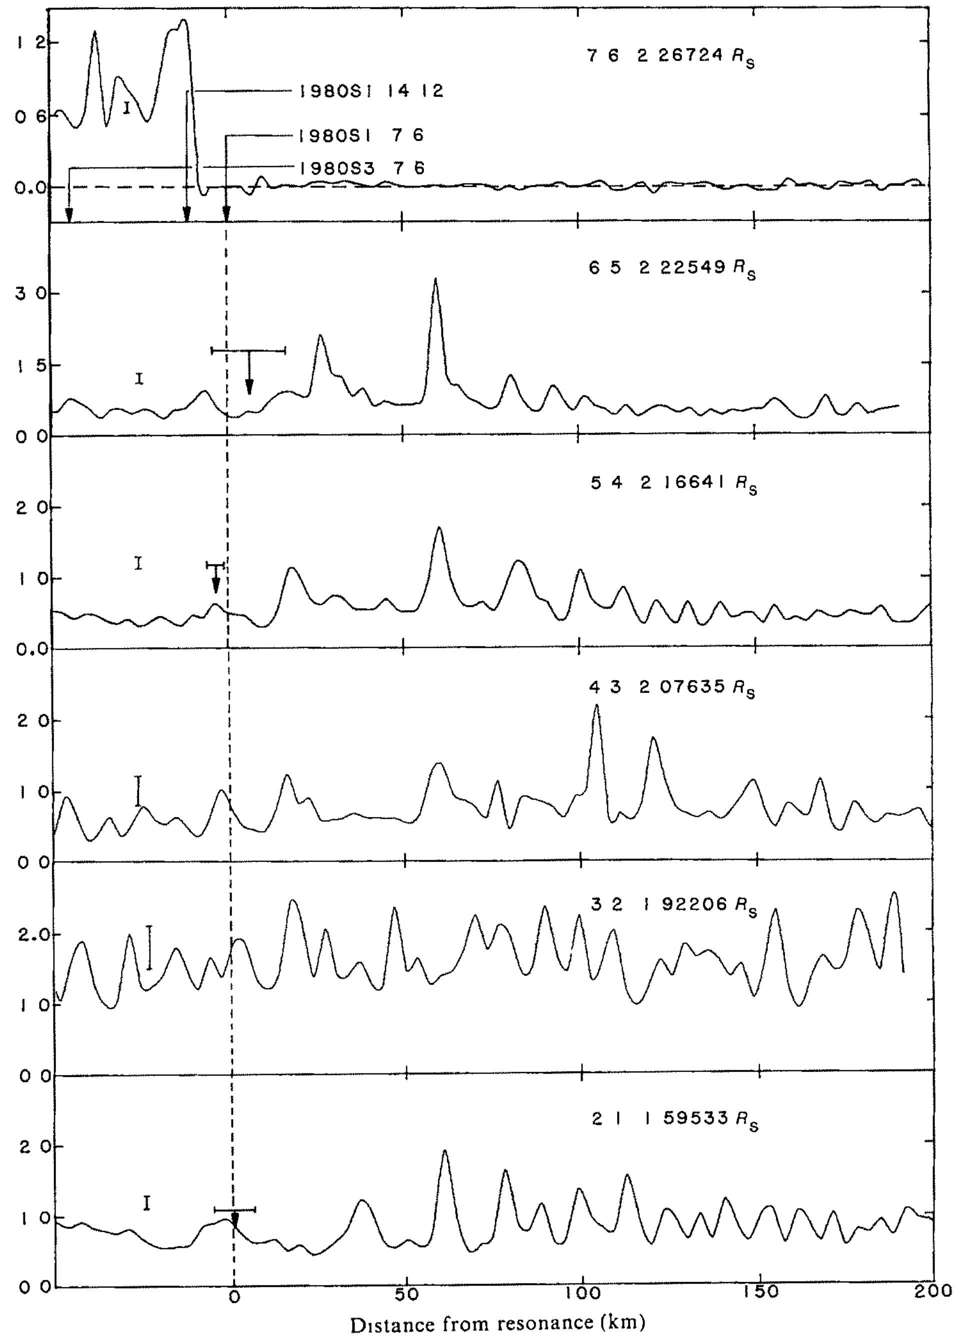

Fig. 2 The normal optical depths for regions located near the six type I resonances due to the co-orbital satellite 1980S1 The origin of the horizontal scale corresponds to the expected location of each resonance Spiral density wave patterns with characteristic damped waves of decreasing wavelength are seen exterior to the 2 1, 5 4 and 6 5 resonances The appearance of the rings at the 3 2 and 4 3 resonances is more chaotic Vertical error bars show the single sample noise level at the indicated τ Arrows and horizontal error bars show the resonance locations deduced from analysis of the density waves

Table 1 Ring features corresponding to resonance locations

Source	Resonance	Expected location (R_S)*	Surface density σ (g cm^{-2})	Opacity K (cm^2 g^{-1})	Type of feature
1980S27	2 1	1 47043			Narrow ringlet/gap
1980S26	2 1	1 49456			Narrow ringlet/gap
1980S1	2 1	1 59535	70±10	0 01±0 002	Density waves[6]
	3 2	1 92206			?
	4 3	2 07635			Disturbance

Iapetus	1 0	2 00867			? (Density waves[5])
Saturn	3 2	1 43163			Outer edge of gap?
	3 4	2 25543			None

* $1R_S$ = 60,330 km

† Measured outside region of enhanced surface density, densities in parentheses refer to region of enhancement

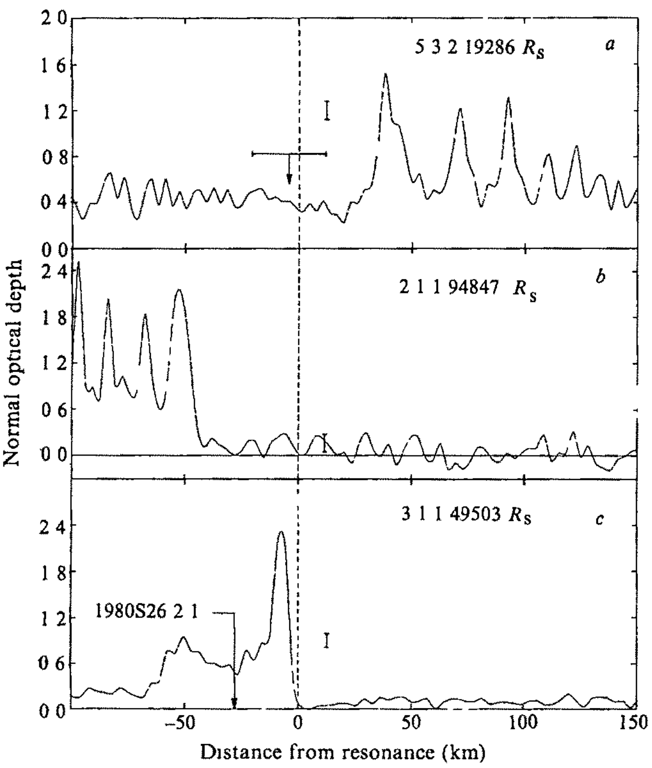

Fig 3 The normal optical depths for regions located near the three Mimas resonances The origin of the horizontal scale corresponds to the expected location of each resonance The 5 3 resonance (a) is an excellent example of density waves propagating outwards from a resonance location The 2 1 resonance (b) is located 48 km outside the outer boundary of the B ring but within the region over which this boundary is observed to vary[3] The 3 1 resonance (c) is located at the outer edge of a narrow ringlet in the C ring and may interact with the 1980S26 2 1 resonance to produce the sharp peak in the ringlet Note the near zero optical depth exterior to this ringlet Vertical error bars show the single sample noise level at the indicated τ The arrow and horizontal error bar near the 5 3 resonance indicate the location of the resonance deduced from analysis of the density waves

of the region in which the resonances reside Looking first at regions of low optical depth (τ<0 2), we note that there are three locations containing major resonances in the C ring (Fig 1) The Titan apsidal resonance lies farthest inward, while the 2 1 resonances with 1980S27 and 1980S26 are located near the outer edge of the C ring, the latter of these two being very nearly coincident with the Mimas 3 1 resonance (see Fig 3) All three of these resonances occur in regions characterized by a gap of lower than average optical depth containing a narrow optically thick ringlet The gap associated with the Titan apsidal resonance is several hundred kilometres wide and completely empty The 1980S27 resonance is situated in a region of lower than average, but apparently non-zero, optical depth while the region just exterior to the 1980S26 2 1 and Mimas 3 1 resonance is devoid of ring material to within our level of detection

The Titan apsidal resonance, the only one of these features for which there exist multiple UV spectrometer observations, is associated with a narrow, double-peaked, optically thick ringlet of substantial eccentricity[3,10] The two Voyager 2 UV spectrometer δ Sco occultations locate this ringlet at 111 km and 67 km exterior to the Titan apsidal resonance at longitudes separated by 149° and 3 53 h of time The 1980S27 2 1 resonance and the close pair formed by the 1980S26 and Mimas resonances are also associated with narrow, double-peaked, optically thick ringlets The Mimas 2 1 resonance at the inner edge of the Cassini division also manifests itself in a gap containing an opaque double-peaked ringlet In this case, not only is the ringlet eccentric but the inner edge of the gap also varies in radius and is shaped like an ellipse centred on Saturn[3] In the UV spectrometer data the outer edge of the B ring was located 48 km inside the theoretical location of the Mimas 2 1 resonance At the time of the stellar occultation Mimas, which controls the orientation of the B ring's outer edge, lagged the point of observation in the rings by a phase of 194° This datum, when combined with imaging measurements, should give a more precise picture of the location and shape of the outer edge of the B ring

We do not understand fully why resonances which occur in regions of low optical depth manifest themselves as gaps containing narrow double-peaked ringlets Resonantly induced collisions are more likely to clear gaps in very low τ regions[8], however, t is questionable whether τ is sufficiently low for this process to occur even in the C ring, also in most cases the size of the gap is larger than the collision predicted width Density

waves may also be more effective in clearing a gap in low surface density regions because they will quickly become nonlinear, depositing their negative angular momentum over a smaller region[7] A complete theory of these gaps must involve the opaque ringlets embedded within them These ringlets, which seem to be characterized by a double-peaked structure similar to some of the uranian rings[12], also occur within some non-resonant gaps in the C ring Imaging data will be important for the determination of the azimuthal structure of these ringlets as well as the gap edges

Resonances in regions of medium and high τ

The predominant effect of resonances in regions where τ is between 0 4 and 1 0 is the excitation of density waves We have selected for analysis the four clearest examples of such density waves, those associated with the Mimas 5 3 resonance (Fig 3), and the 6 5, 5 4, and 2 1 resonances with 1980S1 (Fig 2), the 2 1 having been previously studied by Lane *et al*[6] The two other 1980S1 type I resonances are noisier in our data The 4 3 occurs in the inner and most opaque part of the A ring and clearly causes some stirring but a clean wave pattern is not present The 3 2 occurs in a high τ region of the B ring and is not immediately evident in our data At present it is unclear whether the lack of observable density waves in the highest τ regions is due to their absence, their confusion with the crowded ringlet structure of the B ring[2] or simply our low signal level when τ becomes very large

One of the theoretical predictions concerning the development of density waves near a resonance is the opening of a gap just exterior to the resonance[7] Not only do we find no evidence of density waves clearing gaps, the average τ in resonance regions is in general higher than that of surrounding regions Density waves seem to damp and thereby deposit negative angular momentum over a region of several hundred kilometres, so it may be that material is brought inwards towards a resonance faster than it can be cleared from the region by damping of the first wave An equilibrium may be reached when surface mass density (σ) is increased enough for viscous diffusion out of the region to create a balance Another possibility is that collisions alter the particle size distribution by increasing the numbers of small particles, thereby increasing τ

The density waves excited at the Mimas 5 3 and at the 1980S1 type I resonances are also quite highly nonlinear (shocked) for the first few wavelengths These waves have a distinctly non-sinusoidal character with a sharp peak at the location of the shock and a broad flat trough (see ref 13 for a theoretical analysis of nonlinear density waves in galaxies)

Density waves are a very useful tool for deducing such ring properties as surface mass density and viscosity, unmeasurable by any other currently available means[5,6], however, some caution must be exercised First, the shocking of the waves removes a great deal of their angular momentum, thus viscous damping plays a minor part and any measure of viscosity from wave damping would only constitute a crude upper bound (a slight phase shift also results when the waves shock, thus changing the apparent wavelength between crests, however, this small effect should not significantly affect our estimates of σ derived in equation (1)) Second, the mean (wavelength-averaged) surface density can be non-uniform over the region of a particular wave train (we see evidence of this in the A ring) This may lead to problems in the determination of the resonance location as the mean resonance wavelength decreases as σ/d, where d

Table 2 Ring mass

Ring	Boundaries (R_S)	Mass ($10^{-8} M_S$)
C	1 2342–1 5259	0 2
B	1 5259–1 9477	5 0
Cassini division	1 9477–2 0232	0 1
A	2 0232–2 2676	1 1
	Total	6 4

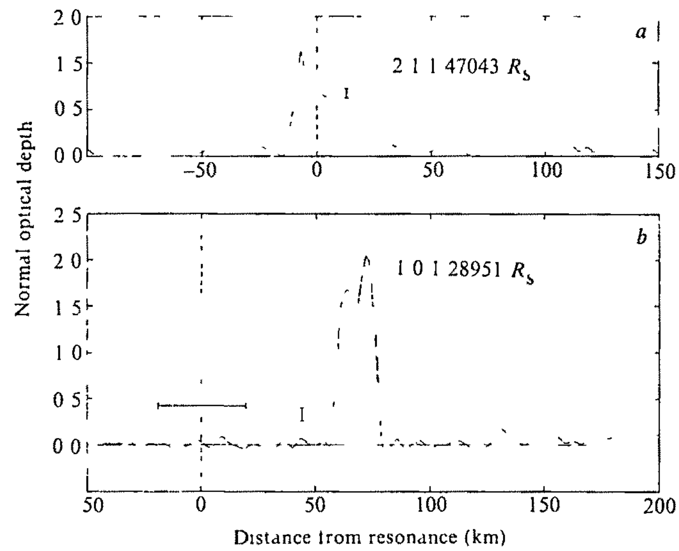

Fig 4 The normal optical depths for regions located near the 1980S27 2 1 (a) and Titan apsidal resonances (b) The origins of the horizontal scales correspond to the expected location of each resonance The horizontal error bars corresponding to the Titan apsidal resonance location are due to the uncertainty in Saturn's zonal harmonics[15] The vertical error bars in each panel show the single sample noise level at the indicated τ

is the distance from the resonance[14] A more severe problem would develop from changing σ if we were to try to determine viscosity, because the wave amplitude can change significantly with changes in σ

With these cautions in mind we proceed to determine σ and the opacity K via the following relations

$$\sigma(\mathrm{g\,cm^{-2}}) = \frac{0\ 325(m-1)\lambda d}{R^4} \quad (1)$$

$$K(\mathrm{cm^2\,g^{-1}}) = \frac{\tau}{\sigma} = \frac{R^4}{0\ 325(m-1)d}\frac{\tau}{\lambda} \quad (2)$$

where R is the resonance location in Saturn radii, and the wavelength λ and the distance from the wave source d are measured in kilometres We find that all three of the A ring density waves exhibit strong enhancements of local (wavelength-averaged) τ over the initial 100 km of each wave train, indicating that density waves cause changes in local σ or K We therefore analysed our data separately assuming constant α and constant K The assumption of constant σ (equation (1)) does not provide an adequate fit to the observed wavelengths as a function of d The assumption of constant K does, however, give a satisfactory fit to the data On this assumption, the quantity τ/λ in equation (2) is determined from the observed wavelength-averaged τ for each wave The A ring results for K and σ given in Table 1 and the wave source locations shown in Figs 2 and 3 are based on the constant opacity assumption

Ring boundaries and ring mass

As we have noted previously, the 7 6 resonance is in extreme proximity to the outer edge of the A ring (Fig 2) We feel it is not chance that the second strongest resonance in the rings should coincide with the outer edge of the ring system while the strongest resonance, the Mimas 2 1, lies at the outer boundary of the B ring Satellites exert a torque on particles at resonances, removing angular momentum from them and thus pushing the particles closer to Saturn A similar satisfactory explanation of the inner boundaries of the major rings is not yet available

A detailed study of the outer edge of the A ring requires azimuthal coverage available only from imaging data We would expect a seven-lobed pattern in analogy with the two-lobed

oval pattern seen at the Mimas 2 1 resonance Observation of more frequently spaced undulations in the outer edge of the A ring boundary would be indicative of the effects of the higher m-order resonances present in the region (Fig 2)

Our determinations of surface mass density at three points in the A ring constitute the first such measurements for this ring Our single mass density measurement in the B ring at the 1980S1 2 1 resonance is in good agreement with the 60 g cm^{-2} at this resonance obtained earlier by Lane *et al*[6] All of our surface densities are consistent with a constant ring opacity of 0 01 $cm^2\ g^{-1}$, as are prevous measurements[5,6] Using this result, together with our optical depth atlas, we can estimate ring masses as follows

$$M_{\rm ring} = 2\pi \int_{R_i}^{R_0} \sigma r\, dr = 2\pi \int_{R_i}^{R_0} \frac{\tau r dr}{K} = \frac{2\pi}{K} \int_{R_i}^{R_0} \tau r\, dr \qquad (3)$$

where $M_{\rm ring}$ is the total mass of the ring, r is a radius in the ring and R_i and R_0 are the inner and outer ring boundaries, respectively The results of these integrations for the major rings are given in Table 2, together with UV spectrometer measurements of the ring boundaries Our determination of the B ring mass may be underestimated due to the fact that we have assumed a maximum optical depth of $\tau = 2\ 85$ over the 15% of the B ring where we see no stellar signal Measurements from other Voyager instruments may help to establish accurate optical depths in these regions The A ring may also be more massive if the opacities we determine at the resonances are higher than the rest of the A ring due to an enhancement of small particles produced by collisions in the shocked region of the density waves

We find the total mass of the ring system to be 6 $4\times10^{-8}\ M_S$, approximately the same mass as Mimas Assuming uniform ring opacity, this total mass could be in error by perhaps 30% The best previous estimate of the mass of the rings was the upper limit of $170\times10^{-8}\ M_S$ from the Pioneer 11 gravity results[15] Our much smaller measurement indicates that an actual measurement of ring mass is probably unobtainable from existing spacecraft gravity measurements

Conclusions

We have shown that resonances are associated with a wide range of morphological features in the rings In low optical depth regions such as the C ring and inner Cassini division they are linked with gaps containing narrow double-peaked ringlets, while in higher τ regions they appear as density waves and wave-like disturbances The two strongest resonances are coincident with the outer edge of the B ring and the outer edge of the A ring Known resonances have a major role in determining the structure of the A ring but can explain only a small fraction of the observed features in the B and C rings, where resonances are less frequent We have analysed the four density wave trains to determine their point of origin and the local surface mass density These estimates of surface mass density in combination with our optical depth atlas make possible an estimate of the total mass and mass budget of the ring system

Stratospheric condensation nuclei variations may relate to solar activity

D. J. Hofmann & J. M. Rosen

Department of Physics and Astronomy, University of Wyoming, Laramie, Wyoming 82071, USA

Observations of increases of stratospheric condensation nuclei suggest a photo-initiated sulphuric acid vapour formation process in spring in polar regions It is proposed that the sulphuric acid rapidly forms condensation nuclei through attachment to negatively charged multi-ion complexes and that the process may be modulated through variations in solar activity

THE possible connections between solar variability and the weather on the one hand and climate on the other have been widely debated[1,2] In studies of the correlation of solar activity with both weather and climate, there has been little or no experimental evidence to show by which mechanism minute changes in solar energy incident at the Earth's orbit may be transformed to observed weather or climate variations A direct coupling through variations in the solar constant has generally been discarded in favour of a triggering mechanism which utilizes charged solar corpuscular radiation The latter may take the form of solar control of galactic cosmic radiation through the waxing and waning of solar magnetic irregularities in the interplanetary medium The triggering mechanism may also appear as direct magnetospheric intrusion of solar flare accelerated charged particles and/or energetic electrons released from the magnetosphere by enhanced geomagnetic activity due to active Sun processes

The intermediary in the solar variation–weather connection may be the stratospheric ozone layer which can be depleted by the production of nitric oxide during charged particle bombardment (solar or galactic) of the upper atmosphere and thereby may affect the intensity of solar UV radiation in the Earth–atmosphere system It may also take the form of the creation of atmospheric ionized species through charged particle bombardment which alter the electrical characteristics of the atmosphere and thereby modulate the occurrence of thunderstorms

One of the more effective ways of altering climate, variations in cloudiness or the particulate content of the atmosphere, has perhaps the least amount of observational support as far as solar activity correlations are concerned Increased strato-

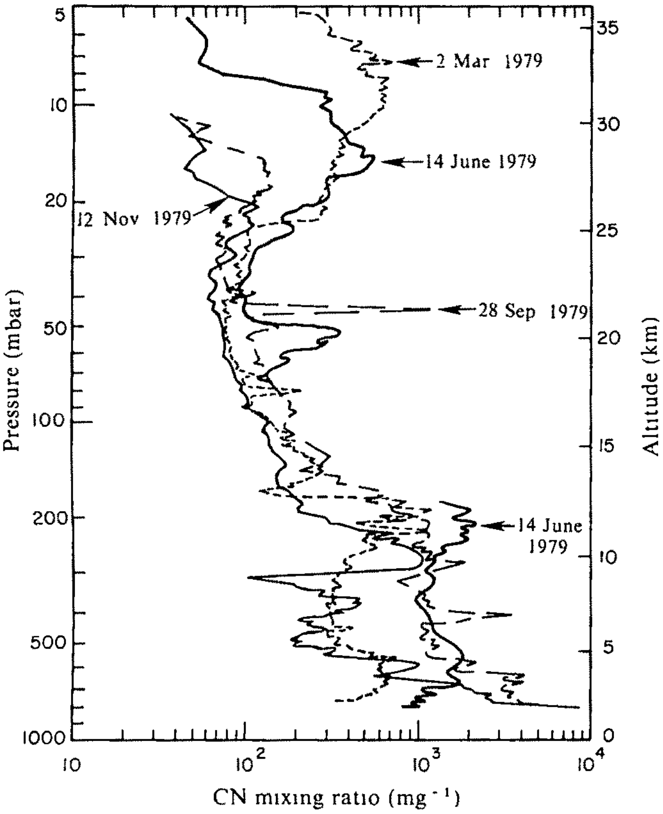

Fig. 1 Condensation nuclei ($r \geq 0.01$ µm) mixing ratio profiles during 1979 showing the time variation of the high altitude event

spheric particulates, due to volcanic eruptions, are capable of heating the stratosphere and cooling the surface Thus, any mechanism which can create material particles in the atmosphere is a likely candidate for climatic studies

Ney[3] suggested that the logical place to look for solar–weather effects was the solar modulation of galactic cosmic radiation Later Roberts and Olson[4] proposed that atmospheric ions may serve as condensation nuclei (CN) for the formation of cirrus clouds in the 10–12 km region, thus forming a solar activity connection with climate Dickinson[5] proposed that ions formed by the galactic cosmic radiation may be important in the formation of stratospheric sulphuric acid aerosol which, in turn, could nucleate cloud droplets in the upper tropospheric environment With primary ionization control ascribed to the galactic cosmic radiation, minimal ion density at solar maximum would suggest fewer growth sites, less competition for the available sulphuric acid vapour and thus larger though fewer particles at this time

The formation of stratospheric aerosol through ions has largely been neglected Thus, the stratospheric aerosol formation models of Rosen *et al*[6] and Turco *et al*[7] included only a tropospheric source of pre-existing CN which diffused into the stratosphere and served as sites for larger aerosol particle growth by accretion of sulphuric acid vapour This assumption of a tropospheric source of CN was justified by the measurements[8,9] wherein the CN mixing ratio peaked just below the tropopause and fell off sharply in the stratosphere However, the observation of an essentially constant, albeit low, mixing ratio from 20 km to the highest altitude of observation (~32 km) left some room for speculation that a high altitude source (for example, meteoritic) may be operative

The possibility that this source could be ionic in nature was not considered because even at typical stratospheric ion concentrations of 5,000 cm^{-3}, ion-induced nucleation cannot compete with heterogeneous nucleation on pre-existing particles for typical stratospheric particle concentrations[10] and only following major solar flare particle events (which are very rare), can ion induced nucleation be important

Recent observations have cast new light on this problem Following the initial stratospheric ion-mass spectrometer measurements[11], Ferguson[12] interpreted the results as indicating the clustering of ions, forming stable ion pairs, and suggested their possible importance in nucleation processes in the stratospheric sulphate layer

Arnold and Henschen[13] followed the initial positive ion measurements with measurements of negative ion clusters which suggested the presence of sulphuric acid in these clusters Arnold[14] suggested that attachment of free ions to these clusters could lead to larger multi-ion complexes (MIC), or that they may even mutually coalesce He suggested that formation of MIC and subsequent growth could result in a gas-to-particle conversion mechanism which does not require high gas supersaturations In the presence of a supersaturated gas, such as sulphuric acid vapour, MIC which have grown to embryonic size could act as condensation nuclei Arnold and Henschen[15] found a pronounced layer of MIC at 30 km having masses in excess of 327 AMU and labelled them 'pre-condensation nuclei' These new observations have prompted us to examine some of our recent stratospheric particle observations, the results indicating that a high altitude ion–CN relation may exist

Observations

We have recently reported[16] the observation of an unusual increase in the CN ($r \geq 0.01$ µm) concentration above 25 km which lasted about 6 months in 1979 (March through September) and some evidence for its repetition in March, 1980 at Laramie (41°N) Measurements were made using a balloon-borne thermal growth chamber, attached to a light scattering particle counter In 1979 the increase was peaked at ~32 km with a mixing ratio of ~650 mg^{-1} above a normal background of ~30 mg^{-1} at this altitude (a concentration of ~9 cm^{-3} above a background of ~0 4 cm^{-3})

No attempt was made to explain the nature of this event as it was not conclusive if the feature was really annual on the basis of the data at hand Earlier measurements probably would not have detected such an annual event, if it existed, because the CN growth chamber only functioned satisfactorily to an

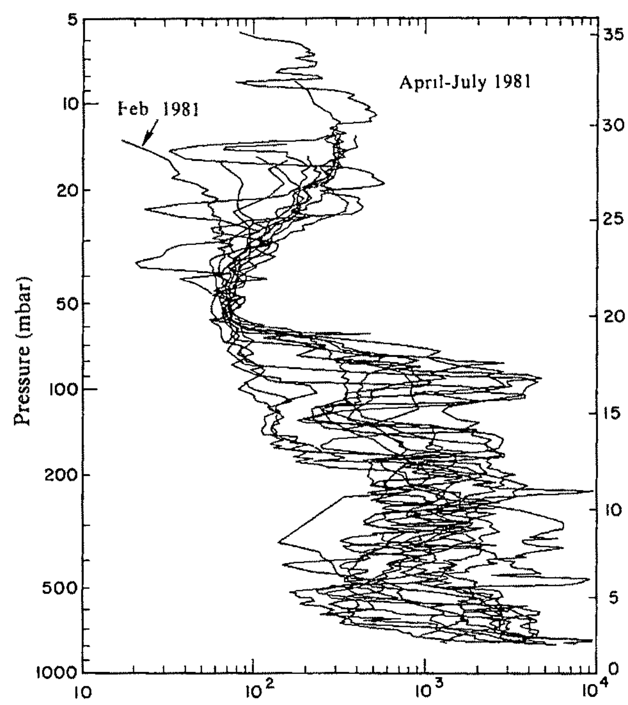

Fig. 2 Condensation nuclei ($r \geq 0.01$ µm) mixing ratio profiles during 1981 showing the high altitude event Enhanced CN layers in the 13–18 km region were due to the volcanic eruption of Alaid on 28 April 1981

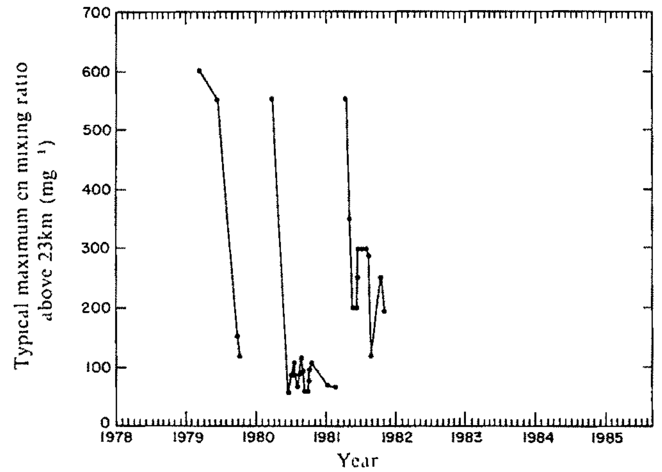

Fig. 3 Condensation nuclei ($r \geq 0.01$ µm) time variation showing the occurrence of the springtime events at Laramie.

altitude of 25 km (refs 8, 9). The 1980 investigations were complicated by the eruption of Mt St Helens in May 1980 and while numerous measurements were made, smaller balloons were used to study the 20–25 km effects of Mt St Helens and the 30–35 km region was not effectively studied until September when CN levels appeared normal[17].

Five soundings during 1979, shown in Fig. 1, indicated that the excess CN decayed exponentially with a e^{-1} time of 130 days. As the layer decayed, the mixing ratio peak appeared at successively lower altitudes, finally blending into the background at about 25 km. Initial attempts to explain the event as being due to the burnup of a large piece of space junk in the atmosphere were rapidly discarded. One tonne of such material, distributed uniformly in a 10-km thick cloud with a particle concentration of 10 cm^{-3} (mixing ratio of 600 mg^{-1} at 30 km) would have a horizontal extent of only 38 km for particle sizes of 0.07 µm (typical CN sizes in the unperturbed stratosphere) and 700 km for sizes of 0.01 µm, a lower limit of detection for the instrument. Such a small cloud would not have been detected on all five CN flights conducted in 1979. Considerations of a large meteor would result in the same conclusions. The observation that the CN mixing ratio displays a well defined maximum between 25 and 35 km further rules out objects entering the atmosphere from space. The latter, if observable, would display a broad mixing ratio maximum extending to great altitudes. It was considered more likely that the layers observed in 1979 were all derived through *in situ* production at their origin but that variable transport from a source region resulted in the observed characteristics.

In 1981 the high altitude enhancement did not seem to be present in February, at least in the 25 km region, but it was very apparent in April and persisted through 12 subsequent soundings. The data are shown in Fig. 2. Some complications resulted from the volcanic eruption of Alaid in the Kurile Islands in April 1981 but these disturbances were restricted to the 13–18 km region[18]. Figure 3 shows the high altitude CN mixing ratio versus time and clearly demonstrates the periodic nature of the events.

Discussion

The observation that the CN events are seasonal, favours variable transport to midlatitudes from a remote source region as there is no known seasonally varying production source at midlatitude. Little is known about the nature of meridional transport or its seasonal variations at altitudes in the 30 km region. If one associated possible meridional transport with regions of high wind speed, then likely candidates at 30 km in the Northern Hemisphere are the polar vortex region at 50–80° N during December–February ($v = 20$–40 m s^{-1}) and the region 0–30° N during June–August ($v = 20$ m s^{-1}) (ref. 19). In view of our observation that the enhanced CN layers appear in March, the polar regions appear to be the most promising. In addition, soundings in Panama (9° N) in 1976 and 1977 and in Brazil (5° S) in 1978 did not reveal excess CN mixing ratios in the upper stratosphere although the CN detector used then was suspect above 25 km (ref. 9).

In view of the more probable source region for the CN enhancements being at high latitude, and the fact that multi-ion complexes have been observed in a layer at the same altitude as the CN enhancements appear, we feel that there may be a logical connection between the two and thus possibly a connection between solar activity and stratospheric aerosol formation.

The enhancements are not observed until March at the earliest while the polar vortex 30 km wind system is operative throughout winter. This suggests that excess CN may not be formed at 30 km during the polar winter night but begin to form in spring. Thus a sunlight effect in the formation of CN appears to be a possible mechanism.

As large aggregate negative ion clusters contain sulphuric acid, and since stratospheric CN is largely volatile at 150 °C, suggesting a sulphuric acid composition[16], it seems possible that a sunlight effect may be manifested through the photochemical production of sulphuric acid. Thus we propose that production of the acid is limited during the winter night while sulphur-bearing precursor gases such as SO_2, following volcanically active periods, or OCS, during background conditions[20], are transported poleward and build up along with O_3. Sulphuric acid may be formed following the oxidation of SO_2 either by OH or O. For relative humidities >1%, OH formed through the photodissociation of O_3

$$O_3 + h\nu \rightarrow O(^1D) + O_2$$

$$O(^1D) + H_2O \rightarrow OH + OH$$

is the dominant oxidizing agent while at lower relative humidities, ground state atomic oxygen, formed through the photodissociation of O_2 and O_3, is dominant[21]. In addition, because at least one of the initial steps in the conversion of OCS to sulphuric acid in the stratosphere involves photolysis

$$OCS + h\nu \rightarrow CO + S$$

it appears likely that sunlight reaching the polar stratosphere

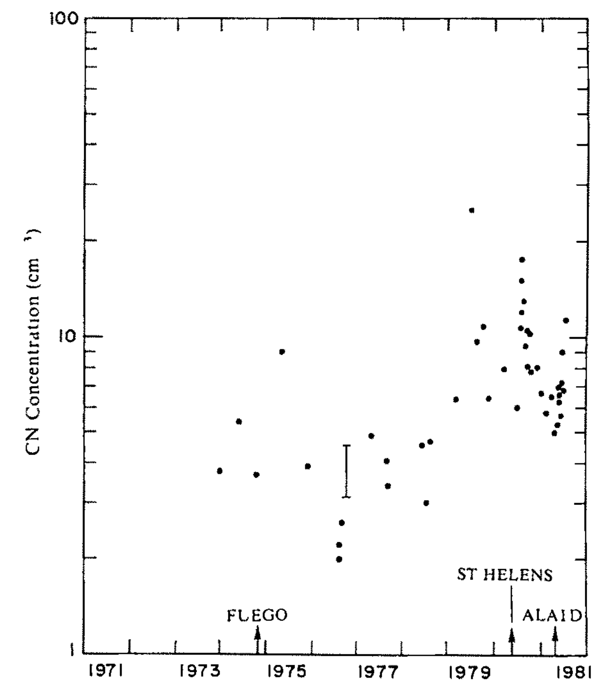

Fig. 4 The condensation nuclei concentration at 20 km as a function of time since measurements began at Laramie in 1973. The vertical bar is the range of concentration observed in four soundings over a 12-day period. The arrows indicate major volcanic eruptions which perturbed the stratospheric $r \geq 0.15$ µm particle concentration.

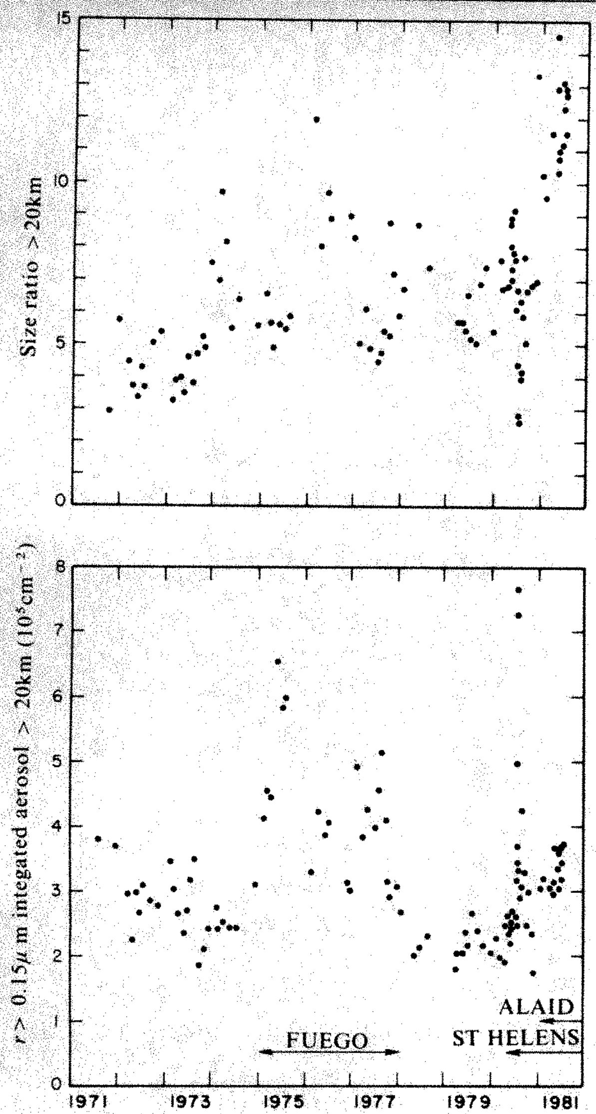

Fig. 5 $r \geq 0.15$ μm particle loading and the ratio of $r \geq 0.15$ μm to 0.25 μm particle loading above 20 km as a function of time since measurements began at Laramie in 1971. Periods when the stratospheric aerosol was perturbed by volcanic eruptions are indicated.

in spring would enhance the production of H_2SO_4 and allow ion complexes to grow rapidly into CN and subsequently be transported to middle latitudes beginning in March.

As the formation of CN in this model is related to multi-ion complexes, it may be related to solar activity which modulates the atmospheric ion density through modulation of the galactic cosmic radiation intensity, large solar flare accelerated particle events, and enhanced auroral activity or precipitation of energetic electrons during geomagnetic activity.

To investigate these speculations, measurements of MIC, CN and larger aerosol at 30 km are required over a solar cycle. Our measurements of CN date back to 1973 and of larger aerosol ($r \geq 0.15$ μm) to 1971. Balloon altitudes in the 27–29 km range were generally attained. Volcanic effects can be large in the 20-km region especially for the larger aerosol. CN are also affected by volcanic eruptions, but these effects are comparatively shortlived due to rather rapid coagulation of these small particles with themselves and with the larger aerosol. While the CN detector functioned satisfactorily only to ~25 km before 1979, CN data at 20 km are reliable and relatively free of volcanic perturbations.

Thus, of the data at hand, it would appear most fruitful to examine the time variation of the CN concentration at 20 km for solar cycle effects. These data are shown in Fig. 4. There seems to be an increasing trend which was evident even before the eruption of Mt St Helens which severely disturbed stratospheric CN concentrations from June to August 1980 at 20 km. The higher concentrations seem to occur at the time of maximum solar activity. In fact, the increasing trend may simply be the result of an accumulation of high altitude events over the past several years. Most of the increase has taken place since early 1979; sunspot maximum occurred in December 1979.

Thus there seem to be more particles at solar maximum, at least for the CN size range. We can investigate the size aspect for the larger aerosol from $r \geq 0.15$ μm measurements. By measuring two sizes ($r \geq 0.15$ and 0.25 μm), we can calculate a size ratio (ratio of the concentrations of the two sizes) which will vary as the size distribution varies. Statistics are poor above 25 km, but if one integrates the concentration above 20 km, a reasonable set of data can be obtained. Figure 5 shows integrated concentration or particle loading (particles cm^{-2}) above 20 km for the $r \geq 0.15$ μm particles and the ratio of loading for $r \geq 0.15$ μm to $r \geq 0.25$ μm for all soundings which reached altitudes in excess of 27 km.

The period 1975–77 was severely disturbed at 20 km by the volcanic eruption of Fuego[22] and the period after May 1980 by the Mt St Helens eruption[17] and the Alaid eruption in April 1981[18]. The period 1978–early 1980 appears to have been free from volcanic eruption.

Sunspot numbers were about 40 in 1973 compared with 140 in 1979 so that the 1972–74 data would represent solar inactive conditions and the 1978–80 data an active solar period. The data in Fig. 5 do not indicate sizable trends between these periods. The size ratio suggests a general trend towards smaller particles (a higher ratio) during the active period. This would accord with the observed increase in condensation nuclei over the period and thus refute Dickinson's hypothesis that ionization control of CN formation could be through the galactic cosmic radiation.

While volcanic effects seem to muddle the interpretation, they may also be used to clarify stratospheric conditions for particle growth between periods. A noticeable effect has been that particles which formed in the stratosphere following the eruption of Fuego in 1974 were substantially larger than those which formed following the eruption of La Soufriere and Sierra Negra in 1979, St Helens in 1980 and Alaid in 1981. The ratio of $r \geq 0.15$ μm to $r \geq 0.25$ μm particle concentrations at the stratospheric maximum was typically 3–4 following the Fuego eruption, 5–6 at background in 1978–79 and 6.5–7.5 following the La Soufriere–Sierra Negra, Mt St Helens and Alaid eruptions. Thus the data are consistent with smaller particles forming during solar maximum periods.

The parameters which control the size to which particles grow in the stratosphere are the amounts of H_2SO_4 and H_2O vapours available and the number of condensation sites present. While the Fuego eruption may have injected relatively more vapours than the other eruptions, it is of interest that the background CN levels were considerably higher at the time of the recent eruptions compared with the time of the Fuego eruption. Higher levels of condensation sites would result in generally smaller particles due to increased competition for the available sulphuric acid and water vapour. Thus, if increased ionization activity during solar maximum results in enhanced levels of ion complexes which form CN, then one would expect volcanically created particles to be smaller during solar maximum, as has been observed.

Conclusions

If solar activity directly affects the stratospheric aerosol, then this influence is probably most readily observable in the number of CN present in the upper stratosphere so that continued monitoring of this important constituent at the highest altitudes is imperative. It appears that a possible mechanism, which

relates ionization produced during solar active periods to the production of CN, now exists and can be used as a basis for further study of this possibly climatic related phenomenon.

Expression of two proteins from overlapping and oppositely oriented genes on transposable DNA insertion element IS*5*

Bodo Rak, Monika Lusky* & Majka Hable

Institüt für Biologie III der Universität Freiburg, Schänzlestrasse 1, D-7800 Freiburg, FRG

IS5, the 1,195 base pair transposable DNA element of Escherichia coli, *contains two genes. One gene, which encodes a protein with an apparent molecular weight of 12,300, is, together with its promoter, completely contained within a larger gene which encodes a protein of molecular weight 37,000. The two genes are transcribed in opposite directions.*

TRANSPOSABLE DNA elements have been found in prokaryotic and higher cells (for recent reviews, see refs 1–3). Although there is a large body of information on structural and genetic properties of these elements, the process of transposition itself remains to be elucidated. The differences in the structural organization of various transposable elements may be an indication of differences in at least some of the reaction steps involved in transposition. Several models of transposition propose a two-step reaction[4,5]. In the first step, a transposition intermediate with co-integrated donor and recipient DNAs is formed (provided both molecules involved are circular DNA molecules). Co-integrated molecules have been detected in the cases of Tn*3*[6], IS*1*[7], IS*903*[8] and several others. In the second step, the co-integrated intermediate is resolved. General recombination or, as has been shown for Tn*3*[6], site-specific recombination in recombination-deficient (*recA*) cells, can perform this step. This pathway of transposition is now widely accepted for Tn*3*, although it is still unclear for other elements. In the 5,000 base pair (bp) element Tn*3*, the region carrying the functions required for transposition is at least 3,800 bp long and contains two genes plus an internal resolution site (IRS) for site-specific recombination[6,9–11]. Tn*501* and Tn*1721*[12,13] appear to be similarly organized and, together with Tn*3* and several others, constitute one class of large transposable elements. A different model for transposition, not requiring a co-integrated structure as an intermediate, has recently been proposed for the transposable element *mu* (the 38,000 bp genome of bacteriophage Mu) on the basis of electron microscopic observations[14].

An additional class of transposable elements is represented by the insertion (IS) elements, the first transposable elements to be discovered in *Escherichia coli*[15,16]. They are considerably smaller (800–1,500 bp) and do not carry any detectable phenotype although they are autonomously transposable. The mechanism of transposition of IS elements remains to be elucidated, but their genetic organization is expected to differ from that of the large transposable elements of the Tn*3* type mainly because their coding capacity is restricted. Recent determinations of the DNA sequences of several insertion elements (IS*1*, IS*2*, IS*4*, IS*5*, IS*903* and IS*102*)[8,17–23] have revealed an open reading frame extending over most of the elements' lengths. A corresponding protein has only been detected for IS*4*[24]. Interestingly, all these elements also possess a second, shorter reading frame of significant length and totally contained within the first one. This reading frame is in opposite orientation to the longer one and has the same codon–codon register. Here we present evidence for the simultaneous expression of two proteins from both opposing reading frames on IS*5* under the control of element-coded transcription and translation start signals.

Two promoters on IS*5* precede the large and small reading frames

Analysis of the DNA sequence of insertion element IS*5*[20–22] revealed two overlapping reading frames in opposite orientations. If both reading frames represent functional genes they must be preceded by start signals for transcription and translation. To test IS*5* for potential promoters we cloned different IS*5* DNA fragments in front of a structural gene whose gene product could easily be measured and which did not possess a promoter. Plasmid vector pKO1 (ref. 25), which carries the galactokinase structural gene without a preceding promoter sequence, was used. Readthrough of ribosomes from any gene that may be inserted proximal to the galactokinase gene is prevented in this vector by nonsense codons in all three reading frames. DNA sequences inserted into restriction sites in front of the galactokinase gene could thus be tested for promoter

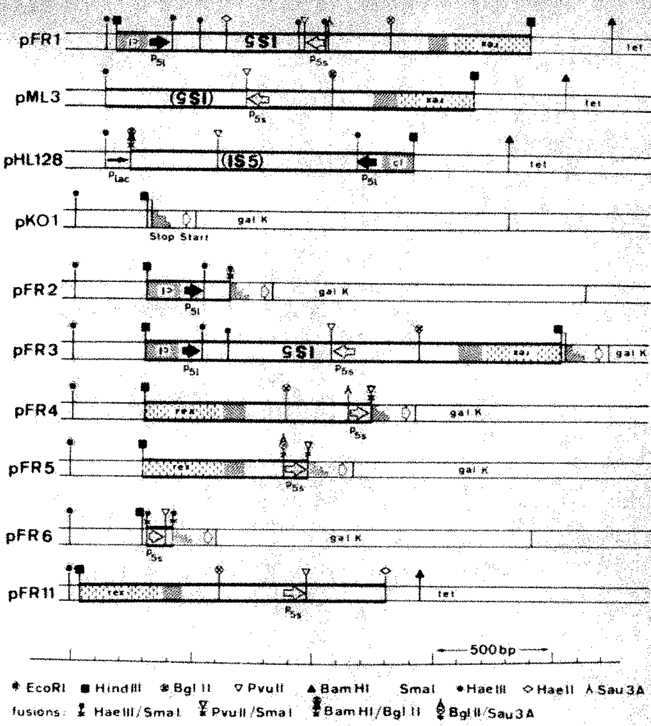

Fig. 1 Relevant structures and restriction sites of plasmids used. Note that the right arm of IS*5* is defined as the one carrying the *Eco*RI recognition site. A 1,720 bp *Hin*dIII fragment including the entire IS*5* element[32] was prepared from λKH100:IS*5* DNA[26] and ligated into the *Hin*dIII site of the vector pML2 to yield pFR1. Plasmid vector pML2 is a derivative of pBR322 in which a DNA fragment from position 1,095 to 2,485 (ref. 46) is deleted (ref. 47 and M.L., unpublished). Plasmid pML3 was obtained by *in vitro* deletion of the small *Eco*RI fragment of pFR1. The construction of pHL128 has been described earlier[32]. Plasmid pKO1 (ref. 25) consists of a segment of pBR322 DNA from the *Pvu*II restriction site at position 2,067 (which is destroyed) to the *Eco*RI site at position 4,361 plus the galactokinase gene. Single restriction sites for *Eco*RI, *Hin*dIII and *Sma*I are located proximal to the galactokinase gene, followed by translation stop codons in all three reading frames ( ). A translation start sequence precedes the galactokinase gene (⇒). There is no proximal promoter sequence that could give significant transcription of the galactokinase gene. Plasmid pFR2 was constructed by substituting the 17 bp *Hin*dIII–*Sma*I fragment of pKO1 with the 357 bp *Hin*dIII–*Hae*III fragment of pFR1 containing the right end of IS*5* up to the first *Hae*III site (IS*5*: 1,195–980, IS*5* sequence coordinates as in refs 20, 21). Plasmid pFR4 was similarly constructed, but the *Hin*dIII–*Pvu*II fragment of pFR1 containing the left end of IS*5* (IS*5*: 1–517) was used as the substituting fragment. For the construction of pFR3, pKO1 was cut with *Hin*dIII, treated with calf intestinal alkaline phosphatase and ligated with the *Hin*dIII fragment of pFR1, which contained the entire IS*5* element. To construct pFR5, plasmid pFR1 DNA was digested with *Hin*dIII, *Bgl*II and *Pvu*II and the resulting fragments were separated on a 1.2% agarose gel. The 585 bp *Hin*dIII–*Bgl*II fragment and the 359 bp *Bgl*II–*Pvu*II fragment were eluted[48], and the 359 bp fragment was digested with *Sau*3A, resulting in two fragments of 251 and 108 bp respectively. The fragments were separated on a 7.5% polyacrylamide gel and the 108 bp *Sau*3A–*Pvu*II fragment was eluted[49]. It was then mixed with the 585 bp *Hin*dIII–*Bgl*II fragment and pKO1 DNA deleted for the 17 bp *Hin*dIII–*Sma*I fragment and the mixture was ligated. Lysates of independent transformants[50] were analysed for the structures of the plasmids present using *Sau*3A digests as well as *Hin*dIII–*Taq*I and *Hin*dIII–*Hae*II double digests. To construct pFR6, a 975 bp *Hin*dIII–*Bst*EII fragment (which contains the left end of IS*5* up to IS*5*:548; the *Bst*EII site lies 8 bp to the right of the *Hae*III site at IS*5*:540, not marked in the figure) was isolated from pFR1 DNA. This DNA fragment was digested with *Hae*III and the resulting fragments separated on a 7.5% acrylamide gel and eluted. The 105 bp fragment bordered by the *Hae*III sites at IS*5*:435 and IS*5*:540 was ligated into pKO1, cut with *Sma*I and treated with calf intestinal alkaline phosphatase. Small lysates from individual transformants were analysed by double digestion with *Eco*RI and *Pvu*II and with *Taq*I and *Pvu*II. Plasmid pFR11 was constructed as follows. (1) The IS*5*-containing *Hin*dIII fragment of pFR1 was inverted by digestion of pFR1 DNA with *Hin*dIII and re-ligation. (2) The plasmid containing the inversion (pFR8) was digested with *Bst*EII and *Bam*HI, and both resulting fragments separated on a 0.8% agarose gel and eluted. (3) The smaller of the two fragments, containing IS*5*:543–1,195, the λ*cI* part plus pBR322 sequences of pML2 from position pBR322:29 to position 375 (ref. 46), was restricted with *Hae*II and fractionated on a 1.8% agarose gel. (4) The *Bst*EII–*Hae*II fragment (IS*5*:543–838) and the *Hae*II–*Bam*HI fragment (pBR322:236–375) were eluted, ligated and then digested with *Bst*EII and *Bam*HI to eliminate head-to-head ligation products. (5) The large *Bst*EII–*Bam*HI fragment containing the pML2 moiety (see step 2) was added together with additional ligase. Small lysates were made from individual transformants and identified by restriction with endonucleases *Bam*HI, *Bst*EII and *Eco*RI. (6) One plasmid (pFR10) carried a deletion of pFR8 from the *Hae*II site at IS*5*:838 to the *Hae*II site at pBR322 coordinate 236 of vector pML2. (7) Since pFR10 carries a deletion of the C-terminal part of the tetracycline gene, the small *Eco*RI–*Bam*HI fragment of pBR322 was substituted for the small *Eco*RI-*Bam*HI fragment of pFR10 giving rise to pFR11. The structure of pFR11 was verified by analysis with restriction endonucleases *Eco*RI, *Bst*EII, *Pvu*II, *Hin*dIII, *Bam*HI, *Pst*I and *Hae*II. Plasmid pFR11 contains the promoter, translation start and 104 amino acids of the IS*5* small reading frame plus leader and coding sequence of the larger tetracycline gene which, when transcribed and translated, would give a protein of 450 amino acids.

activity. Figure 1 shows the pertinent structures of vector pKO1 and its derivatives harbouring different IS*5* DNA fragments. Table 1 shows the Gal phenotypes on indicator plates of *galK*$^-$ strains harbouring these plasmids, as well as the amounts of galactokinase expressed by the various plasmids *in vivo* and in a cell-free system. Nucleotide map positions are those given in ref. 20. Orientation of IS*5* is defined with respect to its integration site in the *cI* gene of bacteriophage λ in mutant λKH100 (ref. 26), and its short *Eco*RI arm (right arm) points towards the beginning of gene *cI*. The source of the different subfragments inserted into pKO1 was pFR1 (Fig. 1), which contains the 1,195 bp IS5 element on a 1,720 bp *Hin*dIII fragment derived from λKH100 DNA.

Plasmid pFR2 contains the right arm of IS*5* up to the *Hae*III site at position IS*5*: 980 inserted in front of the galactokinase gene as a *Hin*dIII–*Hae*III fragment. The data presented in Table 1 show that a promoter of moderate strength active both *in vivo* and in the cell-free system, is located on this cloned fragment. In addition to IS*5* sequences (IS*5*: 980–1,195), the *Hin*dIII–*Hae*III fragment contains an internal segment of the λ*cI* structural gene, λ: 38,150–38,291 (G. Hobom, personal communication), known not to contain any promoter signals[27,28]. We therefore conclude that a promoter, p_{5I}, which transcribes towards the centre of IS*5*, is located on the right arm of the element. Deletion of the hybrid vector insert *Eco*RI fragment from pFR2 results in a Gal$^-$ phenotype on transformation of a *galK*$^-$ strain (pFR7, data not shown). This defines the location of p_{5I} between the *Eco*RI site on IS*5* (IS*5*: 1,097) and the end of the element (IS*5*: 1,195). The localization of a functional promoter in this region agrees with the prediction of a promoter (p_{5I}) at IS*5*: 1,175–1,139 from the sequencing data[20]. This promoter precedes the long open reading frame of IS*5*. Galactokinase activity was significantly reduced when all of IS*5* was inserted proximal to the galactokinase gene in the same orientation as the IS*5* fragment in pFR2 (pFR3). This reduction in expression of *galK* may be due to partial termination of transcription at a terminator sequence, t_{5I}, located on the left arm of IS*5*[20].

Cloning of the left arm of IS*5* (as *Hin*dIII–*Pvu*II fragment) into pKO1 in front of *galK* (pFR4; Fig. 1) resulted in synthesis of galactokinase in a cell-free system but not *in vivo* (Table 1). This rather low but significant promoter activity should be located in the IS*5* segment of this fragment, because the λ segment also present, which contains the end of the λ*cI* gene and the beginning of the λ*rexA* gene (λ: 37,727–38,153; G. Hobom, personal communication) should not code, in this orientation, for any promoter reading towards the galactokinase gene[27,28]. Deletion of the DNA between the *Bgl*II site at IS*5*: 158 and the *Sau*3A site at IS*5*: 409 within pFR4, giving rise to pFR5 (Fig. 1), did not abolish the observed promoter activity (Table 1).

The position of this promoter was mapped more precisely by constructing hybrid plasmids each carrying one of the different fragments that can be generated by *Hae*III digestion of the 975 bp DNA segment between the *Hin*dIII site at λ: 37,727 and the *Bst*EII site at IS*5*: 548. The fragments were inserted in front of the galactokinase gene in both possible orientations. Only one of the *Hae*III fragments (IS*5*: 435–540) was capable of promoting galactokinase synthesis in the cell-free system when inserted into pKO1 (pFR6, Table 1). Its

Table 1 Activity of promoter signals on IS*5*

Plasmid	Gal phenotype	Galactokinase (units) Cell free	*In vivo*
pKO1	−	13.0	5.4
pFR2	+	82.4	91.5
pFR3	(+)	29.5	11.8
pFR4	−	35.2	1.5
pFR5	−	38.5	2.3
pFR6	−	46.6	4.8

E. coli strain N100 (*galK, recA*) was transformed with the different plasmids indicated and Gal phenotypes were detected on McConkey galactose ampicillin agar plates. N100/pFR2 colonies were immediately red on these plates whereas N100/pFR3 developed red colonies only after 1 day incubation at 37 °C. All other plasmids gave white colonies in N100. Galactokinase synthesis directed by the various plasmids was also measured in strain N100. Bacteria were grown to $A_{546} = 1.0$ in minimal salt medium supplemented with casamino acids and glucose, collected by centrifugation and frozen. Cell-free synthesis of galactokinase directed by the different plasmid DNAs was carried out as described by Zubay *et al.*[42] with modifications[43]. Synthesis was for 45 min with 40 μg ml^{-1} of plasmid DNA. Galactokinase was assayed from the frozen cells or from the cell-free reaction mixture as described elsewhere[25,43,44]. Galactokinase activity is expressed in nmol of ^{14}C-galactose phosphorylated per minute and per 1.0 A_{546} bacteria (*in vivo*) or per ml reaction volume (in the cell-free system). Galactokinase synthesis directed by plasmid pKO1 alone may be explained by readthrough from promoter p_4 of pBR322, which is the most efficient promoter present on pBR322, located around position 2,900 in clockwise orientation[45]. Data given represent the average of three or more independent measurements with variations not exceeding 3 units for the *in vivo* assays or 5 units for the cell-free assays.

orientation in this clone is the same relative to *galK* as to the small reading frame in IS*5* (Fig. 1). This DNA fragment overlaps with the beginning of the IS*5* small reading frame. Its promoter activity can, therefore, be correlated with a DNA fragment immediately preceding the IS*5* small reading frame. Other hybrid plasmids directed galactokinase synthesis in this system to the level of pKO1 or below (data not shown).

The 105 bp *Hae*III DNA fragment in pFR6 contains the sequence CAAATTG (IS*5*: 479–485) which qualifies as a Pribnow box and, in the −35 region, the sequence CTTGGTAGCC[29,30]. We suggest that this promoter, which we have called p_{5s}, is the transcription start signal for the IS*5* small gene. The position of the p_{5s} promoter is thus different from its localization on the basis of sequence analysis (ref. 20). There are two possible translation start codons for the IS*5* small reading frame at IS*5*: 495 and IS*5*: 525, coding for proteins of 118 and 108 amino acids respectively. The location of the Pribnow box at IS*5*: 479–485 suggests that translation starts at IS*5*: 525, where a translation start codon is preceded by a Shine–Dalgarno[31] sequence. The absence of activity of p_{5s} *in vivo* may indicate that its activity is negatively regulated, possibly by the other IS*5* elements present in the host strain (see below).

The positions of both promoters have been confirmed by the electron microscopic analysis of transcription complexes with purified *E. coli* RNA polymerase (P. Langridge, personal communication).

Expression of two proteins from opposite strands of IS*5* DNA

Plasmids containing all or part of IS*5* DNA (Fig. 1) were used to direct the incorporation of ^{35}S-methionine into proteins synthesized in a cell-free protein-synthesizing system and in minicells (Fig. 2*A*). In both systems, pFR1, which contains the entire IS*5* element, directed the synthesis of a protein with an apparent molecular weight of 37,000 (Fig. 2*A*, lanes *b, f*). This protein was not detectable when the parental vector DNA (pML2) was used as template (lanes *a, e*). Another plasmid (pML3), containing only the long *Eco*RI arm of IS*5* (IS*5*: 1–1,097), directed the synthesis of the pML2 vector proteins only (Fig. 2*A*, lanes *c, g*). This is consistent with the analysis of IS*5* sequence data, which leads to the prediction that the NH_2-terminus and promoter of the IS*5* large gene are located on the small *Eco*RI arm of IS*5* (IS*5*: 1,097–1,195) with direction of transcription from right to left.

Correlation between the IS*5* large gene of 326 codons and the 37,000 molecular weight (MW) protein is further supported by the data obtained using pHL128 (ref. 32) as template. In pHL128, a large IS*5* fragment from the intact right end to the penultimate codon of the large gene at position IS*5*: 158 on the left side has, by *Bgl*II–*Bam*HI fusion, been linked to a foreign DNA fragment containing the *lac*UV5 promoter sequence. This fusion eliminates the carboxy terminus of the IS*5* protein and the reading frame is extended into the *lac* promoter fragment. The resulting fusion protein should contain 344 amino acids. As predicted, pHL128 directed the synthesis of a new protein with an apparent molecular weight of 39,000, about 2,000 larger than the original IS*5* protein (Fig. 2*A*, lanes *d, h*).

When ^{3}H-leucine, the most abundant amino acid in the IS*5* small gene coding sequence (18/108 amino acids[20–22]), was used for protein labelling using pFR1 and pML3 as templates, a second protein with an apparent molecular weight 12,300 was detected. This protein was not observed with the parental vector pML2 as template (Fig. 2*B*). The λDNA sequences present in pFR1 and pML3, as well as the different vector–insert fusion sequences in these hybrid plasmids, do not contain any reading frame long enough to account for the 12,300-MW protein (G.

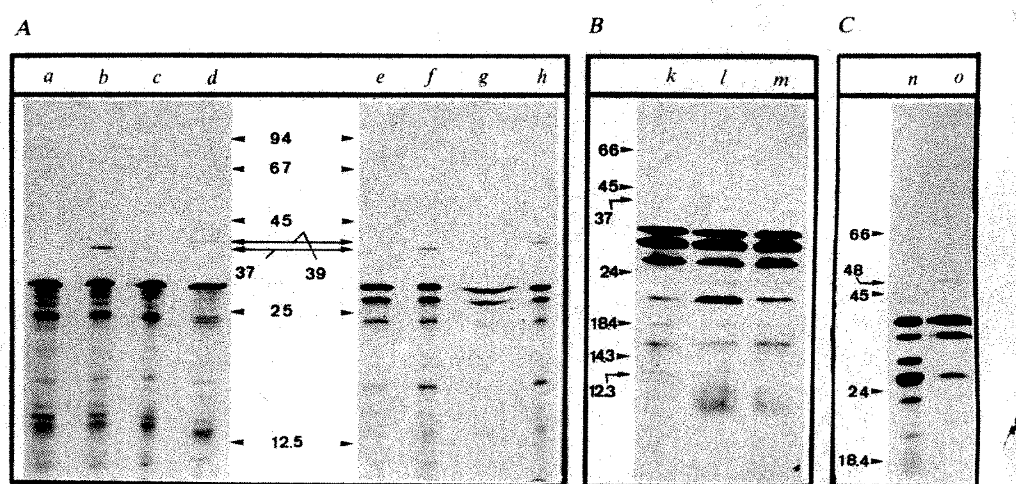

Fig. 2 Expression of proteins encoded by IS*5* in a cell-free protein-synthesizing system and in minicells. *A*, results obtained with ^{35}S-methionine. Cell-free protein synthesis was carried out as described in Table 1 legend with ^{35}S-methionine (1,007 Ci mmol^{-1}; 20 μCi per 100 μl assay). Minicell-producing strain P678-54 was transformed with the different plasmid DNAs, inoculated 1:50 into LB medium containing ampicillin (30 μg ml^{-1}) and grown overnight. Isolation and labelling of minicells were performed as described previously[24] using 0.5 A_{600} units of minicells and 40 μCi ^{35}S-methionine (1,007 Ci mmol^{-1}) in a total volume of 0.5 ml. Proteins (5×10^5 c.p.m. per track) were separated on 12.5% SDS-polyacrylamide gels[51] and the gels were dried and autoradiographed. The position of standard protein size markers are indicated ($\times10^3$). Lanes *a–d*: cell-free synthesis; lanes *e–h*: minicell synthesis. *a, e*, pML2; *b, f*, pFR1; *c, g*, pML3; *d, h*, pHL128. *B*, minicells were prepared as above and labelled with ^{3}H-leucine (65 Ci mmol^{-1}, 130 μCi per assay). Proteins (4×10^4 c.p.m. per track) were separated on 17% SDS-polyacrylamide gels which were fluorographed at −70 °C (ref. 52). Lane *k*, pML3; *l*, pFR1; *m*, pML2. *C*, minicells were prepared and assayed as described above with 110 μCi ^{3}H-leucine (65 Ci mmol^{-1}) and 110 μCi ^{3}H-arginine (53 Ci mmol^{-1}). Proteins (8×10^4 c.p.m. per track) were fractionated on 12.5% SDS-polyacrylamide gels and the radioactive bands visualized by fluorography. Lane *n*, pBR322; *o*, pFR11. The high background (seen previously[24]) is due to the low specific activity of the tritiated amino acids and the necessity to optimize the minicells' protein-synthesizing capacity.

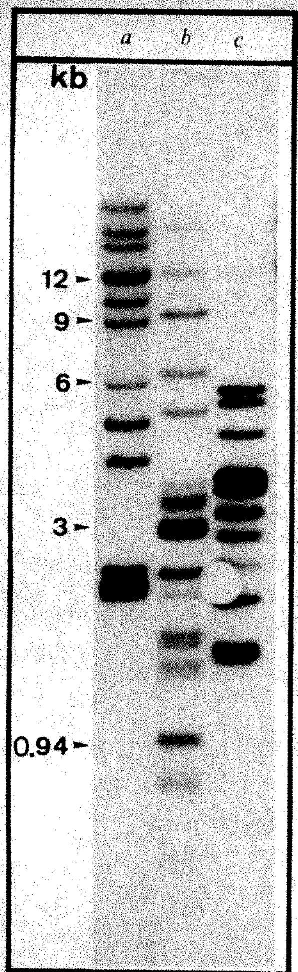

Fig. 3 Southern analysis of IS*5* sequences in *E. coli* K-12 strain 431 Δ (*chl*D–*nad*A). *E. coli* DNA (5 μg) was digested with restriction endonucleases *Bgl*II (*a*), *Pvu*II (*b*), *Hin*dII (*c*) and electrophoresed on a 1% horizontal agarose gel. The fractionated DNA fragments were transferred to nitrocellulose by the method of Southern[37] and hybridized to the radioactively labelled IS*5* internal *Bgl*II–*Eco*RI fragment. Note that *Pvu*II cuts once within IS*5*, between the *Bgl*II and the *Eco*RI site.

Hobom and M. Kröger, personal communication) and we conclude that this protein is the product of the IS*5* small gene. The 12,300-MW protein was produced in the presence and absence of expression of the IS*5* large gene (Fig. 2*B*, lanes *k*, *l*) and is, therefore, not a degradation product of the 37,000-MW protein.

Further support for expression of the IS*5* small gene in minicells was obtained by gene fusion studies. In plasmid pFR11 (Fig. 1), the left arm of IS*5* DNA up to the fourth codon from the end of the small gene was fused, in frame, to the coding sequence of the large tetracycline-resistance gene of pBR322. The resulting fusion protein would be expected to have a molecular weight of 48,800 if the IS*5* small protein translational start is used. In accordance with this prediction, a 48,000-MW protein was encoded by pFR11 in minicells provided with tritiated leucine and arginine (which comprise 118 (59+59) out of 450 amino acids of the fusion protein) (Fig. 2*C*).

IS*5* is present in multiple copies in *E. coli* K-12 genome

Most of the insertion elements found in the *E. coli* genome seem to be present in multiple copies (IS*1*[33], IS*2*[34] and IS*3*[35]), with the exception of IS*4* of which only a single copy has been found in most *E. coli* strains tested[36]. Hybridization data using the gel blotting technique described by Southern[37] revealed 10–12 copies of IS*5* in the DNA of the *E. coli* K-12 strain used (Fig. 3). This strain is a derivative of W8, a prototrophic *E. coli* K-12 from J. Weigle's collection. Interestingly, the same number of IS*5* copies has recently been determined for four different *E. coli* K-12 strains kept separately for many years[21,53].

Discussion

Our data on the functional analysis of IS*5* are summarized in Fig. 4.

From the DNA sequence of IS*5*, two overlapping genes can be proposed: a small one of 324 bp which is completely contained within a large gene of 978 bp. These genes have identical codon registers although transcription would have to proceed in opposite directions. They are preceded by signal structures for the initiation of RNA and protein synthesis. Our data present evidence that the transcription signal structures are indeed functional: RNA synthesis is initiated from the cloned promoter of the large gene both *in vivo* and in a cell-free system. Both genes are transcribed and translated in minicells and the gene products identified correspond in molecular weight to the values expected from the coding regions of their genes (Fig. 2). Activity of the isolated promoter p_{5s} on the other hand was only observed in the cell-free system and not *in vivo*. If we assume that both IS*5* genes carry functions required for transposition, this observation may indicate a complex regulation of the small gene and, hence, of transposition on the level of transcription. Indeed, regulation of transposition has been observed for transposons Tn*5*[38] and Tn*10*[39] which are flanked by IS elements as well as for Tn*3*[9–11,40]. The data presented here are consistent with the hypothesis that the small gene may require its own product *in vivo* for functioning and/or it underlies negative control mechanisms.

The data provide evidence for the unprecedented case of complete genes being transcribed and translated in an antiparallel fashion from the same nucleotide sequence. The highest degree of freedom for the sequence of coding triplets in two genes evolved in an antiparallel fashion from the same DNA fragment could be achieved by codon/codon register. DNA sequence analysis shows that the two IS*5* genes are arranged in this mode.

Comparison of the available DNA sequence data for seven insertion elements revealed similar sequence organization with overlapping, antiparallel, long and short reading frames in codon/codon register in all[8,17–23] but one[41] case. This arrangement of genetic information may thus possibly be a common feature of IS elements.

We do not understand the selective advantage for a genetic structure with such a highly condensed information content, as shown by IS*5*. Selective pressure may have been favourable for a small size of genetic elements which themselves lack selective genes and face the elimination mechanism of the bacterial host cell. Alternatively, selection for a limited size of the element may lie in some step of the yet unknown mechanism by which insertion elements transpose.

We thank K. McKenney for providing plasmid pKO1 before publication, W. Szybalski for bacteriophage λKH100, M. Kröger and G. Hobom for communicating and discussing results before publication, and P. Langridge and C. F. Beck for carefully reading the manuscript. This work was supported by grant Ra276/2 from the Deutsche Forschungsgemeinschaft.

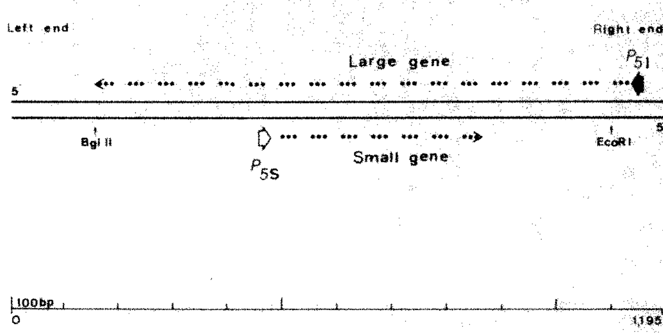

Fig. 4 Schematic presentation of the functional structures on IS*5*. P_{5l} and P_{5s} denote the locations of the promoters functionally detected on IS*5*, preceding the IS*5* large gene and IS*5* small gene respectively. The large arrows indicate the direction of transcription. Dots represent the codon/codon register of the triplets used by the two IS*5* genes.

Controlled transcription of a human α-interferon gene introduced into mouse L cells

Ned Mantei & Charles Weissmann

Institut für Molekularbiologie I, Universität Zürich, Hönggerberg, 8093 Zürich, Switzerland

Mouse L cells were transformed with a cloned chromosomal human interferon-α_1 gene, linked to a herpes thymidine kinase gene as selectable marker. In 8 out of 12 cell lines containing the human interferon gene, infection with Newcastle disease virus stimulated synthesis of messenger RNA for the human interferon—in parallel with that of the endogenous mouse interferon genes.

HUMAN interferons are assigned to three major classes[1]: α, β and γ. The α-interferons (IFN-α) are encoded by a gene family consisting of a dozen or more non-allelic members[2–9]. IFN-α preparations derived from induced human leukocytes or lymphoblastoid cell lines consist of five or more[10,11] species, indicating that many of the genes are expressed *in vivo*.

Normal cells usually do not produce interferon and do not contain detectable levels of interferon mRNA[12]. Treatment with inducers such as viruses or double-stranded RNA leads to the transient formation of IFN-α and/or IFN-β mRNA as well as interferon, 4–24 h after induction[1].

We show here that mouse L cells transformed with a cloned chromosomal IFN-α_1 gene produce correctly initiated IFN-α_1 mRNA in parallel with the appearance of mouse interferon mRNA after induction with Newcastle disease virus (NDV), but not in normal growth conditions. Thus the foreign gene seems subject to the normal control mechanisms of the host cell. A preliminary report of this work has been presented at the International Meeting on the Biology of the Interferon System, Rotterdam (21–24 April 1981).

Human IFN-α transcripts with correct 5′ termini are produced in virus-induced transformed mouse cells

The hybrid phage ML-Ch (*Eco*)/Hchr(AH)IFN-35 carries the gene for human IFN-α_1 (ref. 3). A 7.5-kilobase (kb) *Bam*HI fragment from this phage DNA, containing the IFN-α_1 gene, 5.4 kb of 5′-flanking and 1.2 kb of 3′-flanking sequences, was subcloned into the *Bam*HI site of pBR322 (pChr35-BB; S. Nagata, unpublished). The plasmid TK-M2 carries a thymidine kinase (TK) gene from herpes simplex virus type I (ref. 13). The two plasmids were cleaved at their single *Sal*I sites and joined by T_4 DNA ligase to form concatenates. LMTK$^-$ cells were transfected with the concatenates using the calcium phosphate method[14,15]. After 21 days in hypoxanthine/aminopterin/thymidine medium[16], TK$^+$ colonies were picked and expanded.

The IFN-α_1 DNA content of 13 TK$^+$ cell lines (M2/IFN-1 to M2/IFN-13) was estimated by Southern blotting of *Eco*RI-cleaved cell DNA[17,18] and hybridization with ^{32}P-labelled nick-translated IFN-α_1 cDNA[19]. All cell lines of the M2/IFN series except M2/IFN-3 contained IFN-α_1 DNA, ~0.25 to more than 20 copies per haploid genome (data not shown).

The human IFN-α_1 mRNA content of the cellular RNA was measured by an S_1 mapping procedure[20]. A 480-base pair (bp) *Mbo*II–*Bgl*II fragment of the human chromosomal DNA, which spans the 5′ terminus of the mRNA (see Fig. 6 of ref. 3), was 5′-terminally labelled at the *Bgl*II end. The denatured fragment was hybridized to the RNA, digested with S_1 nuclease and analysed by polyacrylamide gel electrophoresis[21]. Correctly initiated RNA is predicted to protect a ^{32}P-labelled fragment of 330 nucleotides[3]. As little as 0.14 ng poly(A)$^+$ RNA from interferon-producing human leukocytes[19] gave detectable

0028–0836/82/190128—05$01.00

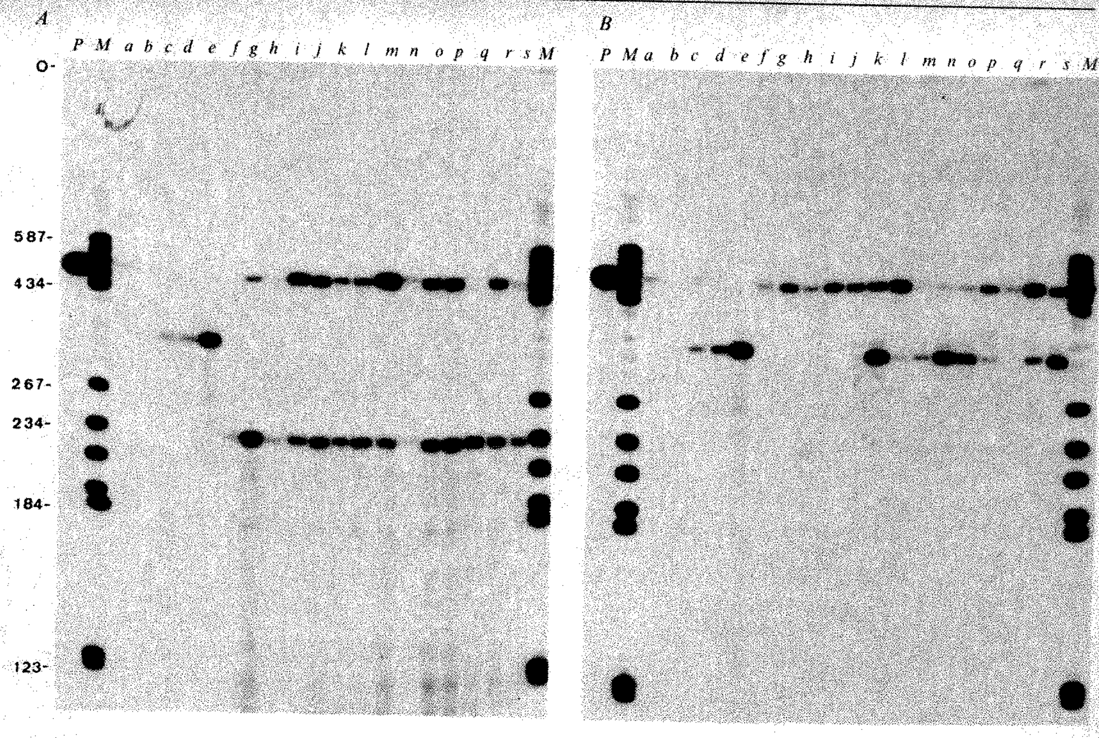

Fig. 1 Detection of human IFN-α_1 RNA with correct 5′ termini in transformed mouse L cells. TK-negative mouse L cells (LMTK$^-$) were transfected with concatenates of the plasmids TK-M2 (ref. 13) and pChr35-BB, which contains a 7.5-kb *Bam*HI fragment from the IFN-α_1 chromosomal DNA[9]. 1.6 µg TK-M2 and 9 µg pChr35-BB were cleaved with *Sal*I and joined with ligase. Ten 9-cm plates of LMTK$^-$ were transfected and TK-positive colonies selected as described previously[15,23]. Control cells were transfected with *Sal*I-cleaved TK-M2 without ligation. RNA was prepared as described in ref. 27. To prepare the probe for S_1 mapping, plasmid pChr35-HBα (ref. 3) was cleaved with *Bgl*II (New England Biolabs) and the 5′ termini labelled with ^{32}P-phosphate[12]. After *Mbo*II cleavage, the 480-bp fragment was isolated. Probe (0.01 pmol, 27,000 c.p.m.) was denatured, hybridized in 80% formamide to 50 µg cell RNA, digested with S_1 nuclease (P-L Biochemicals) and analysed by polyacrylamide gel electrophoresis on a 5% gel, all as described earlier[12,21]. *A*, RNA from uninfected cells. Lanes *a–e*, 0, 0.14, 0.42, 1.25 and 3.75 ng poly(A)$^+$ RNA from interferon-producing human leukocytes[19]. Lane *f*, RNA from cell line M2/S-33, transformed only with TK-M2. Lanes *g–s*, RNA from cell lines M2/IFN-1 to M2/IFN-13, transformed with TK-M2 linked to pChr35-BB. *B*, analysis of RNA from transformed cells infected with NDV. Transformed cells were grown for three generations with hypoxanthine and thymidine but without aminopterin, then infected with an optimal dose of NDV. RNA was extracted after 11 h. Samples as in *A*. Lane *P*, undigested probe. Lane *M*, size marker: pBR322 digested with *Bsp*I and 5′-^{32}P-labelled. Exposure for 21 days at −70 °C with an Ilford intensifying screen.

amounts of this fragment (Fig. 1*A*, lane *b*), whereas 50 µg RNA from transformed cell lines M2/IFN-1 to M2/IFN-13 (Fig. 1*A*, lanes *g–s*) did not. There are therefore fewer than 0.5 human IFN-α_1 mRNA molecules with correct 5′ termini per mouse cell transformed with IFN-α_1 DNA (see below for calculations). The 480-nucleotide fragment corresponds to completely protected probe, and is due, as shown below, to protection by complementary RNA longer than the probe and/or to self-renaturation. RNA from all mouse lines tested, including the line M2/S-33, transformed only with TK-M2 (Fig. 1*A*, lane *f*), gave a labelled fragment apparently 230 nucleotides long. We later found that this fragment and one of ~200 nucleotides (see Fig. 2) appear on electrophoresis of large amounts of undigested probe or undigested probe mixed with nuclease S_1-digested cell RNA (data not shown).

To test whether gene expression could be induced, the transformed cell lines were infected with NDV and RNA prepared 11 h later. As shown by S_1 mapping, RNA from 8 of 13 lines gave the 330-nucleotide fragment (Fig. 1*B*) indicative of correctly initiated human IFN-α_1 mRNA. The level of this mRNA was estimated from the amount of cell RNA per cell (~25 pg)[22], the molecular weight of IFN-α_1 mRNA (~330,000) and the intensities of the 330-nucleotide bands relative to those given by RNA from induced human leukocytes, ~0.4% of which is IFN-α_1 RNA (N.M., unpublished). We estimate that eight of the cell lines contained ~0.5–10 IFN-α_1 transcripts with correct 5′ termini per cell. No transcripts were found in cell line M2/S-33, transformed with TK-M2 alone (Fig. 1*B*, lane *f*).

To examine the kinetics of IFN-α_1 induction, cultures of M2/IFN-5 and of M2/S-34 (transformed with TK-M2 alone) were infected with NDV or mock-infected. After 20 h, media from both infected cultures contained about 4,000 units ml^{-1} of mouse interferon, indicating that mouse interferon was induced in both cell lines. RNA was prepared after 4, 11, 20 and 27 h, and poly(A)$^+$ and poly(A)$^-$ RNA separated by chromatography on oligo(dT)-cellulose[23,24]. IFN-α_1 RNA was assayed by the S_1 mapping procedure described above. In poly(A)$^+$ RNA from infected cultures of M2/IFN-5, correctly initiated IFN-α_1 RNA was present after 11 h (Fig. 2, lane *l*) and, in lower amounts, after 20 h (lane *c*), but not after 4 h (lane *a*) or 27 h (lane *e*). Neither cell line M2/S-34 (lanes *n*, *o*) nor mock-infected M2/IFN-5 (lanes *b*, *d*, *f*, *m*) ever gave a 330-nucleotide fragment. The mobilities of the 330-nucleotide fragments given by M2/IFN-5 RNA (Fig. 2, lane *l*) and by human leukocyte RNA (lane *k*) are the same, implying that the 5′ ends of the RNAs are identical. The signal from poly(A)$^+$ RNA from 150 µg M2/IFN-5 RNA at 11 h after infection (lane *l*) was about 15 times stronger than that from poly(A)$^-$ RNA from 50 µg of the same cell RNA (lane *p*). About 80% of the IFN-α_1 RNA is therefore polyadenylated.

The kinetics of induction of mouse interferon mRNA was followed by injecting samples of poly(A)$^+$ cell RNA into *Xenopus* oocytes and determining antiviral activity on mouse cells. Activity was undetectable at 4 h, reached a maximum at 11 h and dropped to about one-tenth of maximum at 20 h after infection.

The identification of human IFN-α_1 mRNA in virus-induced mouse cells depends on the formation of perfect or almost perfect hybrids between the mRNA and the human DNA probe in stringent hybridization conditions. Human and mouse IFN-α coding sequences differ in about 26% of their residues (G. Shaw and N.M., unpublished), so that only very imperfect hybrids could be formed even in non-stringent hybridization conditions. In fact, no fragments characteristic for correctly initiated human IFN-α_1 mRNA were found when 5′ probes were hybridized to RNA from interferon-producing mouse cells transformed with TK plasmid alone (Fig. 1*B*, lane *f*). The results of the S_1 mapping of RNA from virus-induced mouse cells containing the human IFN-α_1 gene therefore cannot be explained by cross-reaction with mouse interferon mRNA.

Human IFN-α transcripts with incorrect 5′ termini in uninduced, transformed mouse cells are relatively stable

The 3′ ends of the IFN-α_1 transcripts were mapped with a probe spanning the known 3′ terminus. Even after hybridization to only yeast RNA, the S_1-treated probe gave several discrete bands, probably due to incomplete digestion (Fig. 3, lane *a*). Poly(A)$^+$ RNA from induced human leukocytes gave three additional protected fragments of 550, 600 and 780 nucleotides (Fig. 3, lanes *b, c, f*). The 3′ end of the plus-strand IFN-α_1 cDNA in plasmid Z-pBR322 (*Pst*)/HcIF-2h is 554 nucleotides downstream from the *Bgl*II site[12], accounting for the 550-nucleotide fragment. The other protected fragments probably represent other 3′ ends further downstream. Two or more 3′ ends have been found for IFN-α_2 RNA[7] and other RNAs[25,26]. An artefact of the S_1 assay is less likely. RNA from both NDV-infected and mock-infected M2/IFN-5 cells gave the same bands found with induced human leukocyte RNA, albeit at different relative intensities (Fig. 3, lanes *d, e*). This shows that both induced and mock-induced, transformed cells contain human IFN-α_1 transcripts with correct 3′ termini. As no correct 5′ termini had been found in mock-induced cells, we conclude that either the 5′ moiety of these transcripts was degraded or they initiated far upstream of the 'cap' site. In the latter case, the labelled probe used previously to map 5′ ends would be protected over its full length, giving a signal indistinguishable from renatured probe.

To determine whether IFN-α_1 RNA in mock-infected cells originated upstream of the cap site, we used a probe with a 5′-^{32}P-labelled *Eco*RI end at nucleotide 633 in the IFN-α_1 gene, extending upstream to nucleotide −675 in the 5′-flanking region and continuing 103 nucleotides into the adjoining pBR322 DNA (see Fig. 4). All '3′ halves' of IFN-α_1 RNA found in the experiment of Fig. 3 will be detected by this probe, as the *Eco*RI site lies 372 nucleotides downstream from the labelled *Bgl*II end used for the 3′-end mapping. Transcripts initiated further upstream than position −675 will yield a protected fragment of ~1,375 nucleotides which is easily distinguished from undegraded probe (~1,480 nucleotides). Figure 4*B*, lane *e*, shows that RNA from NDV-infected M2/IFN-5 yielded as the major product the 700-nucleotide fragment expected for correctly initiated RNA, with lesser amounts of 1,100- and 1,375-nucleotide fragments. RNA from mock-infected M2/IFN-5 protected fragments of 1,100 and 1,375 nucleotides only (Fig. 4*B*, lane *f*). Mapping of 3′ ends of RNA from the same batch showed that the 5′ ends detected account for most or all of the 3′ ends (data not shown).

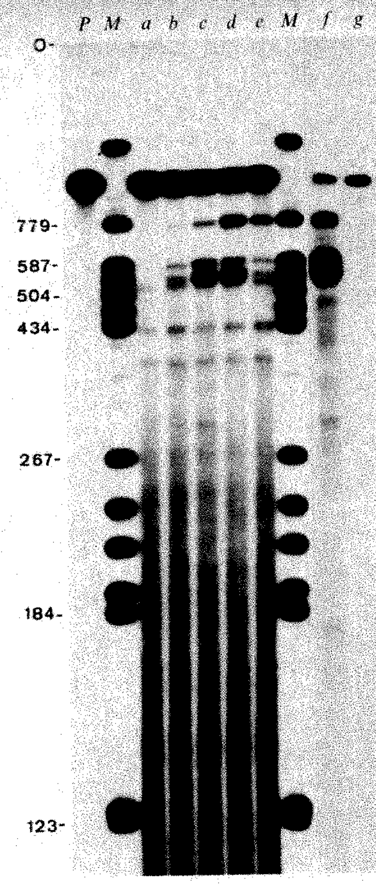

Fig. 3 S_1 mapping of 3′ ends of human IFN-α_1 RNA. The plasmid pChr35-HBα containing the human chromosomal IFN-α_1 sequence was incubated with *Bgl*II and then with T_4 DNA polymerase (P-L Biochemicals) at 15 °C in the presence of 0.1 mM dCTP[35]. After phenol extraction and ethanol precipitation, the termini were 'filled in' with the Klenow fragment of DNA polymerase (Boehringer) in the presence of 0.2 mM each dCTP, dGTP and TTP, and 2.4 µM [α-^{32}P]dATP (NEN). Following cleavage with *Bsp*I, the resulting 1,000-bp *Bgl*II–*Bsp*I fragment (see map in ref. 3) was isolated. S_1 analysis as for Fig. 1. Lanes *a–c, f, g*, 0, 1.2, 3.6, 300 and 0 ng poly(A)$^+$ RNA from interferon-producing human leukocytes[19]. Lanes *d, e*, poly(A)$^+$ RNA (from the preparation described in Fig. 2 legend) derived from 120 µg cell RNA of cell line M2/IFN-5, either 11 h after NDV-infection (*d*) or mock infection (*e*). Lanes *P* and *M* as in Fig. 1. Exposure for 25 days, except that lanes *f* and *g* were exposed for 16 h.

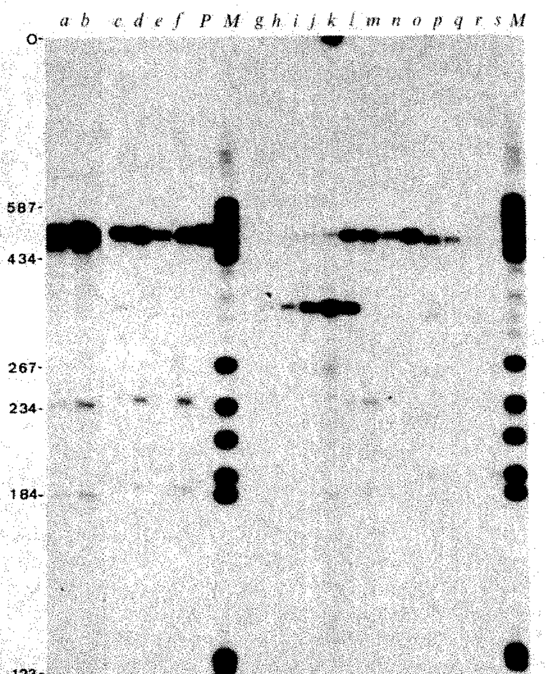

Fig. 2 5′ termini of human IFN-α_1 RNA in transformed mouse cells at different times after infection with NDV. M2/IFN-5 and M2/S-34 cells (see Fig. 1 legend) were infected with NDV or were mock-infected. RNA was prepared at 4, 11, 20 and 27 h after the end of the adsorption period and fractionated by chromatography on oligo(dT)-cellulose[23,24] (P-L Biochemicals, type 7). Poly(A)$^+$ RNA derived from 150 µg cell RNA and poly(A)$^-$ RNA from 50 µg cell RNA were analysed as for Fig. 1. Lanes *g–k*, 0, 0.16, 0.5, 1.5 and 4.5 ng poly(A)$^+$ RNA from interferon-producing human leukocytes[19]. Lanes *a, c, e* and *l*, poly(A)$^+$ RNA from M2/IFN-5 at 4, 20, 27 and 11 h after NDV infection. Lanes *b, d, f* and *m*, poly(A)$^+$ RNA from M2/IFN-5 at 4, 20, 27 and 11 h after mock infection. Lanes *n, o*, poly(A)$^+$ RNA prepared 11 h after infection (*n*) or mock infection (*o*) of M2/S-34. Lanes *p–s*, poly(A)$^-$ RNA prepared 11 h after infection (*p, r*) or mock infection (*q, s*) of M2/IFN-5 (*p, q*) and M2/S-34 (*r, s*). Lanes *P* and *M* as in Fig. 1. The autoradiograph was exposed for 25 days.

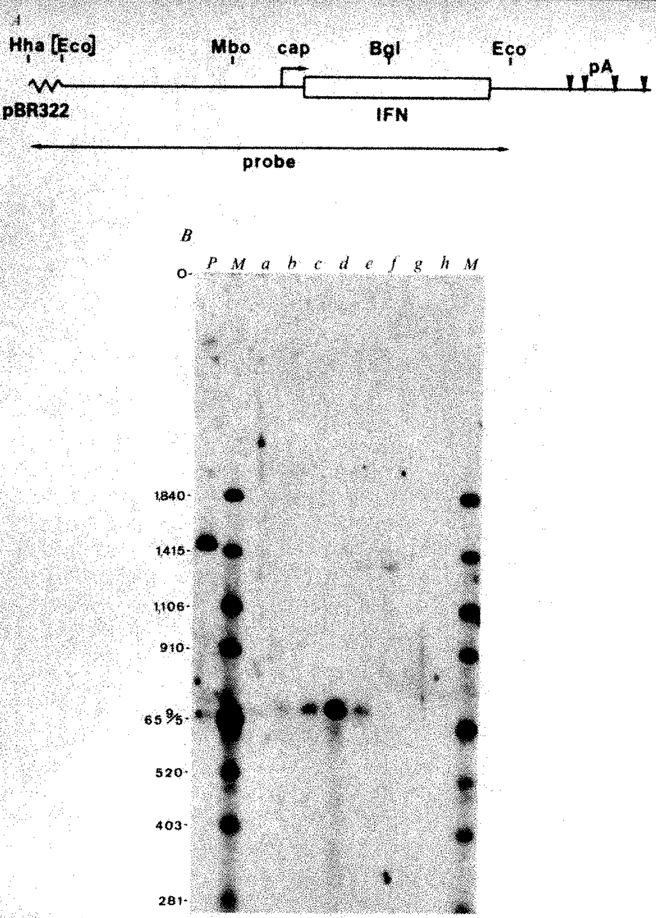

Fig. 4 S_1 mapping of 5′ ends of human IFN-α_1 RNA in transformed mouse cells. M2/IFN-5 and M2/S-34 cells were infected with NDV or mock-infected, and poly(A)$^+$ RNA prepared after 11 h. *A*, the plasmid pChr35-675 is a derivative of pChr35-HBα (ref. 3) in which the *Eco*RI fragment between −675 and the *Eco*RI site of pBR322 was deleted and the new *Eco*RI site destroyed [*Eco*]. pChr35-675 was cleaved with *Eco*RI and the 5′ termini labelled. After cleavage with *Hha*I and *Pst*I, the 1,480-bp *Hha*I-*Eco*RI fragment was isolated. *B*, mapping of 5′ ends. The fragment described above (0.01 pmol, 40,000 c.p.m.) was hybridized to poly(A)$^+$ RNA derived from 125 μg cell RNA, digested with S_1 nuclease at 24 °C and the products analysed by electrophoresis through a 1.6% alkaline agarose gel[36]. Lanes *a*–*d*, 0, 0.42, 1.25 and 3.75 ng poly(A)$^+$ RNA from interferon-producing human leukocytes. Lanes *e*, *f*, RNA from cell line M2/IFN-5 after infection (*e*) or mock infection (*f*). Lanes *g*, *h*, RNA from cell line M2/S-34 after infection (*g*) or mock infection (*h*). Lane *P*, undigested probe; lanes *M*, pBR322 cleaved with *Hin*cII and *Pvu*II, plus pBR322 cleaved with *Alu*I, both terminally labelled. Exposure for 14 days.

The S_1 mapping of poly(A)$^+$ RNA from induced, transformed mouse cells, from the *Bgl*II site to the 5′ and 3′ termini and from the *Eco*RI site to the 5′ termini, gives signals identical to those found with poly(A)$^+$ RNA from induced human leukocytes. We conclude that the induced, transformed mouse cells contain complete human IFN-α_1 mRNA which has the correct termini and is polyadenylated.

Conclusions

Mouse L cells, transformed with a cloned human IFN-α_1 gene, produce a low level of incorrectly initiated interferon transcripts. Most, if not all, of these transcripts initiate upstream of the cap site. Transcripts initiated upstream of the cap site have also been found in the case of the rabbit β-globin gene and the chicken ovalbumin gene introduced into mouse L cells[27,28]. When mouse L cells transformed with the IFN-α_1 gene are infected with NDV, correctly initiated, polyadenylated IFN-α_1 transcripts appear, at levels of 0.5–10 strands per cell. We believe this to be due to *de novo* synthesis, and not to processing of the pre-existing overlong transcripts: if such processing were accidental, it is unlikely that newly formed 5′ termini would coincide precisely with the 5′ termini of natural IFN-α_1 mRNA. On the other hand, it is unlikely that, in physiological conditions, overlong transcripts give rise to mature interferon RNA by processing, because human leukocytes contain no IFN-α-related transcripts before induction[12]. The time course of appearance and disappearance of the human IFN-α_1 RNA in mouse cells is similar to that of the mouse interferon mRNA in the same cells, suggesting a common control mechanism. Whereas mouse interferon was easily measured in the medium, human IFN-α_1 could not be detected, probably because the interferon mRNA level was low, and the specific antiviral activity of IFN-α_1 on human cells is lower by an order of magnitude than that of other human interferons[29].

Induction of interferon mRNA in normal cells could be explained in two ways: (1) although interferon mRNA is synthesized at a similar rate in non-induced and induced cells, transcripts are rapidly degraded in non-induced cells but stabilized in induced cells. (2) There is no (correct) transcription of interferon genes in non-induced cells, and induction activates transcription. The fact that non-induced transformed mouse cells contain about as many incorrectly initiated IFN-α_1 mRNA transcripts as induced cells suggests that, unless a correct 5′ terminus is required for degradation, the stability of interferon transcripts is similar in both cases. Thus, induction would not suppress interferon mRNA degradation, but rather stimulate correct transcription of IFN-α genes, which does not occur to a measurable extent in non-induced cells.

The interferon gene flanked by 5.4 kb of 5′- and 1.2 kb of 3′-chromosomal DNA seems to contain sufficient information to respond to physiological induction, at least to some extent. We estimate that there is about 50 times less human than mouse interferon mRNA in an induced, transformed mouse cell line containing two IFN-α_1 genes per haploid genome; this may be due in part to the fact that the cells contain many more mouse interferon genes, probably more than 10 copies per haploid genome. In addition, there may be some incompatibility between the human and mouse system, and/or effects due to incorrect positioning of the transplanted genes in the mouse genome.

Recently, other cloned genes introduced into host cells have been found to respond to induction—the cloned mouse mammary tumour virus genome[30,31], the rat α2 globulin gene[32] and a *Drosophila* heat-shock gene[33]. Thus, several systems now provide an approach to the identification of the DNA sequences responsible for control of transcription.

This work was supported by the Schweizerische Nationalfonds (3.481.79) and the Kanton of Zürich. We thank S. Nagata and U. Weidle for plasmids, C. Arnheiter for NDV, M. Streuli for injecting oocytes, P. Dierks and J. Fujisawa for [γ-^{32}P]ATP, and C. Arnheiter and J. Fujisawa for helpful advice.

Note added in proof: Ohno and Taniguchi[34] have found that mouse FM3A cells transformed with the human IFN-β gene produce IFN-β and increased amounts of IFN-β mRNA after treatment with NDV or poly(I) · poly(C). Similar results have been obtained by H. Hauser *et al.* (personal communication).

Dynamical features in the northern hemisphere of Saturn from Voyager 1 images

Garry E. Hunt, David Godfrey, Jan-Peter Müller & Robert F. T. Barrey

Laboratory for Planetary Atmospheres, Department of Physics and Astronomy, University College London, London WC1E 6BT, UK

Results of the analysis of Voyager measurements of divergence and inferred vertical velocity of convective cloud features in the northern hemisphere of Saturn are presented here. The winds in this region have been measured by tracking the cloud elements observed in sequences of images. The derived zonal winds imply that these convective features reside at the maximum of strong easterly jets centred at 41° N planetocentric latitude and that the jet is barotropically unstable. The divergences and local dynamics of the Saturn features are found to differ from those of the jovian equatorial plumes.

During the encounter of Saturn by Voyager 1, Smith *et al.*[1] reported observations of distinct cloud features occurring in the northern hemisphere of the planet's atmosphere. In the region bounded by 35–42° N, several bright V-shaped features have been seen, while at ~29° N, a distinct cloud oval is apparent (Fig. 1, feature 3.) (All latitudes in this article are planetocentric.) The large spot is particularly evident in the UV images and was seen to persist throughout the Voyager 1 observational period from 24 August to 10 November 1980. The V-shaped features varied greatly in shape during the observation period but persisted in their longitudinal distribution as they drifted in an easterly jet centred at 41° N. The changes in the visible appearance of these features suggests that they are convective clouds where the rapid variations in the shape and structure of these cloud systems is associated with local vertical motions. There is no evidence from the IR observation of Hanel *et al.*[2] that these features affect the temperature structure of the upper troposphere. However, the IRIS field of view is large compared with the visible cloud structures observed by the imaging system[3]. The IRIS instrument essentially measures the average temperature for the total region seen in the imaging frame. Indeed, any upper atmosphere aerosol layers present would further reduce any possible temperature contrasts.

In the atmosphere of Jupiter, we have shown that the equatorial plumes are convective cloud structures[3,4] and their meteorological characteristics have been estimated by procedures developed using the University College London (UCL) Interactive Planetary Image Processing System[3]. We apply these techniques for the analysis of the Saturn observations and present here the first measurements of divergence of saturnian cloud systems. Using this information, we then calculate the vertical velocities which relate to the observed changes in the cloud structures. In addition, we measure the wind speeds of the clouds in the latitude band 30–45° N and estimate the stability of the flow for the period of the observations. These new measurements provide valuable insight into the variations of the cloud structures and through comparison with our jovian studies[4] this will provide information on the differences in the observed meteorologies.

For this study, a series of blue filter narrow angle images of Saturn was used. The observations were made for the period 3–8 November 1980 when the spatial resolution varied between 120 and 60 km pixel^{-1}.

The images were first radiometrically decalibrated at the Jet Propulsion Laboratory (JPL) using the standard procedures[5]. To provide an accurate navigation of the images that transforms the line and sample system into a planetocentric latitude/longitude coordinate system, two independent procedures were used. At JPL, the method used simultaneous wide and narrow angle frames to locate the centre of the planet from which the subsequent transformation is then determined[5]. An interactive procedure, developed at UCL, uses a 'least-squares' minimization method to fit an ellipse to the image, constrained by the spacecraft navigation and camera data. We have shown elsewhere[6] that both of these methods produce similar results although the error in determining the position of the centre of the planet becomes greater than 1 pixel when 20% or less of the planet's limb is available (see ref. 7).

Measurements of velocities of the upper clouds in the Saturn atmosphere have been made by interactively tracking individual features observed in the images. The techniques have been shown[6] to be accurate to within $\pm 3\ \mathrm{m\ s^{-1}}$ in zonal and meridional winds at a spatial resolution of 60 km pixel^{-1} and produce results that compare favourably with other schemes[1]. The velocities are measured relative to the SYSTEM III radio period of 10 h 39.4 min (ref. 8) using images separated by time intervals of 10–20 h. Considerable contrast enhancement of the image was first necessary to show clearly the cloud elements to be tracked.

The measurements of the divergence of the V-shaped clouds were made by the procedures set out in ref. 4. The sequence of 10 blue narrow angle images were first map projected into a Mercator format centred at 41° N using a single pixel interpolation scheme developed at UCL[6]. Then, the divergence of these features was estimated from the changing cloud areas. We estimate the area of the convectively active region from the assumption that the brightness in the cloud system, which we have previously shown[4,9,10] to be a reliable approach.

If we now assume that the vertical motion in the layer of outflow takes place over a vertical scale D, then the vertical velocity required to produce the observed divergence field is:

$$W \leq D\ \mathrm{div}\ \mathbf{V} \qquad (1)$$

We estimate D as the scale height of the atmosphere at the cloud top, which will then enable an estimate to be made of the vertical motions associated with these cloud systems.

0028-0836/82/190132—03$01.00

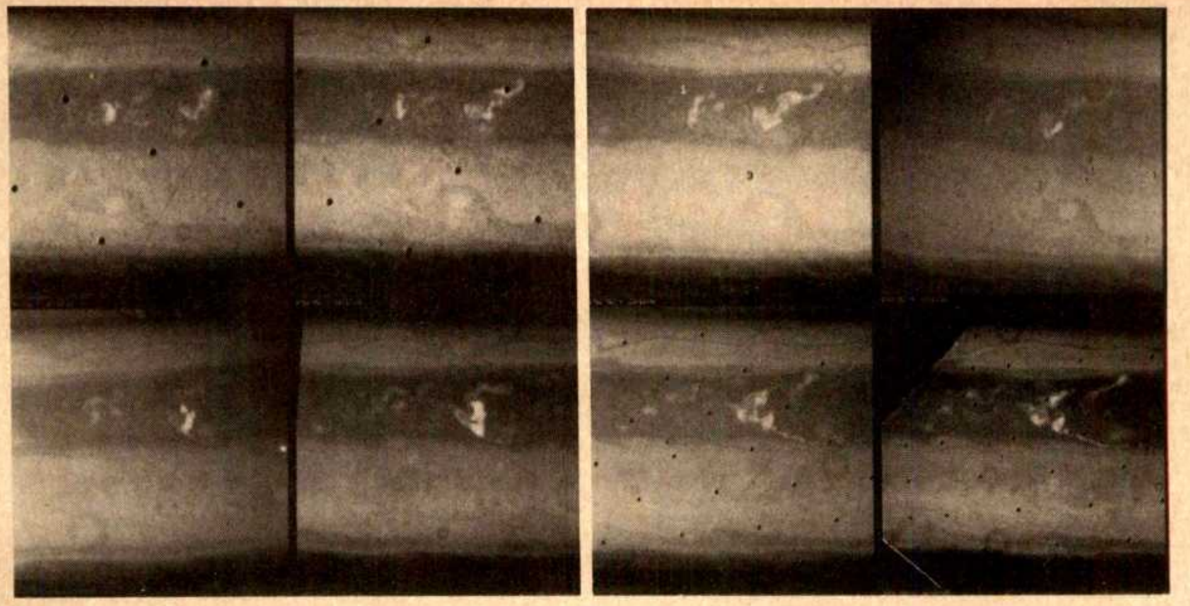

Fig. 1 Sequence of eight blue Mercator narrow angle images of the mid-latitudes of Saturn. The dates and times of the images are: 15:05:22, 3 November 1980; 11:57:22, 4 November 1980; 22:11:46, 4 November 1980; 08:25:22, 5 November 1980, 20:46:58, 5 November 1980; 17:22:10, 6 November 1980; 12:08:34, 8 November 1980; 22:24:34, 8 November 1980.

Figure 1 shows the variation in the V-shaped cloud structures for the period 15:05:22, 3 November to 22:24:34, 8 November 1980. All times are GMT at the spacecraft. This time sequence clearly indicates the large morphological change in the convective cloud structures. At the edge of feature 2, considerable developments in the clouds become apparent in the final three images of the sequence. Figure 1 shows less noticeable changes during this time.

The third main cloud feature seen in Fig. 1 is the UV spot. The prominence of this feature at short wavelengths is consistent with it being higher than its surrounding clouds. A well defined flow pattern can be seen to the west of this feature in Fig. 1, which is morphologically similar to the 'turbulent' regions to the west of the Great Red Spot and White Ovals on Jupiter.

In Fig. 2, we summarize the basic characteristics of the motions in the mid-latitude region bounded by 30–50° N. The mean zonal velocity is shown in Fig. 2*a*; a strong easterly jet is situated at 41° N which corresponds to the apex of the V features. We find also that the strongest shear occurs along the southern edge of this jet. The small inflection in the zonal velocity profile at 42–43° N is associated with small changes in the cloud morphologies.

To discuss the significance of these results and the stability of the flow, we estimate $\bar{u}$, $d^2\bar{u}/dy^2$, and their associated errors, using the procedures set out in ref. 11. The measured zonal flow is composed of contributions from the mean flow, the eddies and errors which arise from effects of spacecraft navigation, preprocessing of the data and uncertainties in the identification of individual features. Following the procedures of Ingersoll *et al.*[11], we estimate the error in $\bar{u}$, $\sigma(\bar{u})$ as ± 5 m s^{-1}. We compute $d^2\bar{u}/dy^2$ at latitudinal position y_n by:

$$(d^2\bar{u}/dy^2)_n = (\bar{u}_{n+2} - 2\bar{u}_n + \bar{u}_{n-2})/\Delta y_n^2$$

where $\Delta y_n = y_{n+1} - y_{n-1}$.

Then the error in $d^2\bar{u}/dy^2$ is $\sim \pm\sqrt{6}\sigma(\bar{u})/\Delta y^2$ (ref. 11).

The stability of the retrograde jet may be investigated by examining the barotropic stability condition for a zonal velocity $\bar{u}$ (see, for example, ref. 12), given by:

$$\beta - d^2\bar{u}/dy^2 \geqslant 0$$

where $\beta = (2\Omega/r) . \cos\theta$, Ω is the planetary rotation, r the planetary radius (local radius or curvature), θ the planetodetic latitude and y the northerly direction. In Fig. 2*b*, we have superimposed the value of β with $d^2\bar{u}/dy^2$, while the additional

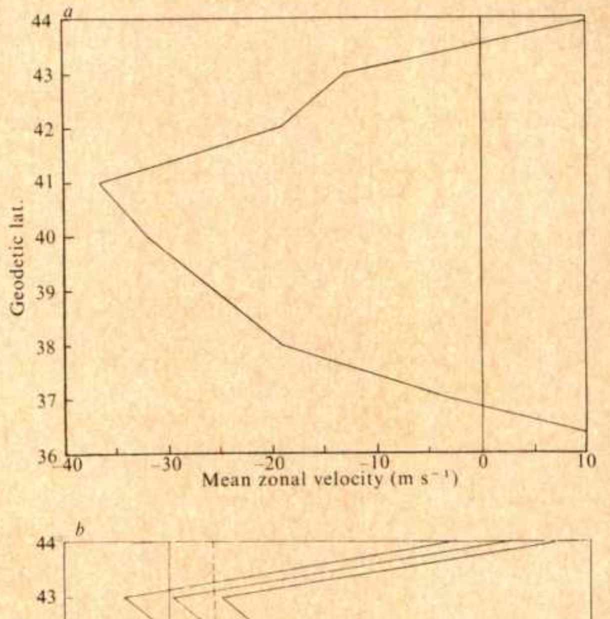

Fig. 2 The dynamical properties of the region 30–50° N derived in this study. *a*, The zonal wind $\bar{u}$ is shown with 1σ r.m.s. values. *b*, The curve for $d^2\bar{u}/dy^2$, together with the value of β at 41° N. The central curve is the variation of $d^2\bar{u}/dy^2$. The curves at the left and right show the variation in $d^2\bar{u}/dy^2$ when the errors are taken into account.

curves illustrate the errors in $d^2\bar{u}/dy^2$ estimated by the procedures set out above. We see that the flow between 40 and 41.5° N is barotropically unstable in more stringent conditions. The figure further suggests that the region extending to 37° N is close to being unstable in these conditions. The V-cloud features reside in the centre of the unstable region, which is also the maximum in the easterly jet. The stable region of the flow lies outside the latitudes of 37–42° N.

Figure 3 shows the divergence of these active regions. There is little change in the characteristics of the UV spot, which is apparent from the image sequence seen in Fig. 1. The changes in area shown in Fig. 2 for the convective features were used to determine the 90% of maximum brightness threshold contour using the procedures described in ref. 4. These variations in area of the active clouds may then be used to estimate the divergence of the features which are shown in Fig. 3. As expected, feature 2 is the most active, with values reaching $\sim 5\times10^{-5}\,s^{-1}$. The other convective feature is less active, with a maximum value of $3\times10^{-5}\,s^{-1}$. A negative divergence implies the dissipation of the cloud feature.

Comparing the results with those of our study[4] of the jovian equatorial plumes, we find that the divergences are much stronger for the saturnian features. The largest Saturn values are more than three times greater than those associated with the most active jovian plume. Assuming that the anvil expansion we are measuring takes place at ~500 mbar level[2] over a depth of a density scale height of 40 km (ref. 13), then the divergence maxima imply vertical motions of $\sim 2\,m\,s^{-1}$.

On Jupiter, these large scale motions are propagated throughout the troposphere[3]. Although the saturnian vertical motions are apparently stronger, the IR observations do not suggest any large scale perturbations in the temperature structure in a horizontal or vertical direction. It is possible that the larger aerosol layers in the troposphere of Saturn provide sufficient opacity to diminish the temperature contrasts. Furthermore, the IRIS observations are essentially the average response for the narrow angle field of view, so that these small scale convective clouds may not produce a sufficiently large signature to be noticeable.

The present estimates of larger vertical motions in the atmosphere of Saturn compared with Jupiter are consistent with the differences in the zonal velocity and internal structure of the two planets. The internal heat source on Saturn supplies approximately twice as much energy to the atmosphere as solar heating[2]. This situation, together with the smaller gravity, which then leads to a larger atmospheric scale height on Saturn, is consistent with the larger convective motions discussed above.

From these first estimates of divergence and vertical motions of cloud features observed in the northern hemisphere of Saturn we find that the associated flows of the convective clouds are stronger than the similar cloud features observed in the atmosphere of Jupiter. The vertical velocities we estimate for these motions are of a similar magnitude to large scale terrestrial convective storms (see, for example, ref. 9), although on Saturn these storms occupy a considerably greater spatial scale.

We find that the Saturn convective cloud features are situated in the maximum of the easterly jet which corresponds to a barotropically unstable region of the atmosphere (Fig. 2). It is possible that these mesoscale cloud features are generated by large scale convergence in the deep cloud layers beneath the visible surface of the planet. These stronger motions are consistent with the differences in the structures of Saturn and Jupiter.

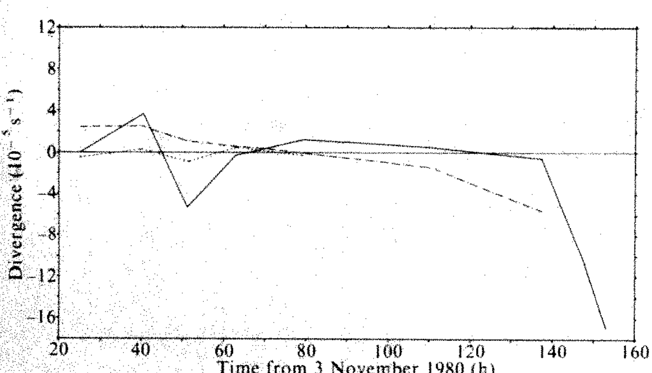

Fig. 3 Measurements of divergence of cloud features in the northern hemisphere of Saturn for 150 h, commencing at 00 h, 3 November 1980. The convective clouds are features 1 (—·—); feature 2 (——); · · · · , the UV spot.

Enhancement of the number of muon catalysed fusions

L. Bracci & G. Fiorentini

Istituto di Fisica dell'Università di Pisa, and INFN, Sez. di Pisa, 56100 Pisa, Italy

We discuss here the effect of an external electric field on the motion of the $(\mu\alpha)$ ions which are produced in the reaction $(dt\mu)\rightarrow(\mu\alpha)+n$. We find that appreciable enhancements of the $(\mu\alpha)$ stripping probability can be achieved for strong fields. This effect can be useful for enhancing the number of nuclear fusions which a muon can catalyse in a deuterium–tritium mixture.

The possibility of using the muon catalysis of nuclear reactions for the purpose of energy production has been a long-standing dream of particle physicists[1]. Recently, Petrov[2] presented a scheme which, although based on some optimistic assumptions, can yield a positive energy balance. This scheme involves the muon catalysis of $d+t\rightarrow\alpha+n$ reactions and is supported by the recent discovery[3] of a very high formation rate of the d–μ–t molecular ion, $\lambda_{d\mu t}\geq 10^8\,s^{-1}$ at liquid hydrogen density. Indeed, the theoretical analysis of the process, based on the so-called resonant mesomolecule formation[4,5], allows for the possibility of extremely high values of $\lambda_{d\mu t}$.

In the d–t mixture, the most serious limitation to the efficiency of the fusion chain is the possibility that the muon could stick to the α particle produced in the nuclear reaction, the sticking probability being $W=1.2\%$ (refs 6, 7). The kinetic energy of the $(\mu\alpha)$ ion is $T_{in}=3.5$ MeV, which corresponds to a velocity $v_{in}=5.8\,e^2/\hbar$. During the slowing down process there is a chance for the $(\mu\alpha)$ to be stripped, so that the muon can take part again to the fusion chain. At a density $\rho_0=10^{19}$ atom cm^{-3} a fraction $R=0.20$ of the sticked muons are reactivated, so that the effective sticking probability is $W_{ef}=W(1-R)=0.96\%$ while at $\rho=10\rho_0$ one has $R=0.21$ and $W_{ef}=0.95\%$ (see refs 6, 7). The reason for such a limited gain (as depicted in Fig. 1) is that the stripping rate λ_{st} becomes very small as the $(\mu\alpha)$ reaches low velocity, $v\leq e^2/\hbar$. To improve the value

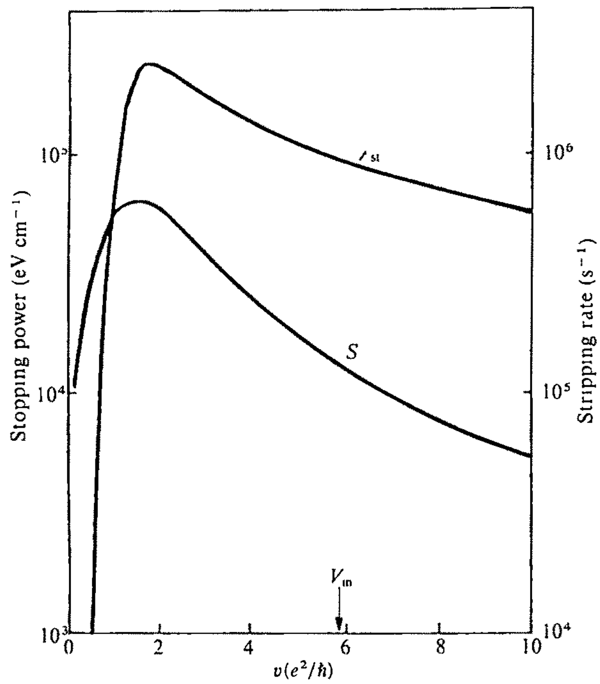

Fig. 1 Stopping power S in eV cm^{-1} and stripping rate λ_{st} in s^{-1} versus $v\hbar/e^2$ at density $\rho = 10^{19}$ atoms cm^{-3}

of the reactivation coefficient R the $(\mu\alpha)$ should be kept as long as possible in the velocity range where the stripping rate is high In principle, this can be achieved by making up for the energy loss due to the stopping power $S(v)$ of the medium by means of an applied electric field

Clearly the strength E of the electric field which is needed for this purpose is of the order $E \simeq S(v_{in})/e$, which means $E \simeq 15$ kV cm^{-1} at density $\rho = \rho_0$ This is a rather large value and consequently one has to keep the target density as low as possible On the other hand, lower limits to the value of the density are required by the condition that the processes relevant to the fusion chain (muon slowing down, atomic capture and atomic cascade, mesomolecule formation) are fast compared with the muon decay rate, $\lambda_\mu = 4\ 5 \times 10^5$ s^{-1} We assume the mesomolecule formation to be fast at $\rho \geq \rho_0$, which is optimistic but consistent with the present experimental observation and needs comparison with future measurements of $\lambda_{dt\mu}$ In this way one gets $C = \rho/\rho_0 \geq 1$ We consider two cases, $C = 1$ and $C = 10$

To calculate the reactivation coefficient we solve numerically the equations of motion of the $(\mu\alpha)$ under the combined action of the electric field and of the dissipative force $S(v)$ This allows us to solve the evolution equation for the number of stripped $(\mu\alpha)$s We first consider the case of a static, uniform electric field E a field that is constant as long as the muon is present in the target and in the region travelled by the $(\mu\alpha)$ One can envisage several configurations depending on the geometry of the apparatus Of course, the value of R is configuration dependent We focus on two extreme cases first where the initial velocity of all the $(\mu\alpha)$s is aligned with the electric field and second where the initial velocity is randomly oriented The results, presented in Fig 2, allow a straightforward interpretation The peak for the parallel case corresponds to the critical value of the field $E/C = 13\ 1$ kV cm^{-1}, when the dissipative force $S(v_{in})$ is exactly balanced by the electric field In this case the $(\mu\alpha)$ velocity is constant and the reactivation probability is $R = \lambda_{st}(v_{in})/(\lambda_{st}(v_{in}) + \lambda_\mu)$ In a higher electric field the $(\mu\alpha)$s are accelerated and therefore the stripping probability is diminished, as is clear from Fig 1 In lower electric fields the $(\mu\alpha)$s are slowed down but it takes longer to reach thermal energy than in the zero-field case and consequently $R(E) > R(0)$ Lower values of R are generally found in the isotropic case because for a fraction of the $(\mu\alpha)$s the slowing down time is shortened by the electric field In any case there are significant enhancements of R for sufficiently high electric fields

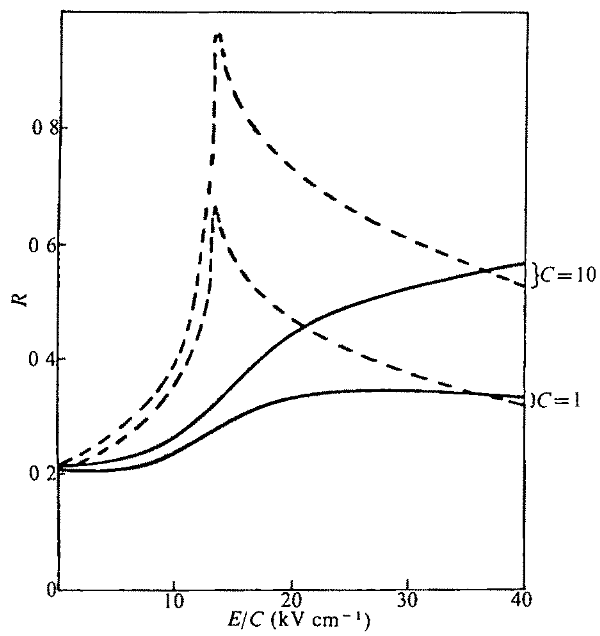

Fig 2 Reactivation coefficient R versus E/C for the parallel case (dashed line) and the isotropic case (solid line)

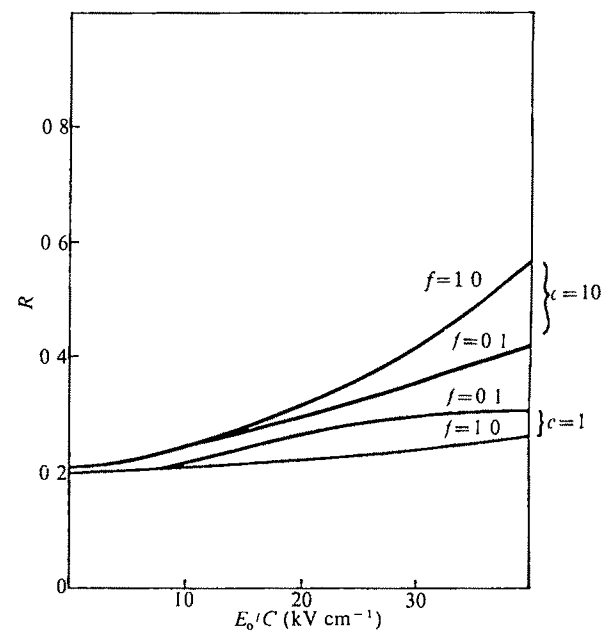

Fig. 3 Reactivation coefficient R versus E_0/C for different values of $f = \omega/\omega_0$ with $\omega_0 = 10^7$ s^{-1}

Another situation of interest is that of an oscillating electric field, $E = E_0 \cos(\omega t + \varphi)$ As the phase (φ) of the field at the time of the $(\mu\alpha)$ formation $(t = 0)$ is random, one needs to take a statistical average over φ for the calculation of the reactivation probability This is equivalent to averaging over the initial orientations of the $(\mu\alpha)$ velocity and consequently one expects the geometry of the apparatus to be irrelevant for the reactivation effect For this reason we only consider the isotropic case The qualitative features of the $(\mu\alpha)$ motion are as follows The velocity is exponentially unstable near the initial value, with a time constant $\tau \simeq M/S'(v_{in})$ where M is the $(\mu\alpha)$ mass and S' is the derivative of the stopping power with respect to the velocity In the range of field strength and frequency of interest (see Fig 3) this results in a slowing down of the $(\mu\alpha)$ The time the $(\mu\alpha)$ spends with $v \geq e^2/\hbar$ is a decreasing function of ω because, as soon as the electric field becomes opposite to v, the

($\mu\alpha$) is quickly decelerated Next, for $\omega > 2\pi\lambda_\mu$ the ($\mu\alpha$) velocity can perform several oscillations around zero, with an amplitude $A = eE_0/(\omega^2M^2 + S'(0)^2)^{1/2}$ before muon decay In this stage, for a strong electric field and a high density, the ($\mu\alpha$) spends some time in a region where the stripping rate is appreciable These considerations allow an easy explanation of the results depicted in Fig 3 The opposite behaviour with respect to ω at $C = 1$ and $C = 10$ arises from the different contributions of the slowing down stage and of the oscillatory regime to the reactivation probability R

We conclude that one can enhance the reactivation efficiency by supplying energy to the ($\mu\alpha$)'s by means of an electric field, provided that it is strong eneough On the other hand severe limitations to the strength of the electric field arise because the spark breakdown, is initiated for $E/C \simeq 3$ kV cm^{-1} (ref 8) Thus pulsed and oscillatory field seem preferable, because there it is possible to reach higher peak values than with static fields

An interesting case would be to use the oscillating electric field in conjunction with a magnetic field B At the cyclotron frequency $\omega_c = eB/Mc$ one gets the same situation as with a static electric field Furthermore, the magnetic field can be useful in inhibiting the spark breakdown

We feel that this approach, despite technical difficulties, can be a help to bring muon catalysed fusion closer to practical applications

We thank F Kottman, L Olivo and, particularly, G Zweig for helpful discussions

Search for superheavy elements in monazites using chemical enrichment

R. Stakemann, R. Heimann, G. Herrmann, G. Tittel & N. Trautmann

Institut fur Kernchemie, Universitat Mainz, D-6500 Mainz, FRG

Evidence for the existence of superheavy elements in monazite inclusions embedded in Madagascan mica and surrounded by giant radioactive haloes was given by Gentry *et al.*[1] who observed photons with energies corresponding to predicted $L_{\alpha1}$ X-ray energies of element 126 (at 27.25 keV) and also of elements 116, 124 and 127 in irradiations of such crystals with collimated proton beams. For an unambiguous identification, the detection of further members of the L X-ray series would be most important. In X-ray spectra of monazite samples these transitions are buried under the strong K X-ray peaks of the lanthanide elements. They should, however, become visible after chemical enrichment of the superheavy elements[2]. Such a treatment would also solve background problems due to a γ ray at 27.2 keV from the ^{140}Ce(p, n)^{140}Pr nuclear reaction[3–6] and to K X rays of ordinary trace elements[7]. Although our search remained negative we wish to report the results because our approach differs from that followed by others[3,8–14] in experiments which also remained negative or did not provide compelling evidence[6,15].

Due to a lack of monazite inclusions surrounded by giant haloes we have used bulk monazites as there is no obvious geochemical reason that superheavy elements should not occur in such material if they exist in inclusions although their concentration may be considerably lower First, we inspected a variety of samples, 18 monazites (from Madagascar, Nigeria, South Africa, Malaysia, Singapore, Thailand, Australia, Brasilia, Uruguay and Norway) and 2 bastnasites (from Madagascar), for superheavy element X rays by photon-induced X-ray fluorescence using the 60-keV γ ray of ^{241}Am for excitation When low-energy γ radiation rather than protons are used for fluorescence excitation, interferences by nuclear reactions can be ruled out 35-mg samples of the material were mounted on filter paper and exposed to an annular ^{241}Am source which was covered with a 0 05-mm thick rhodium foil to absorb the interfering weak 26 35-keV γ radiation of ^{241}Am The X-ray spectra were measured with a Si(Li) detector having a resolution of 0 175 keV at 5 9 keV Two spectra were taken per sample, one for 20 min to determine main constituents, and one for 10 h for trace elements In the longer exposures, spectra with good statistical quality (about 10^4 counts per channel) were obtained in the most interesting region between 23 and 29 keV

Table 1 Concentrations of some trace elements in monazites

Locality	Type of sample	In	Sn	Sb	Te
		Concentration† (p p m)			
Madagascar	Bulk	0 8	10	0 2	0 15
	Crystal*	0 3	1 0	1 2	≤0 03
Nigeria	Sand	0 9	350	0 3	0 1
Australia	Sand	0 7	12	1 2	0 9

* Collected[3] in the region of Ambatofotsikely where giant haloes occur in the surrounding biotite

† Average values, due to inhomogenities individual values can vary up to one order of magnitude

No evidence for a peak at 27 25 keV energy was found in any of the samples This corresponds to a concentration limit of ~30 p p m for element 126 in bulk monazites and also in bastnasites, a mineral which strongly enriches natural plutonium[16], the most likely chemical homologue of element 126 (ref 17 and B Fricke, personal communication) This is about the same limit (6–45 p p m) placed by the proton-induced X-ray fluorescence analysis of monazite inclusions[6] Clearly present in many samples was the tin $K_{\alpha1}$ X-ray peak, some samples also showed X-ray peaks of indium and antimony

To improve the detection limit significantly, six different samples of monazites (from Madagascar, Nigeria, Malaysia and Australia) and one sample of bastnasite (from Madagascar) were selected for chemical treatment As the chemical behaviour of elements belonging to the superactinide series with 6f–5g electrons cannot be predicted with certainty[17] the procedure applied takes into account that the elements searched for may follow the lanthanides, thorium, uranium or plutonium, even the unlikely case that they form insoluble sulphides or accompany alkaline earth and alkali elements has not been excluded *a priori* The procedure adopted is shown in Fig 1 It essentially consists of the following steps (1) 20-g samples were dissolved in hot concentrated sulphuric acid The insoluble part was fused with sodium peroxide, dissolved in water and hydrochloric acid and combined with the main sample (2) Sulphides were co-precipitated with copper sulphide from acid solution, this fraction should also contain superheavy elements around element 114, eka lead (3) By a hydroxide precipitation the bulk of the cationic elements was separated from alkaline earth and alkali elements (4) After dissolution of the hydroxides uranium- and plutonium-like elements were oxidized and lanthanides and thorium were precipitated as fluorides (5) The plutonium fraction was precipitated by ammonia in presence of carbonate ions which kept uranium in solution from where it was finally collected (6) The fluorides were dissolved in hydrochloric acid plus boric acid and transferred by a hydroxide precipitation into a strong nitric acid solution from which thorium iodate was precipitated, the lanthanides were collected in the filtrate Bastnasites were processed by a very similar procedure Samples of the different fractions obtained were

0028-0836/82/190136—03$01 00

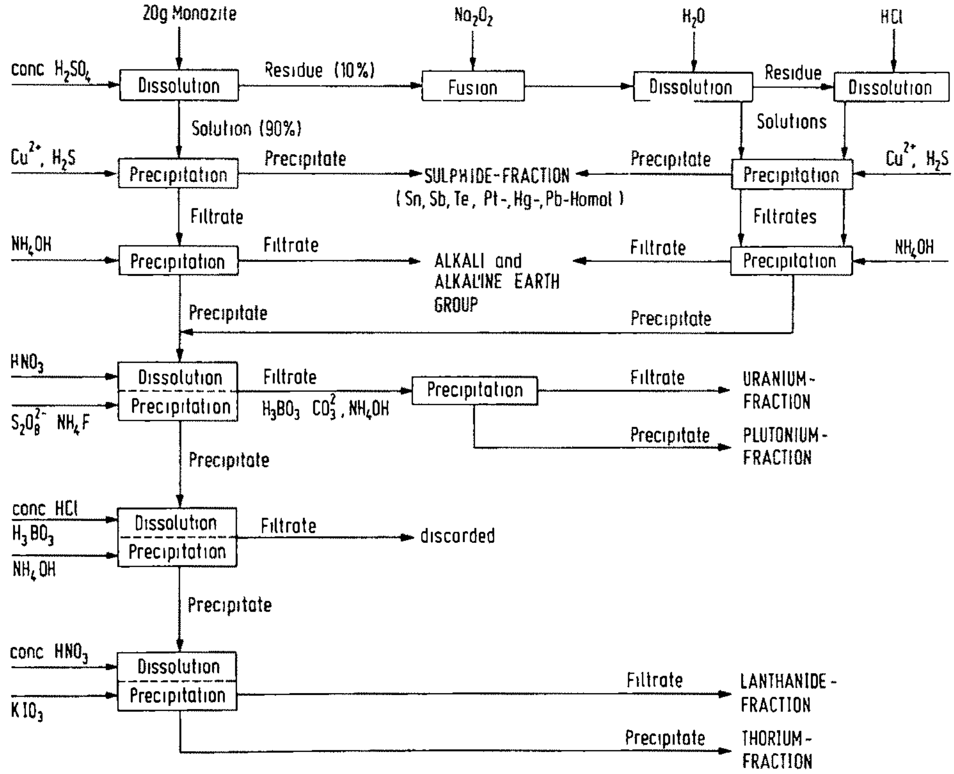

Fig. 1 Flow diagram of the chemical procedure applied in the search for superheavy elements in monazites and bastnasites

mounted for X-ray fluorescence analysis as described for bulk samples

As an example for the spectra obtained after chemical enrichment, Fig 2 shows the spectrum of a plutonium fraction No peaks can be seen at the positions of the $L_{\alpha 1}$ and $L_{\beta 2}$ X-ray transitions of element 126 From such spectra, upper limits of about 5–20 p p b (at 95% confidence level) are estimated for plutonium-like superheavy elements in the monazites investigated Peaks of main constituents are also absent, hence decontamination factors of $>10^7$ have been achieved in the chemical enrichment Similar concentration limits are estimated for the unlikely case that elements around $Z=126$ would be collected in the sulphide fraction For the other fractions, the X-ray fluorescence measurements are less sensitive because only a part of the total fraction could be mounted We estimate upper concentration limits between 1 and 30 p p m for the different fractions These limits hold for both monazites and bastnasites and should be considered as crude estimates

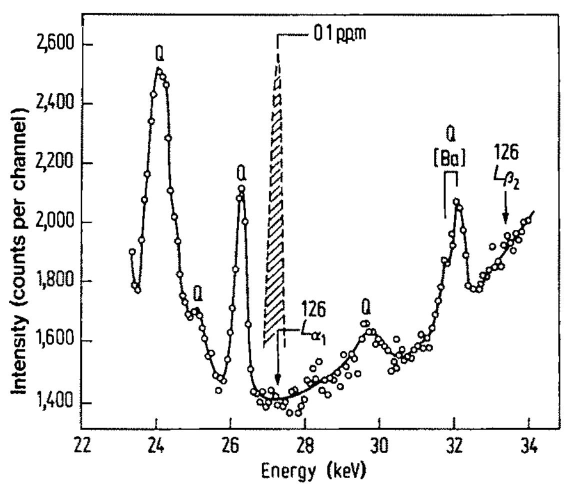

Fig. 2 Photon-induced X-ray fluoresence spectrum of a plutonium fraction isolated from a Madagascan monazite The hatched peak at the position of the $L_{\alpha 1}$ line of element 126 would result for a concentration of 0 1 p p m in the original bulk monazite sample Peaks denoted by Q belong to the background stemming from the ^{241}Am photon source and from trace elements (barium) in the filter paper used for sample mounting

The concentrations of the elements indium, tin, antimony, and tellurium which have K X-ray peaks in the region of interest were determined in some samples by X-ray fluorescence Tin and antimony were measured in the sulphide precipitate of the procedure Fig 1 As part of the tellurium(VI) is found in the hydroxide precipitate, this precipitate was dissolved in concentrated hydrochloric acid, and tellurium(VI) was reduced by boiling and then co-precipitated with copper sulphide Indium was determined in a separate sample after extraction from sulphuric acid into diethyldithiophosphoric acid and back extraction with strong hydrochloric acid Chemical yields were measured with radioactive tracers Residues in the dissolution of monazites were treated separately The results are given in Table 1 With the exception of tin the concentrations are too low to produce peaks in our spectra of unseparated monazites However, more than one order of magnitude higher concentrations were found for antimony and tellurium in X-ray spectra excited by protons[7]

In a selected number of fractions, mainly plutonium fractions, α particle spectra were recorded with semiconductor detectors No evidence for low-energy emitters reported long ago[18] nor for high-energy α particles[19] postulated as an explanation for the giant haloes[1] was found, in accordance with other studies[20,21] Inspection of some fractions by mass spectrometry also did not reveal any anomalies

Environment of Ca^{2+} ions in aqueous solvent

N. A. Hewish*, G. W. Neilson† & J. E. Enderby

H H Wills Physics Laboratory, University of Bristol, Royal Fort, Tyndall Avenue, Bristol BS8 1TL, UK

The ion Ca^{2+} is common in nature and has an important role in many biochemical processes[1]. However, the way in which this ion behaves in aqueous solution is the subject of much controversy. There are two structural parameters which are necessary for a fuller understanding of Ca^{2+} in solution: the number of water molecules to which Ca^{2+} coordinates in solution, $\bar{n}$, and the configuration which a water molecule adopts relative to it (defined by ϕ, the angle between the plane of the water molecule and the Ca–O axis and r_{CaO}, the Ca–O separation). The technique of neutron diffraction in conjunction with isotopic substitution has been successful in giving unambiguous information regarding $\bar{n}$, ϕ and r for a variety of aqueous solutions[2]. Studies have been carried out on Li^+, Ni^{2+} and Cl^- at several concentrations[3] and Ca^{2+} at one concentration[4]. We report here the results of a study of the structure of the Ca^{2+}–D_2O conformation as a function of concentration.

Investigations have been carried out on several calcium halide and calcium nitrate water systems using X-ray diffraction[5–9], and the results have been used to obtain r_{CaO} (ref 2) However, these experiments have not produced information about the concentration dependence of $\bar{n}$ and ϕ, the central problem which we consider here The isotopic substitution made was $^{nat}Ca \rightarrow {}^{44}Ca$ which changes the neutron scattering length b from 4 90 fm to 1 80 fm

Neutron diffraction data were gathered at room temperature on the D4 diffractometer of the ILL, Grenoble for two solutions of $CaCl_2$ in heavy water identical in all respects except for the isotopic state of the calcium (Table 1) Total structure factors, $F(k)$, were derived from the data after correction for multiple scattering and absorption, and were normalized by reference to the scattering from a vanadium standard[2]

The first-order difference $\Delta(k)$ between the two $F(k)$s for a given pair of solutions was derived $\Delta(k)$ is a linear combination of partial structure factors $S_{ij}(k)$ and has the form[2]

$$\Delta(k) = A[S_{CaO}(k)-1] + B[S_{CaD}(k)-1] + C[S_{CaCl}(k)-1] + D[S_{CaCa}(k)-1]$$

where c_i = atomic fraction of species i, b_i = coherent scattering length of species i, $A = 2c_{Ca}c_O\,\Delta b_{Ca} b_O$, $B = 2c_{Ca}c_D\,\Delta b_{Ca} b_D$, $C = 2c_{Ca}c_{Cl}\,\Delta b_{Ca} b_{Cl}$, $D = c_{Ca}^2\,\Delta b_{Ca}^2$, $\Delta b_{Ca} = {}^{nat}b_{Ca} - {}^{44}b_{Ca}$, $\Delta b_{Ca}^2 = {}^{nat}b_{Ca}^2 - {}^{44}b_{Ca}^2$

Fourier transformation of this function leads to the weighted radial distribution function, $\bar{G}(r)$ given by

$$\bar{G}(r) = A(g_{CaO}(r)-1) + B(g_{CaD}(r)-1) + C(g_{CaCl}(r)-1) + D(g_{CaCa}(r)-1)$$

where

$$g_{ij}(r) - 1 = \frac{1}{2\pi^2 \rho r}\int (S_{ij}(k)-1)\sin kr\, k\, dk$$

Here $g_{ij}(r)$ is the correlation function relating to the distribution of j-type particles about i-type particles and ρ is the total number density of the solution $\bar{G}_{Ca}(r)$ is shown in Fig 1, the characteristic twin peaks close to 2 4 Å and 3 0 Å are associated with the oxygen and deuterium atoms respectively of the water molecules forming the first coordination shell around the Ca^{2+} ion Within this first shell, the contribution from the ion–ion

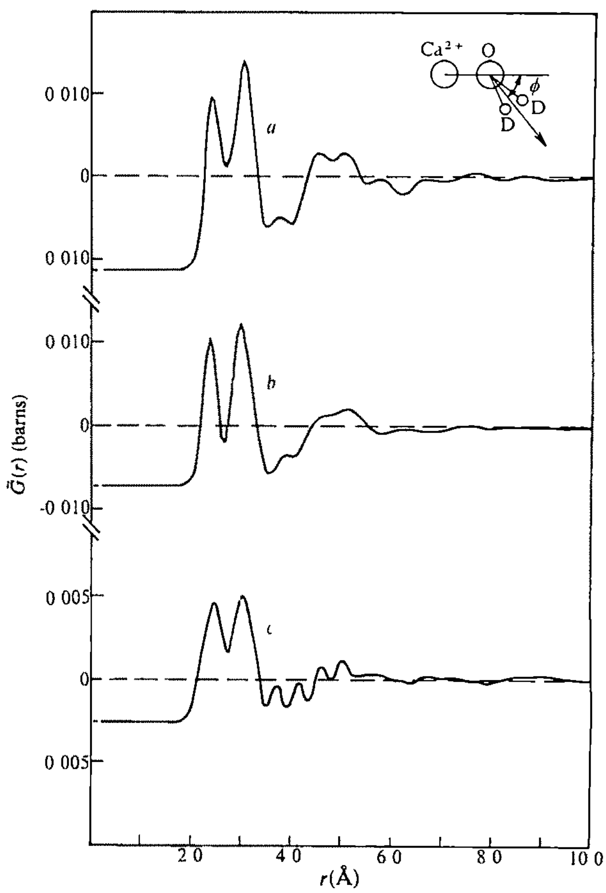

Fig 1 The weighted distribution $\bar{G}(r)$ for three $CaCl_2$ solutions in D_2O (a) 4 5 molal (b) 2 8 molal (c) 1 molal The ion–water geometry is shown at the top right

distribution functions $g_{CaCl}(r)$ and $g_{CaCa}(r)$ are negligible because the coefficients C and D are small relative to A or B (Table 1) The number of atoms, $\bar{n}_i$, to which the areas of any given peak corresponds is calculated using

$$\bar{n}_i = 4\pi c_i \rho \int_{r_1}^{r_2} r^2 g_{Cai}(r)\, dr$$

where r_1 and r_2 are the positions of the minima adjacent to the peak on either side

The above identification of the twin peaks is confirmed by the calculation of $\bar{n}_O$ and $\bar{n}_D$, in which it is found that $2\bar{n}_O = \bar{n}_D$, within experimental error The separation of the two peaks may be used to calculate ϕ assuming a geometry in which r_{OD}

Table 2 Ca^{2+}–water coordination

c(molal)	r_{CaO}(Å)	r_{CaD}(Å)	ϕ	$\bar{n}$
1	2.46±0.03	3.07±0.03	38°±9	10.0±0.6
2.8	2.39±0.02	3.02±0.03	34°±9	7.2±0.2
4.5	2.41±0.03	3.04±0.03	34°±9	6.4±0.3

is 1Å, and the angle DÔD is 105°. The results of the two latest experiments are summarized in Table 2 and Fig. 1, where we include those derived from an earlier study of a 4.5 molal $CaCl_2$.

When we compare these results with those, at comparable concentrations, for a strongly hydrating divalent ion Ni^{2+} (ref. 10) we find the following points of similarity and difference: (1) r_{CaO}, like r_{NiO} does not, when allowance is made for experimental error vary significantly with concentration. In both cases the distances agree within experimental error with those derived from X-ray studies[5–9], (2) for both ions at concentrations in excess of 1 molal, ϕ is independent of ionic strength and is ~35° which is significantly different from both the 'dipole' configuration ($\phi = 0$) and the 'lone pair' configuration ($\phi = 55°$), (3) for Ni^{2+}, $\bar{n}$ is independent of concentration. For Ca^{2+}, by contrast, $\bar{n}$ is strongly concentration dependent, increasing from ~6 to ~10 as the molality decreases from 4.5 to 1, (4) the widths of the first peak for both $g_{CaO}(r)$ and $g_{CaD}(r)$ decrease with increase in concentration, this behaviour is opposite to that observed for $g_{NiO}(r)$ and $g_{NiD}(r)$.

We believe that points (3) and (4) are manifestations of the weakly hydrating nature of Ca^{2+} ions in solution. Unlike Ni^{2+} where our earlier experiments have shown the almost universal nature of the Ni^{2+}–H_2O conformation[11] the aqueous environment of Ca^{2+} will depend crucially on the ionic strength, the counter ion and the temperature. It follows that if the properties of Ca^{2+} in solution are to be understood properly a range of experiments of the type we have reported here must be undertaken in which the principal thermodynamic variables (concentration, pressure and temperature) are changed systematically.

N. A. H. thanks the SERC for a research studentship. We all thank the scientific and technical staff at the ILL, Grenoble, and particularly Dr Chieux and Dr Cummings, for valuable help with the experiments. The aqueous solution programme of research is financed by the SERC and we are grateful for their support.

Evolution of passive continental margins and initiation of subduction zones

S. A. P. L. Cloetingh, M. J. R. Wortel & N. J. Vlaar

Vening Meinesz Laboratory, Instituut voor Aardwetenschappen, University of Utrecht, Budapestlaan, 4, 3584 CD Utrecht, The Netherlands

Although the initiation of subduction is a key element in plate tectonic schemes for evolution of lithospheric plates, the underlying mechanisms are not well understood. Plate rupture is an important aspect of the process of creating a new subduction zone, as stresses of the order of kilobars are required to fracture oceanic lithosphere[1]. Therefore initiation of subduction could take place preferentially at pre-existing weakness zones or in regions where the lithosphere is prestressed. As such, transform faults[2,3] and passive margins[4,5] where the lithosphere is downflexed under the influence of sediment loading have been suggested. From a model study of passive margin evolution we found that ageing of passive margins alone does not make them more suitable sites for initiation of subduction. However, extensive sediment loading on young lithosphere might be an effective mechanism for closure of small ocean basins.

The state of stress at a passive margin is determined by its local geometrical and rheological lithospheric properties and by the system of forces acting on the lithosphere. Of these features the thickness of the oceanic lithosphere[6], its rheological stratification[7], the push exerted by the elevation of the oceanic ridge[8,9] and the forces associated with the (negative) buoyancy of the lithosphere[10] are a function of the age of the oceanic lithosphere. The sediment loading capacity of oceanic lithosphere increases with age, through its continued cooling and densification. One might therefore expect a coupling between the height of the sedimentary column deposited at the passive margin and the age-dependent thermal subsidence of the underlying oceanic lithosphere[11]. In previous studies of the state of stress at passive margins[12–14] the possible implications of age-dependent properties of the oceanic lithosphere were not taken into account. We have studied the interrelations between age-dependent forces, geometry and rheology, to decipher their net effect on the state of stress at passive margins. We have constructed finite element models for a passive continental margin in different stages of evolution at ages of 20, 30, 60, 100 and 200 Myr. For all models a half spreading rate of 1 cm yr^{-1} is taken, characteristic of oceanic lithosphere without downgoing slabs attached to it[15]. The model features are summarized in Fig. 1. As a model for sedimentary loading we adopt triangular wedges at the continental shelf and rise. As our reference we assume that the maximum thickness of the sediments at the margin corresponds with the thickness that results if the sedimentation has been keeping up with the subsidence of a boundary layer model of the cooling oceanic lithosphere[11,16]. This implies for the maximum height of the sedimentary triangular wedge an increase from 3.6 km at 20 Myr to 9.4 km at 200 Myr, following roughly a square root of age relation. Observational data on thicknesses of post-rift sedimentary sequences are now available from geophysical surveys carried out on passive margins during the past few years[17]. From these data it follows that the reference model is representative of most of the sediment loading histories and resulting thicknesses observed at passive margins. The huge sediment accumulations at deltas, however, clearly exceed the thicknesses as given by the reference model. Therefore, a second class of models was constructed in which the full loading capacity of oceanic lithosphere was taken up by sediments with the sedimentary thicknesses ranging from 10 to 15.8 km. The width of the

sedimentary wedges varies between 150 km for very young margins to 250 km for mature margins, based on data compilations[17] As the sediments replace water we consider only excess densities ($\Delta\rho = 2\ 4 - 1 = 1\ 4\ \mathrm{g\ cm^{-3}}$)

Studies on seismicity and flexure of oceanic lithosphere bending at trenches[18 19] and analysis of flexure of the oceanic lithosphere under the influence of seamount loading[20] have demonstrated that the lithosphere is capable of supporting stresses of the order of some kilobars on geological time scales The experimental work of Goetze and co-workers[21 22] shows that the strength of the lithosphere first increases with depth and then decreases rapidly to a level of a few hundred bars in the lower part of the plate, where temperature effects become dominant and the maximum stress achievable is limited by thermally activated ductile flow Deriving temperature profiles from Crough's[23] model for the oceanic lithosphere, which model combines the merits of the boundary layer model and the plate model, we have constructed lithospheric strength envelopes for a wide range of ages These are based on Goetze's ductile flow laws in olivine for power-law and Dorn-creep rheologies, assuming a strain-rate of $e = 10^{-18}\ \mathrm{s^{-1}}$ For the sediments we assume a zero strength A similar approach was followed by Bodine and co-workers[24] Yield envelopes for lithospheric ages of 30 and 100 Myr are given in Fig 2 which shows that both the thickness H of the 'mechanical plate' (given by the depth below which the strength of the plate is <0 5 kbar) and the maximum strength increase strongly with age The flexure of the lithosphere is counteracted by isostasy Isostatic forces proportional to the deflection due to loading are included in the model Of the plate tectonic forces implemented in the models those associated with the ridge push and the negative buoyancy of the oceanic lithosphere are calculated on the basis of Oxburgh and Parmentier's[25] model for the formation of oceanic crust and Crough's[23] model for the thermal evolution of oceanic lithosphere We ignore drag at the base of the lithosphere Zero horizontal displacements are prescribed for the right-hand boundary of the model to simulate a ridge push transmitted through the continent from an adjacent oceanic plate

The deformation of the lithosphere at passive margins and the resulting stress field (order of magnitude of a few kilobars) are dominated by sediment loading[26] The contribution of the plate tectonic forces to the stress field is an order of magnitude smaller Differential stresses are largest at the points of maximum flexure These are located under the rise in the oceanic plate close to the transition of oceanic and rift-stage lithosphere Figure 2a, b shows the stress maxima for 100 and 30 Myr for the reference load The lowermost part of the mechanical plate is in yield due to the tensile stresses developed at the base The main part of the plate remains in the elastic state The effect of the rheological stratification of the lithosphere is twofold stress relaxation in the lowermost part and stress concentration in the mechanically stronger upper part This effect is particularly important if the full loading capacity of the lithosphere is taken up by sediments This can even result in complete failure of the lithosphere as demonstrated in Fig 2c

Figure 2 also shows that the state of stress depends on the age of the margin To illustrate this dependence more clearly we have plotted in Fig 3a the maximum differential (tensional)

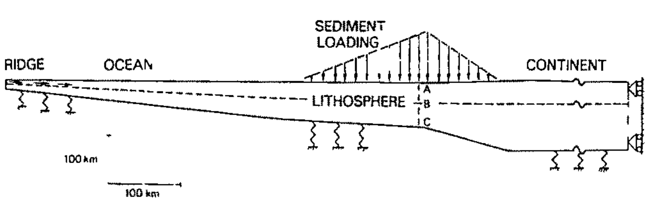

Fig 1 Model features geometry, rheology, system of forces and boundary conditions Mechanical thickness indicated by broken horizontal line Young's modulus $E = 7 \times 10^{10}\ \mathrm{N\ m^{-2}}$ and Poisson's ratio $\nu = 0\ 25$

stresses as a function of age The age dependence is strongest for ages below 100 Myr From 30 to 100 Myr—an interval in which the sedimentary loading, the mechanical thickness and the strength increase—the differential stress maxima increase with age From 100 to 200 Myr the mechanical thickness and the strength of the plate show only a small increase For ages

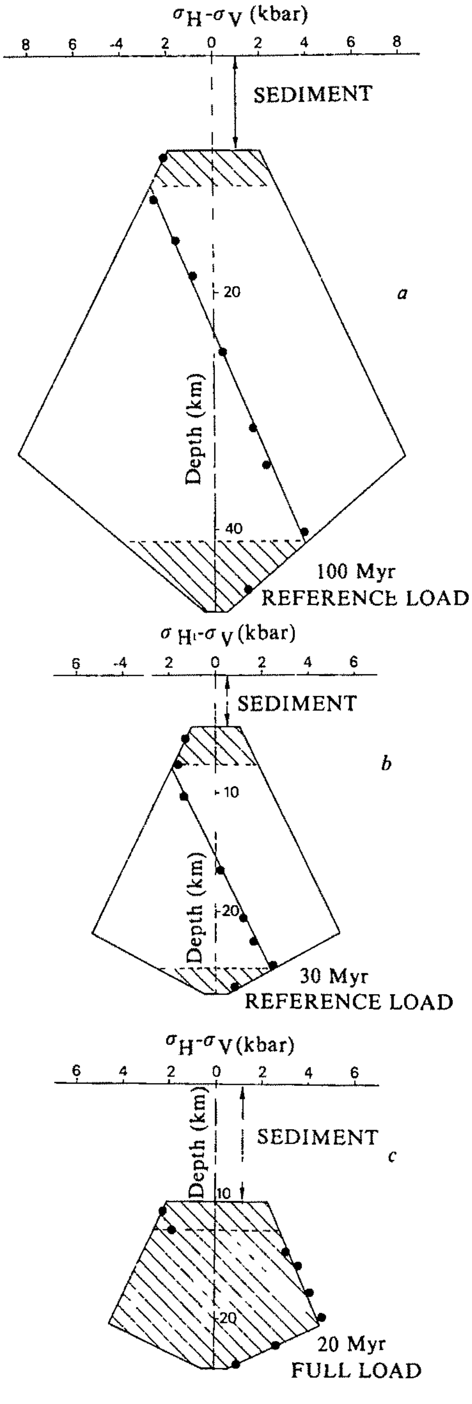

Fig. 2 Strength envelope and results of model calculations (●) at cross-section through the upper part of the lithosphere at the point of maximum flexure (AB of cross-section ABC in Fig 1) The line inside strength envelope connecting the solid dots is the stress distribution Differential stresses ($\sigma_H - \sigma_V$) are plotted versus depth Sign convention for the stresses tension positive, compression negative Zero-strength has been assumed for the sediments Hatched areas in the upper and lower part of the mechanical layer denote failure by brittle fracture and ductile flow respectively *a*, *b*, The results for the reference model of sediment loading for ages of 100 and 30 Myr *c*, The results for the full load model for 20 Myr The horizontal dashed line indicates the neutral surface just before complete failure of 20-Myr old lithosphere takes place

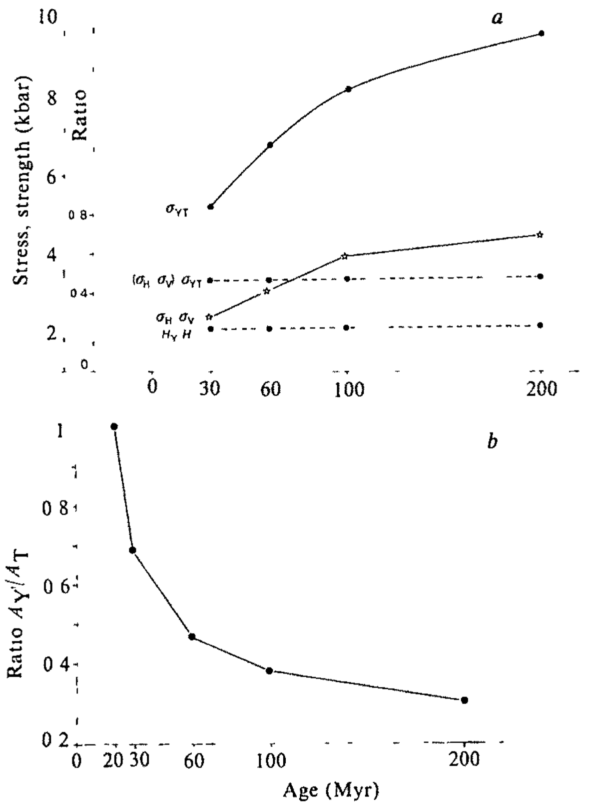

Fig 3 *a*, Model results for reference load maximum differential stresses ($\sigma_H - \sigma_V$), tensile strength σ_{YT}, their ratio and the relative thickness of the mechanical layer in failure (H_Y/H) plotted as a function of lithospheric age *b*, Results full load model ratio of A_Y (the hatched area inside the strength envelope, see Fig 2) and A_T (total area of the envelope) as a function of lithospheric age For ages below 20 Myr complete lithospheric failure is induced

above 100 Myr the increase in sediment loading according to our reference model results in only a minor increase of the stresses Interesting quantities are the ratio of the maximum stress generated and the maximum strength, and the ratio of A_Y, corresponding with the hatched area (inside the strength envelope (Fig 2)) and the total area A_T of the envelope For the reference model of sediment loading these quantities prove to be essentially independent of age because load, strength and plate thickness all exhibit the same square root of age behaviour due to the thermal evolution of the plate The situation changes drastically if the full loading capacity is taken up The surplus load of sediments added to the reference load is most effective in creating high stresses when deposited on a young margin Figure 3*b* and results of numerical calculations made for ages below 20 Myr (not shown here) demonstrate that full loading on a young passive margin (age below 20 Myr) leads to complete failure of the lithosphere Owing to the stabilizing affect of the density changes accompanying the formation of oceanic crust[25] oceanic lithosphere is gravitationally stable for ages <20–40 Myr (ref 16) As a result of its further cooling and thermal contraction the lithosphere becomes unstable for ages above 20–40 Myr (refs 16, 25) Taking into account only the lithospheric instability it was reasonable to expect that chances for initiation of subduction of oceanic lithosphere would increase with the age of the margin[10] Our work shows that if after a short evolution of the plate, subduction has not yet started, continued ageing of the passive margin alone does not result in conditions more favourable for plate rupture and initiation of subduction

Although most of the present deltas of the world are deposited on old oceanic lithosphere[27] and very few examples of modern thick sedimentary cones on young lithosphere are known, extensive sedimentary loading might have been an effective mechanism for closure of small ocean basins in geological history Closure of small oceanic basins has an important role in the process of mountain building In this context, note that in a comprehensive account of the evolution of the central Alps, Frisch[28] presents evidence for closure of oceanic basins within the first 100 Myr after opening

For older margins in general, however, it seems that the stresses generated are insufficient to induce lithospheric failure and initiation of subduction Therefore, pre-existing weakness zones in oceanic lithosphere might be more suitable sites for initiation of subduction than passive margins This view is consistent with the results of a survey of recently initiated subduction zones in the Pacific[29] showing that zones initiated in the Neogene are either at the sites of transform faults or rejuvenated pre-existing subduction zones Many of the present circum-Pacific zones are in fact the successors of subduction zones already present in the configuration before the breakup of Gondwanaland Further back in geological time different plate configurations and a different thermal regime might have provided conditions more suitable for initiation of subduction As an extreme example one might consider the Archaean where, due to the much steeper temperature profiles[30], the lithosphere must have been considerably weaker than nowadays In such a situation plate rupture requires a considerable lower stress level This suggestion is corroborated by geological data on Precambrian orogenic belts[31], showing extensive activation of passive margins bordering small oceanic basins

In the present lithospheric system special circumstances may arise in the process of global plate reorganization, when plate tectonic forces may be concentrated locally This can be important in an oceanic plate attached to a subduction zone where the pull acting on the subducting slab can be concentrated to a high level (order of magnitude of several kilobars)[32] In particular Wortel and Cloetingh[32] have shown that lateral variations in the age of the slab descending in a subduction zone might provide a mechanism for fragmentation of oceanic plates and the formation of spreading centres In an opening oceanic basin, however, the only plate tectonic force to be concentrated is the ridge push, inducing stresses with an order of magnitude of only a few hundred bars Although the concentration factor might be quite high[33] the level of the concentrated stresses due to ridge push is by no means comparable with the stresses resulting from sediment loading Therefore, plate reorganization might take place predominantly by the formation of new spreading ridges In such a process new subduction zones might be subsequently created at the sites of transform faults already present in the plate, when the new spreading direction has a component perpendicular to the direction of the transform fault

We thank Gerald Wisse (Delft University of Technology) for support with the finite element calculations, and Joel S Watkins and Rob van der Voo for critically reading an earlier version of the manuscript

Geological evidence against the Shyok palaeo-suture, Ladakh Himalaya

Hakim Rai

Wadia Institute of Himalayan Geology, Dehra Dun-248001, India

Evolution of the Ladakh Himalaya is related to the Cretaceous–Tertiary subduction of the Indian oceanic plate below the southern margin of the Eurasian plate along the Indus suture zone[1–11]. The plate tectonic reconstruction suggests two stages of subduction due to the presence of a pre-Cretaceous suture along the Shyok valley[12,13]. This hypothesis is based on there being ophiolite belts in the Indus and Shyok valleys. The Indus suture zone is well established but there have been insufficient data on the Shyok suture to confirm the existence of the palaeo-suture. I have studied the Saltoro hills, in the western part of the Shyok valley, and report here the salient geological features. With a few exceptions, the igneous and sedimentary rocks indicate that the Indus and Shyok sutures had the same Cretaceous–Oligocene history. However, the volcanic eruption during the deposition of post-Oligocene molasse in the Saltoro hills of the Shyok valley is the youngest igneous activity in the whole of the Ladakh Himalaya. Hence the geological evidence described here does not accord with the theory of palaeo-suture.

Since the formulation of the plate tectonic theory the occurrence of the Indus ophiolites has been taken as evidence for subduction in that area It has been suggested that the Himalayan mountain chain came into existence due to the subduction of the Indian plate under the Asian plate during the Cretaceous–Tertiary period[1–13] The problem attained a new dimension when an earlier subduction was proposed along the Shyok valley[12,13] to the north of the Indus suture zone (Fig 1) Previous work on the Shyok area has been unsystematic[14–19] Note that rock masses, other than the igneous, occur as thrust slices and the rock units do not maintain lithological or structural continuity in this region Recent workers[16–19] researching in limited and localized areas, have further confused the geology of this area

The eastern part of the Saltoro hills comprises igneous and sedimentary rocks ranging from Cretaceous to post-Oligocene Andesites and basalts (the Shyok volcanics) form the oldest igneous rocks erupted before the deposition of flysch Pyroxenite and hornblende gabbro have intruded into basalt–andesite association along the northern part of the Saltoro hills and in the lower Shyok valley The assemblage of basic rocks along with metasedimentary rocks of pre-Cretaceous age—the southern limit of the Karakoram sediments[15]—has again been intruded by granitoids, causing thermal metamorphism and migmatization

Major igneous activity ended in the region with the emplacement of Tertiary batholithic granitoids of the Ladakh and Karakoram[20] Sandwiched between these igneous rocks are two distinct sedimentary belts of flysch and molasse Both these belts have thrust contacts with each other as well as with the igneous rocks and occur as detached masses The flysch forms a marginal part of the eastern Saltoro hills and separates the basic volcanics from the molasse It is dominated by shale and limestone with occasional sandstone or quartzite The rocks are tightly folded near the thrust contact and are generally dipping due north The limestone, particularly in the lower part of the flysch, is highly fossiliferous and has yielded the following fossils of Upper Cretaceous–Eocene age *Fasciolites oblonga* (d'Orbigny), *Nummulites* sp aff *N obtusus* Sowerby, *N atacicus* Leymerie, *Assilina* sp , *Dictyoconus* sp , *Lockhartia* sp , *Cyclammina* sp , *Cerriocava nilkanthi* Singh, '*Feddenia*' *garkhalensis* Mathur, *Lophosmilia* sp , *Girvanella* sp , *Lithophyllum* sp and charophyte gyrogonite Beside these characteristic fossils, the rocks have yielded turritellid gastropods, brachiopod shells and crinoid stems

A thin belt of molassic sediments, indicative of shallow continental conditions, contain rounded to sub-rounded pebbles and boulders of limestone, chert, basalt, andesite, rhyolite and granitoids The limestone boulders have yielded *Orbitolina* sp , *Dictyoconus* sp , *Nummulites* sp , ill-preserved gastropods (turritellides) and so on The granitic and rhyolitic clasts have been derived from the Tertiary batholiths (Ladakh and Karakoram) and Khardung acid volcanics (38 ± 2 Myr)[21] of the Shyok valley Hence the molasse is post-Oligocene Penecontemporaneous andesitic lava flows and subsequent intrusion of basic and acidic dykes are significant features of this molasse, which is folded and has thrust contacts with flysch in the south and basic volcanics (with associated granitoids) to the north Emplacement of discontinuous bodies of chromite-bearing serpentinites with black shales has taken place along the thrust contacts, especially along the northern border of the molasse

The Himalayan mountain chain has been considered to be a typical example of continent–continent collision[3] It is thought that the subduction of the north-moving Indian plate started along the Indus suture during the end of the Cretaceous and the actual collision of the continental parts of the two plates probably began in the late Eocene or early Oligocene[10,22] Recent studies by Frank *et al*[13] in the Shyok valley, to the north of the Indus suture zone, have also included all the volcanics (undifferentiated) with Shyok ophiolites and assigned an age older than the Indus ophiolites This led them to reconstruct a new plate tectonic model for the Himalayan mountain belt, proposing two stages of subduction separated in space and time Accordingly, the first subduction was initiated in the pre-Cretaceous time (exact time of subduction is not given) along the Shyok suture, which became inactive later The second subduction followed the Indus suture during the Upper Cretaceous–Tertiary period The later predominance of the Khardung acid volcanics younger than the Ladakh Batholith described from the Shyok valley[17,18] was opposed by Bhandari *et al*[16] and Thakur *et al*[19], who established the intrusion of batholithic units into these acid volcanics Hence, the Khardung volcanics are older than the Ladakh batholith They also separated the acid and basic volcanic rocks of this region as Khardung volcanics and the Shyok volcanics, respectively

I have found three distinct volcanic phases in the Shyok valley which differ in composition, age and the environment of eruption The oldest volcanic rocks, representing the Shyok ophiolites, are basic in composition and have suffered thermal metamorphism near the contacts with gabbro, pyroxenite, tonalite and granite This complex volcanic–plutonic association is partially overlain by the Upper Cretaceous–Eocene flysch and post-Oligocene molasse, a case similar to the Indus ophiolites Thus the Shyok valley marks the northern extremity of the Indus ophiolites as there is no evidence to indicate the separation of these two belts during the Cretaceous–Eocene Extensive occurrence of basic xenoliths within the Ladakh batholith suggests that the area between the Indus and Shyok valleys was occupied by the same ophiolitic rocks which are now associated with the Indus and Shyok ophiolites These rocks provided a thick cover for the batholithic intrusion Subsequent erosion has removed the cover rocks over the batholith Consequently, the Shyok ophiolites apparently form a separate belt that runs parallel to the Indus ophiolite belt A second volcanic eruption is documented by the Khardung volcanics having acidic composition and constituting a distinct belt along the northern margin of the Ladakh batholith between Hundar and Khardung villages (Fig 1), and extends eastwards beyond the area under discussion The batholithic units have intruded into these volcanics

0028–0836/82/190142—03$01 00

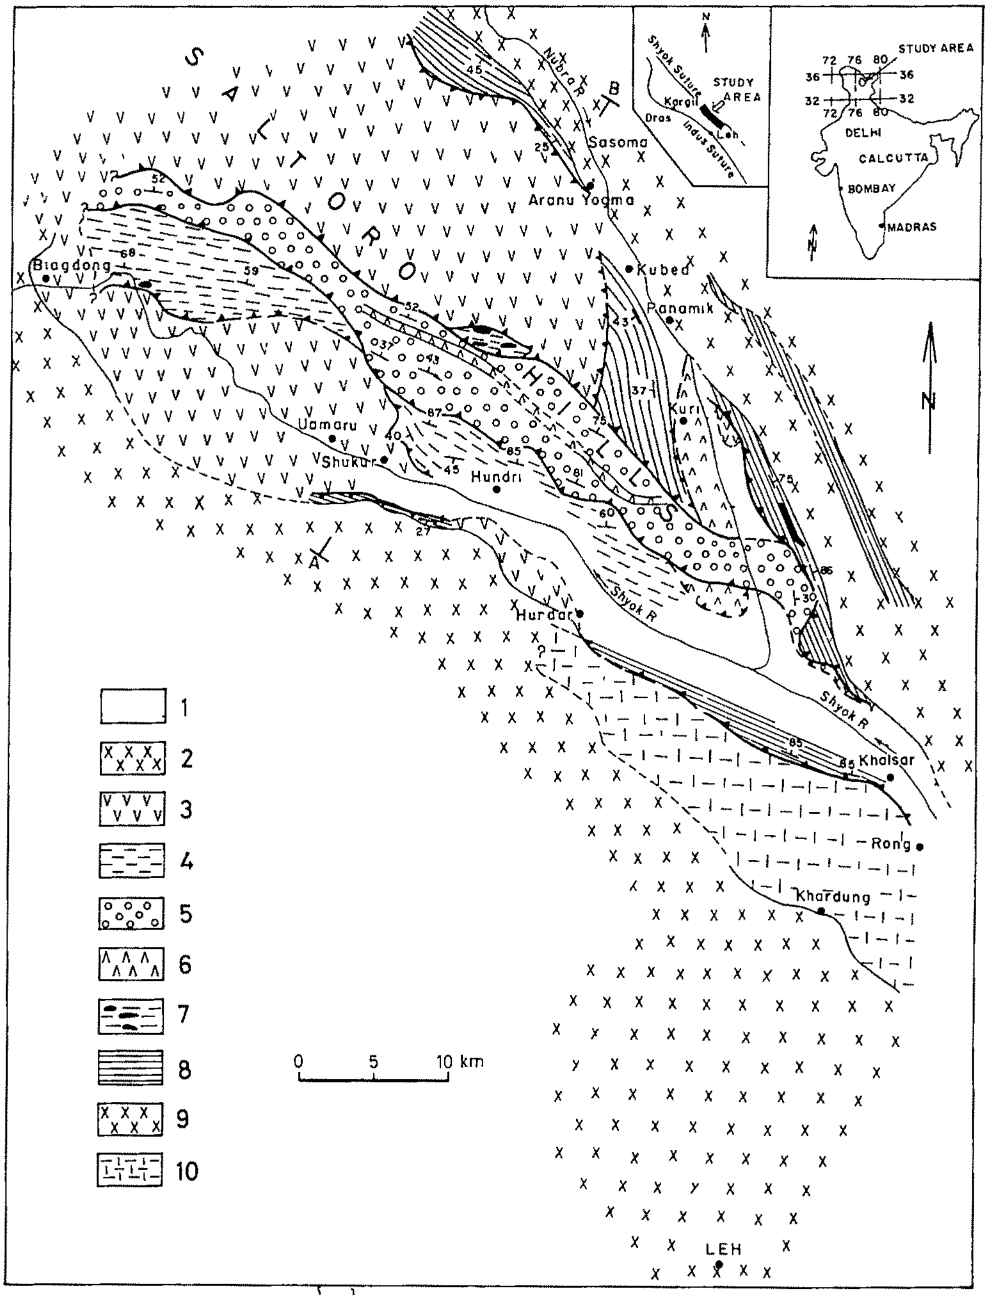

Fig 1 Geological map of the Shyok valley 1, river deposits, 2, granitoids of the Ladakh batholith, 3, Shyok volcanics with pyroxenite, 4, Cretaceous–Tertiary flysch, 5, molasse of Saltoro hills, 6, synsedimentary volcanics associated with molasse, 7, detached serpentinite bodies along with black shales, 8, Karakoram sediments (Permian?), 9, granitoids of the Karakoram batholith, 10, Khardung volcanics (acid volcanics)

at several places The association of lapilli tuffs and conglomeratic beds in the Khardung volcanics suggests that the rocks were erupted in shallow water to subaerial conditions Lapilli tuffs at the top of the main phase of this eruption are conformably overlain by lahars or mud flows having intermittent lava flows of rhyolitic composition The lahars are conformably overlain by coarse clastic, non-marine deposits, essentially composed of a sandstone–shale sequence with conglomerates

The third and the last phase of volcanic activity is preserved within the molasse of the Saltoro hills The reddish-brown volcanic rock is characterized by random distribution of euhedral plagioclase phenocrysts (An_{36-32}) in the fine groundmass Dykes of similar composition have intruded into the basic volcanics along the southern flank of Saltoro hills The molasse with which these andesitic volcanics are associated was deposited in a trough formed within basic volcanics which were intruded by the granitoids of the Ladakh batholith from the south and the Karakoram granitoids from the north

Because the molasse is rich in granitic material, probably derived from the Ladakh batholith (27.6 ± 0.6 Myr)[21], pebbles and boulders of acid volcanics (Khardung volcanics = 38 ± 2 Myr)[21] and limestone containing Palaeocene foraminifera (as in the flysch), it can be correlated with the Kargil molasse of Miocene to Pleistocene age exposed along the Indus suture zone In the absence of fossils no exact age can be assigned to the matrix of the molasse The extrusive and dyke rocks associated with molasse of the Saltoro hills are either Miocene or younger No such igneous activity has been observed in the molasse along the Indus suture zone This evidence suggests a prolonged igneous activity in the Shyok valley The volcanics and dykes of the Saltoro hills appear to be the youngest igneous rocks of the Ladakh Himalaya

It has been proposed that after subduction along the Shyok suture, a new phase of subduction commenced along the Indus suture zone during the Upper Cretaceous and continued up to the late Oligocene or early Miocene If the subduction along the Shyok suture stopped before the initiation of the new site of subduction along the Indus suture then the volcanic rocks in the Shyok valley should be much older than Upper Cretaceous It is

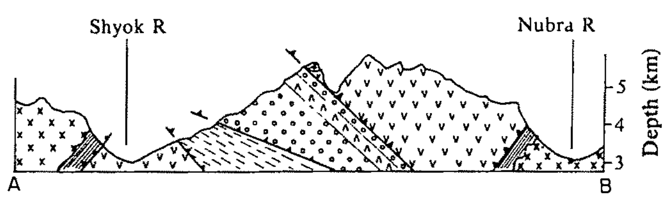

Fig. 2 The geological cross-section along A–B in Fig 1

evident from the above that the palaeo-suture idea[12,13] as proposed does not find any support lithologically, structurally or stratigraphically

A comparison of the present observations from the Shyok valley with the existing geological data from the Indus suture makes it possible to correlate the geological events of these two regions There has been widespread volcanic–plutonic igneous activity in the Ladakh Himalaya, extending from the Indus suture zone to the Karakoram during the initiation of the Himalayan orogeny The emplacement of basic and ultrabasic rocks took place from the Dras to Shyok valley on a regional scale The Ladakh batholith has intruded into this basic and ultrabasic rock association The existence of two parallel ophiolite belts is simply a result of batholithic intrusion and subsequent deep erosion, removing the cover rocks of the batholith which is rich in basic xenoliths Hence the Shyok ophiolites represent the northern extension of the Indus ophiolites emplaced during the Upper Cretaceous–Oligocene

I conclude that shallow marine conditions existed in the Shyok region at least up to the early Eocene Although the Indus suture zone became magmatically inactive during the end of the Oligocene, the Shyok valley represents still younger igneous activity Therefore, the present geological evidence does not favour the two-stage subduction with a palaeo-suture in the Shyok valley

I thank Professor I C Pande, N S Virdi and M I Bhat for comments, N S Mathur for identifying the fossil assemblage and the Director, Wadia Institute of Himalayan Geology, Dehra Dun for permission to publish this paper

Tightly bound β-hydroxy acids in a Recent sediment

Kimitaka Kawamura* & Ryoshi Ishiwatari

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukuzawa 2-1-1, Setagaya-ku, Tokyo 158, Japan

The identification of β-hydroxy acids in Recent sediments[1–6] is considered to be evidence of a bacterial contribution to sedimentary organic matter. In previous studies, β-hydroxy acids have been extracted by saponification with KOH/methanol under reflux. We have now found that β-hydroxy acids are also present in Recent sediment in a tightly bound form which cannot be extracted by ordinary saponification. Release of those β-hydroxy acids requires that the sediment be heated to ~150 °C before saponification, or the use of harsher saponification.

* Present address Institute of Geophysics and Planetary Physics, University of California at Los Angeles, Los Angeles, California 90024, USA

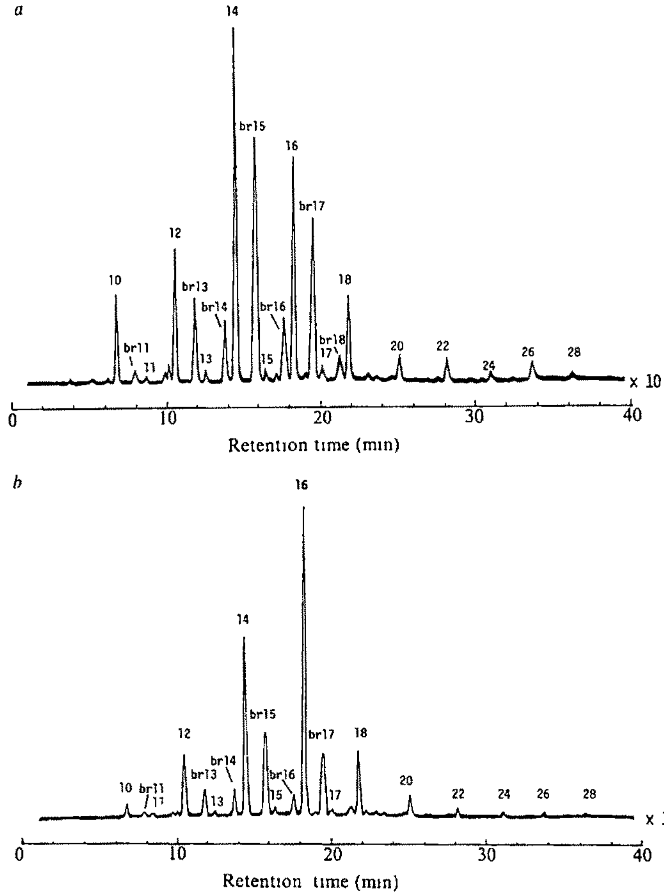

Fig. 1 Mass fragmentogram (m/z 175) of β-hydroxy acid methyl ester TMS ethers from unheated (a) and heated (154 °C, b) sediment samples

The use of mild heating to study the organic matter content of Recent sediments has been shown to increase the amount of extractable fatty acids[7–9] The increase is due to so-called 'tightly bound' fatty acids[9], which are thought to be located in organic and/or inorganic matrices where saponification reagents cannot easily act, or to be tightly linked in some unknown way with the organic and/or inorganic matrices[9] These studies suggested that organic molecules other than fatty acids might also be present in sediments in a 'tightly bound form' As β-hydroxy acids are considered markers of bacterial activity[1–4], it would be of interest to identify a tightly bound form of these compounds in sediment

Surface sediment samples were taken from Lake Biwa, the largest lake (altitude 85 m, area 674 4 km^2, maximum depth 102 m) in Japan, which is oligotrophic A wet sediment sample was homogenized using a Nihon-seiki (AM-1) homogenizer and aliquots of the sample (5–10 g wet wt) were heated at various temperatures (68–325 °C) in a sealed Pyrex tube (12 mm i d × 15 cm) under nitrogen for 24 h The unheated and heated samples were saponified with 50 ml of 0 5 M KOH/methanol containing 5% water under reflux for 2 h Saponification was carried out only once because we found that repeating the procedure increases the amount of β-hydroxy acids obtained by <3% The alkaline solution was extracted with 20 ml of n-hexane/ether (9 1) to remove neutral components The remaining solution was then acidified with concentrated HCl and the acid components extracted with n-hexane/ether (9 1) The extracts were methylated with 14% BF_3/methanol and the methyl esters separated into monocarboxylic acid fraction with n-hexane/benzene (9 1) and hydroxy acid fraction with benzene/ethyl acetate (1 1) by silica gel chromatography (Mallinckrodt 100 mesh, 5 mm i d × 10 cm) The latter fraction was treated with TMS-BA [N,O-Bis(trimethylsilyl)acetamide 25% in acetonitrile Tokyo Kasei Co Ltd] reagent to derive TMS ethers of hydroxy acid methyl

Table 1 Concentrations of β-hydroxy acids released from the sediment, pre-extracted sediment and isolated kerogen

	Sediment*	Pre-extracted sediment	Kerogen
µg per g dry weight sediment	36.3	28.7	6.8

* The amount was obtained by subtracting the concentration (17.2 µg per g) for unheated sample from the concentration (53.5 µg per g) for heated sample at 154 °C.

esters, which were then analysed by gas chromatography–mass spectrometry (Shimadzu-LKB 9000) on a glass column (3 mm i.d.×2 m) packed with 1% OV-1, with programmed temperature increases of 5 °C per min from 100 to 280 °C. The β-hydroxy acids were quantified by comparing the peak heights in the mass fragmentograms scanned at m/z 175, which is a characteristic fragment of β-trimethylsilyloxy methyl esters[1,2], with authentic standards (β-hydroxy normal C_{14}, C_{16} and C_{18} acids).

β-Hydroxy C_{10}–C_{28} acids were detected in the unheated and heated samples. Mass fragmentograms scanned at m/z 175 for the unheated and heated samples (Fig. 1) showed that most even carbon-numbered β-hydroxy acids are unbranched (normal), whereas odd carbon-numbered acids are almost entirely iso/ante-iso branched chain compounds. A similar distribution has been reported[3] for bound β-hydroxy acids from algal mats sediments. As predicted, the amount of both normal and branched β-hydroxy acids increased on heating; in particular, the concentration of normal β-hydroxy C_{16} acid increased by as much as fivefold. With increasing temperature, the total amount of β-hydroxy acids increases threefold and maximizes at 150–180 °C (Fig. 2). As sedimentary β-hydroxy acids are considered to be produced by bacteria[1–4], our observations suggest the presence in the sediment of bacteria which produce specifically a large amount of β-hydroxy n-C_{16} acid. Apart from n-C_{16} acid, the relative proportions of constituents in the unheated and heated samples are similar, suggesting that other acids have a similar origin.

β-Hydroxy acids could not have been formed directly through β-oxidation of saturated fatty acids because we confirmed that authentic n-C_{17} saturated fatty acid did not generate any β-hydroxy acids when heated with wet Ca-montmorillonite at 160 °C for 24 h, and because we could not detect any decrease in the concentration of saturated fatty acids in sediment heated to 150–180 °C. α,β-Unsaturated fatty acids are other possible precursors of β-hydroxy acids. We consider this route unlikely, however, because α,β-unsaturated fatty acids have never been found in sediments[10,11]. It therefore seems that the β-hydroxy acids released on heating may not be artefacts but may have existed originally in the sediments.

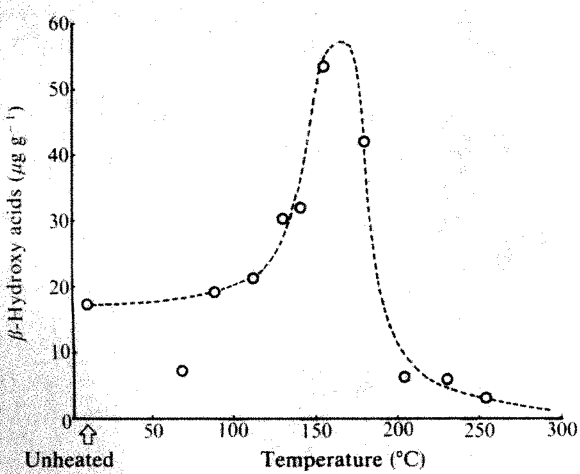

Fig. 2 Changes in the concentrations of β-hydroxy acids in sediments on heating.

Next, we conducted a harsher saponification (180 °C, 3 h) of the pre-extracted sediment (0.5 g) and the isolated kerogen (34.5 mg, ash content 32.5%) using a Pyrex tube (12 mm i.d.× 15 cm) containing 5 ml of 2 M KOH solution[12]. As shown in Table 1, we obtained a considerable amount of β-hydroxy acids. The amount of β-hydroxy acids released from the pre-extracted sediment by harsher saponification (28.7 µg g^{-1}) is almost equal to that released from the sediment by heating (36.2 µg g^{-1}). β-Hydroxy acids were also released from kerogen, although at a lower concentration (6.8 µg g^{-1} of dry sediment) than from the pre-extracted sediment. Harsher saponification with 2 M KOH solution may dissolve and/or decompose some humic materials, amorphous silica and clay minerals. It is therefore likely that most β-hydroxy acids were associated with those materials: that is, 'tightly bound' β-hydroxy acids can be considered to be occluded by (and partly linked with) humic materials, including kerogen and amorphous silica, and to be trapped in the interlayers of clay minerals. Further work is necessary to define the type of binding.

β-Hydroxy acids have been found in bacteria[2,5,13–16], but not in algae. We did not detect these compounds in phytoplankton (*Closterium*) taken from Lake Biwa. Therefore, it is obvious that sedimentary β-hydroxy acids are a result of bacterial activity. As most (68%) of the β-hydroxy acids in the sediment exist in a 'tightly bound form', the quantities of β-hydroxy acids reported previously may be underestimates.

This study was supported in part by a grant from the Ministry of Education, Japan.

Surface coatings on ancient coccoliths

Peter M. Bürki*, Lesley S. Dent Glasser & Douglas N. Smith

Department of Chemistry, University of Aberdeen, Meston Walk, Old Aberdeen AB9 2UE, UK

Coccoliths are rings of calcite plates, often of intricate design, produced by unicellular algae[1] (Fig. 1). Still widespread in modern oceans, these algae must have been extremely abundant in the Cretaceous period, and their skeletal remains form the main component of natural chalk. Both modern and ancient coccoliths are well preserved even in the corrosive environments of seawater and sediments, and the surface properties of natural chalk are said to be different from those of synthetic calcite. It has been suggested that this may be the result of a surface membrane; the present study establishes the existence of a coating on ancient coccoliths, and discusses its nature.

* Present address: Holderbank Management & Consulting Ltd, Materials Division, CH-5113 Holderbank, Switzerland.

0028-0836/82/190145—03$01.00

It has been demonstrated[2,3] that modern coccoliths are surrounded by a thin film of organic material. This could be composed of polysaccharides and amino acids[4] and may be formed when the coccolith is produced within the algal cell[5]. By careful dissolution of Oligocene coccoliths on electron microscope grids, Hamano and Honjo[6] observed residual membranes which they believed to be composed partly of organic matter. They found that the acid-insoluble residue from the coccolith fraction of the chalk contained polysaccharides, amino acids and clay-like material. Taylor (unpublished work) suggested that thin layers of precipitated clay minerals might cover and protect coccoliths in chalk. This postulate is substantiated by the work of Weir and Catt[7] and Jeans[8] who concluded that smectite is precipitated from porewater in chalk sediments. Suess[9] has also postulated organo-clay associations for all pre-Recent limestones.

In the present study, samples of Cretaceous chalk from Swanscombe were gently decalcified on electron microscope

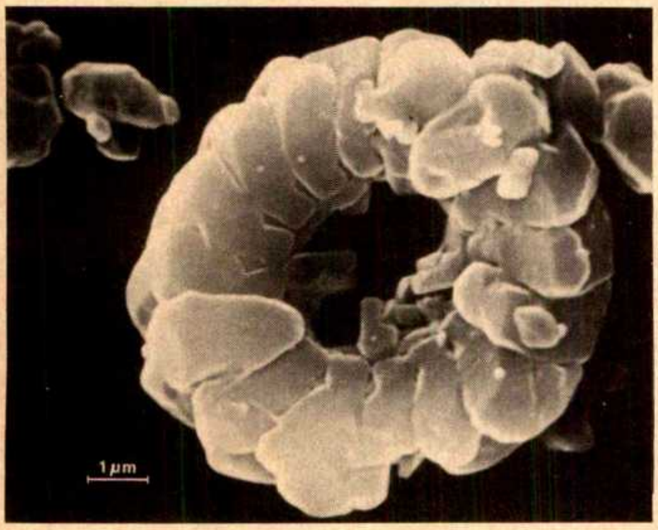

Fig. 1 Scanning electron micrograph of a Cretaceous coccolith. This is only one of the many forms observed.

grids and examined in a CORA analytical transmission electron microscope (Kratos Ltd, AEI Scientific Instruments). Residues of decalcified coccoliths are shown in Figs 2 and 3. These complete 'skins' are clearly replicas of the original structures, an example of which is shown in Fig. 1. Slower dissolution in EDTA buffered with NH_4Cl/NH_4OH produced both partly and completely decalcified rings, confirming that the coatings are on the surface of the coccoliths. Whole skins, however, were rather rare; distorted fragments either partly retaining the original structure or lacking any recognizable form were more common. The coatings may collapse after dissolution or be ruptured by the production of CO_2.

Electron microanalysis was difficult because the coatings are very thin (a few hundred ångstroms at most) giving a low count rate. By examining areas over holes in the substrate, the problem of background count was avoided, and the approximate atomic ratios found were: 1.0 Si : 0.1 Mg : 0.3 Al : 0.04 K : 0.1 Fe. P, from apatite crystals, S and Cl were also occasionally encountered. Significant levels of Ca were present only when visible fragments of calcite remained. These ratios, which were the same with all three dissolution procedures (see legend to Fig. 2), are typical of a smectite, but none of the skins gave a diffraction pattern. Similar ratios were found for the other amorphous debris of ill-defined form. Crystalline clay minerals, quartz and apatite were also observed in the residues, occasionally attached to the coatings (Fig. 3).

Because the microanalyser cannot detect carbon, no conclusion can be drawn about the organic nature of these skins.

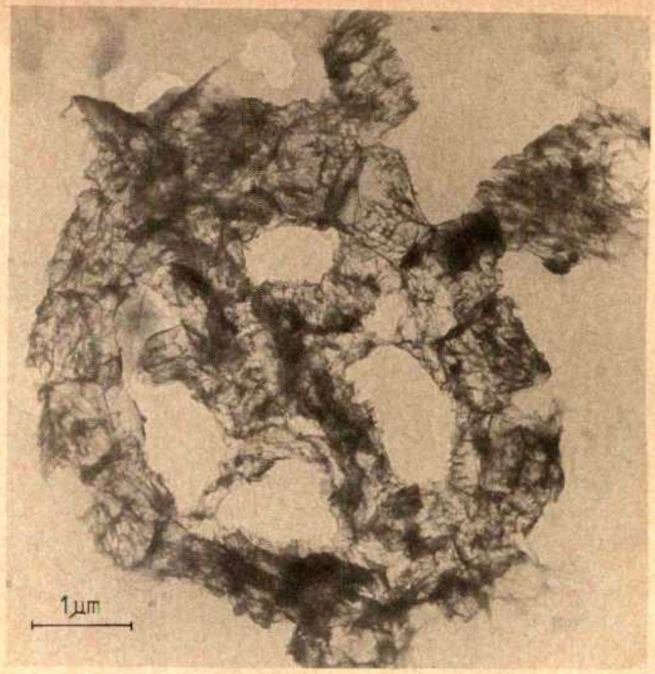

Fig. 2 Decalcified Cretaceous coccolith. The calcite was removed by floating the specimen, mounted on an electron microscope grid, on a 0.005 M EDTA solution for 30 s, then washing in distilled water for 2 h. Slower and more controllable dissolution was achieved by incorporating 5% NH_4Cl/NH_4OH buffer (pH 10) in the EDTA. Removal of the calcite with a dilute sodium acetate/acetic acid buffer (pH 5) is also possible but tends to rupture the skins. In the example shown the coating on the central 'bridge' feature, often found in coccoliths, has remained intact.

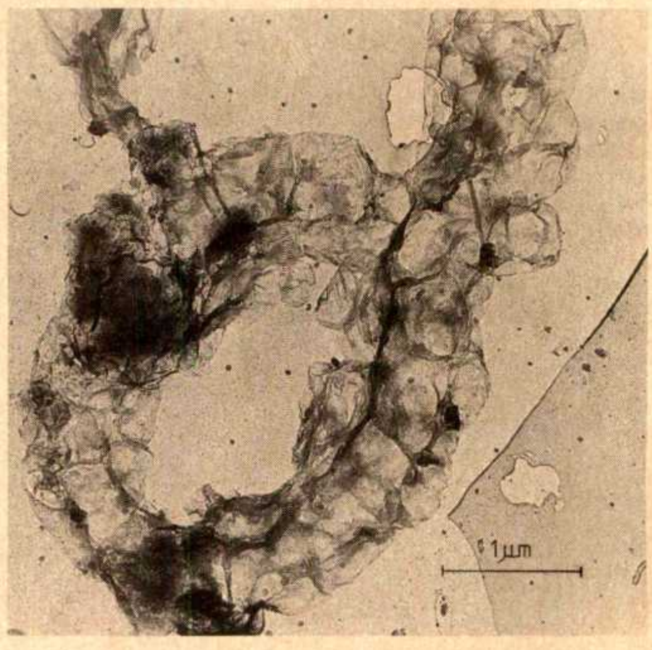

Fig. 3 Decalcified Cretaceous coccolith. The dark area on the left is smectite. The rest of the skin is amorphous.

However, C and H analysis of the chalk before and after treatment with bromine water shows that 68% of the total organic carbon is unavailable for oxidation. This could be because it is incorporated in the coatings as suggested by Hamano and Honjo[6], possibly bedded between the calcite and the amorphous alumino-silicate layer.

From the present evidence we cannot say whether the inorganic part of the coatings was incorporated during their formation or formed subsequently by preferential precipitation of siliceous material dissolved in the mobile porewater[8]. However this may be, the accurate replicas shown in Figs 2 and 3 could plainly be silicified organic membranes, and demonstrate unequivocally that Cretaceous coccoliths can have a coating closely associated with the calcite.

We thank the Welwyn Hall Research Association for financial support for this work.

Flow-field variables trigger landing in flies

Hermann Wagner
Max-Planck-Institut für biologische Kybernetik, Spemannstrasse 38, D-7400 Tübingen 1, FRG

The eyes of moving animals experience a continuously changing flow of stimulation. Information contained in this 'optical flow field' can be extracted to control movement[1–4]. I present here evidence that pre-landing deceleration in flies is determined by such information: onset of deceleration is triggered when the ratio of the image expansion of a target on the retina to the image size ('relative retinal expansion velocity', RREV) reaches a critical value.

Female houseflies (*Musca domestica* L.) flying freely in a cage ($90 \times 70 \times 100$ cm) were simultaneously filmed from two sides at 50, 80 or 100 frames per s while landing on black stationary spheres (radius, $r = 0.25$–1.0 cm). Frame-by-frame analysis allowed the reconstruction of three-dimensional landing trajectories. A sample stereogram is shown in Fig. 1. I evaluated certain variables, including (1) the fly's velocity (v), defined as the distance travelled along the flight path between two frames, divided by the sampling time Δt; (2) the distance from the fly to the centre of the target (x); (3) the change of distance with time ($\Delta x/\Delta t$, which is the component of the velocity in the direction of the target); (4) the solid angle subtended by the target on the retina (retinal size a); and (5) the target's retinal expansion velocity ($\Delta a/\Delta t$). As the retinal image is the only source of optical information directly available to the animal, the physical variables (1–3) can only be derived indirectly via the optical variables (4, 5). x, r and a are related as follows[5]:

$$a = 2\pi(1-\sqrt{1-(r/x)^2}) \approx \pi r^2/x^2 \quad (\text{for } x \gg r) \qquad (1)$$

(if $x = 2r$, the error of the approximation is 7%) and in analogy to Lee[15] for the approximation:

$$\text{RREV} = \frac{1}{a}\frac{\mathrm{d}a}{\mathrm{d}t} = -2\frac{1}{x}\frac{\mathrm{d}x}{\mathrm{d}t} \quad \text{or} \quad \text{RREV} = \frac{\mathrm{d}}{\mathrm{d}t}\ln a = -2\frac{\mathrm{d}}{\mathrm{d}t}\ln x \qquad (2)$$

Flies reduce their flight velocity before landing and the onset of the final deceleration before landing is taken to define the beginning of the landing phase. Figure 2*a* shows the velocity profile of different landing trajectories compared by setting zero time to the onset of deceleration. Tests were carried out to determine whether the onset is related to the variables x, a, $\Delta a/\Delta t$, $1/a \times \Delta a/\Delta t$ and v/x. Table 1 shows data obtained from 31 landing trajectories, pooled at corresponding times to allow calculation of the coefficients of variation (c.v.) for each variable. As the c.v. is a measure of dispersion defined by standard deviation/mean, variables showing a high c.v. cannot be regarded as critical for the initiation of pre-landing deceleration. At each sampling point the c.v. of both the RREV and the velocity/distance quotient are much smaller than all others, which suggests the prime importance of these variables in initiating onset of deceleration. As velocity and distance are only indirectly accessible, it is concluded that the critical cue is the RREV and not v/x.

The RREV is given by the ratio of retinal expansion velocity to retinal size (equation 2). By correlating these variables it

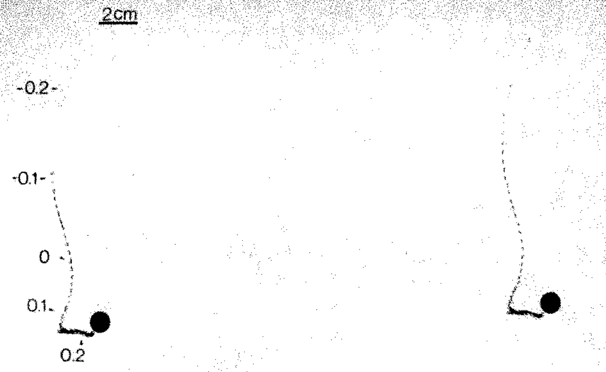

Fig. 1 Example of a fly trajectory viewed from above. It should be viewed with normal stereoglasses. Open circles and lines represent the head and long axis of the fly, respectively. The solid circle indicates the position and size of the target. The legs could not be seen on the films. Numbers represent the time (s) with onset of deceleration set to zero time; 100 frames per s.

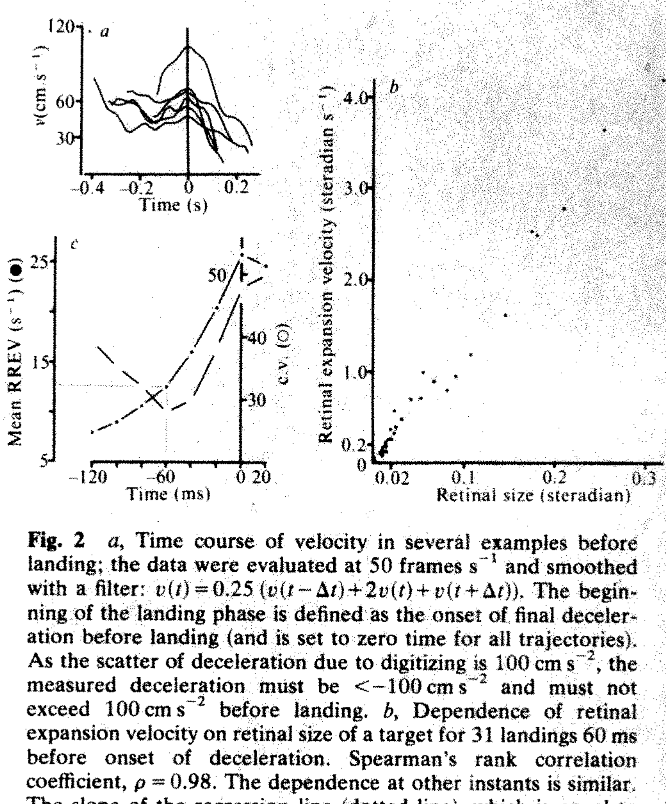

Fig. 2 *a*, Time course of velocity in several examples before landing; the data were evaluated at 50 frames s^{-1} and smoothed with a filter: $v(t) = 0.25\,(v(t-\Delta t)+2v(t)+v(t+\Delta t))$. The beginning of the landing phase is defined as the onset of final deceleration before landing (and is set to zero time for all trajectories). As the scatter of deceleration due to digitizing is 100 cm s^{-2}, the measured deceleration must be < -100 cm s^{-2} and must not exceed 100 cm s^{-2} before landing. *b*, Dependence of retinal expansion velocity on retinal size of a target for 31 landings 60 ms before onset of deceleration. Spearman's rank correlation coefficient, $\rho = 0.98$. The dependence at other instants is similar. The slope of the regression line (dotted line), which is equal to the RREV, is 13.2 s^{-1}; the high correlation coefficient demonstrates that the variance of the RREV is low. *c*, Mean (●) and c.v. (○) of the RREV at different time shifts with respect to onset of deceleration (zero time). Coefficient of variation data for the RREV are the same as in Table 1. The c.v. minimum at $t = -60$ ms may indicate the reaction time from the threshold RREV to the onset of deceleration. Dotted lines show the value of the RREV corresponding to −60 ms.

0028-0836/82/190147—02\$01.00

Table 1 Coefficients of variation for different variables with respect to onset of final deceleration

Time (ms)	+20	0	−20	−40	−60	−80	−100	−120
Distance (x)	78	72	66	62	58	55	53	52
Retinal size (a)	128	124	128	127	128	128	137	143
Retinal expansion velocity ($\Delta a/\Delta t$)	143	132	133	128	128	119	113	109
RREV ($1/a \times \Delta a/\Delta t$)	50	48	38	30	28	32	35	39
Velocity/distance (v/x)	48	36	29	27	28	30	32	32

At each instant only one value per trajectory was used to calculate the c.v.. The c.v. of the RREV and the quotient of velocity and distance from fly to target should be identical if the flies approach the target in a straight line [equation (2)]. The differences between these c.v. indicate that this condition is often not fulfilled.

was shown that during the last 120 ms before onset of the final deceleration their dependence on each other was strong, that is, the variance of the RREV was small, confirming the conclusion drawn from Table 1. This is shown in Fig. 2*b* at 60 ms before onset of deceleration, the instant of maximum dependence corresponding to the minimum of the c.v. of the RREV (Fig. 2*c*, open circles). The mean value of the RREV increases steadily (Fig. 2*c*, solid circles). Together with the correlation analysis, this finding leads to the conclusion that, for onset of deceleration to occur, the RREV must exceed a critical value. The minimum of the c.v. at −60 ms (Fig. 2*c*, open circles) might represent the response delay (see ref. 6). Thus, the threshold value of the RREV is $\sim 13\ \mathrm{s}^{-1}$ (dotted lines in Fig. 2*c*).

Previous experiments on landing using tethered flying insects[7–13] did not yield the same conclusions as presented here from free-flight experiments. In the earlier experiments, extension of the legs before landing ('landing response'[7]), which could not be seen on my films, was taken as a criterion for the initiation of the landing procedure. The conclusions from these experiments are consistent neither amongst themselves nor—partly—with the findings presented here. In particular, a critical retinal target size alone, as proposed by Eckert and Hamdorf[10], does not initiate landing of free-flying flies as shown by the high c.v. (Table 1). Furthermore, as the RREV is almost independent of real target size (equations 1 and 2), the present conclusion can better explain landings on targets of various dimensions than hypotheses which take into account retinal size or retinal expansion velocity alone. Other authors[8,11–13] found that the landing response could be elicited by centrifugal movement of striped patterns. This simulates target expansion and these results are thus qualitatively consistent with those reported here. However, the dependence of the landing response on the RREV has not yet been investigated, either in experiments with tethered flying flies or in electrophysiological investigations of units with selective response to an expanding stimulus[14].

Formally, the RREV is the inverse of 'time to collision', that is, the time needed to reach a target directly approached at constant velocity[15]. As many landing trajectories are neither direct nor of constant velocity, a simple interpretation of the RREV as time to collision is not applicable. The RREV, however, represents the more general case: it gives information about the distance to a target not in absolute, but in relative units dependent on both the translation velocity and the direction of flight with respect to a target. This means that a distance is tagged with a time. Thus, the important cues for landing are times and not distances. Similar arguments might hold for escape responses and even control of cruising flights. The present conclusions agree well with a theory established by Lee and co-workers[4,15] for humans and birds, and prove that exploiting variables in the optical flow field can provide simple solutions for rather complex orientation tasks.

I thank Professor W. Reichardt for discussions and helpful criticism. Drs J. Brede, H. Bülthoff, E. Buchner, T. Collett, M. Egelhaaf, K. Hausen, T. Poggio, K. Vogt, Chr. Wehrhahn and J. Zeil critically read an early draft of the paper and made many useful suggestions. I thank Dr R. Cook for correcting the English. Computer programs were modified from a program package developed by H. Bülthoff, Chr. Koch and T. Poggio.

A peripheral locus for amphetamine anorexia

Michael G. Tordoff, Jill Hopfenbeck, Larry L. Butcher & Donald Novin

Department of Psychology and Brain Research Institute, University of California, Los Angeles, California 90024, USA

The anorexic action of amphetamine is thought to be mediated by central dopaminergic and noradrenergic neurotransmitter systems[1–4]. However, some of its sympathomimetic effects can be attenuated by denervation[5] or by depletion of peripheral noradrenaline[6,7]. This led us to consider the possibility that a component of amphetamine anorexia might be due to excitation of the sympathetic innervation of the viscera. To test this, the amphetamine dose–response curves of free-feeding rats with visceral sympathetic denervation by coeliac ganglionectomy (GAN) were compared with those of sham-operated controls (SHM). We report here that ganglionectomized rats were protected from the anorexic effects of low doses of amphetamine (0.2 or 0.4 mg per kg interaperitoneal, i.p.). We suggest that the anorexia might result from enhanced hepatic glycogenolysis[8], and the subsequent stimulation of hepatic metabolic receptors that inhibit feeding[9].

Sixteen male Long-Evans hooded rats (Charles River) weighing 216–246 g were maintained on a 12 : 12 h light/dark cycle (dark period beginning at 17.00) with food (Wayne lab blox, Chicago) and water continuously available. Half the animals were subjected to coeliac ganglionectomy by the method of Lambert[10]; the others were subjected to identical procedures except that the ganglion was not excised. After surgery, GAN rats showed a transient 2-day hypophagia accompanied by diarrhoea, which is a good indication of complete ganglionectomy. Rats were given 24 days to recover after surgery. They were then tested in groups of four (two GAN and two SHM) every four days. All received four saline injection trials, to habituate them to the drug administration and measurement regimen, followed by counterbalanced injections of saline or (+)amphetamine sulphate (0.2, 0.4, 0.6, 0.8 or 1.0 mg per kg i.p.).

The procedure used for habituation and testing was as follows: 1 h before the start of the dark period, each rat was

0028–0836/82/190148—03$01.00

weighed and placed in a cage designed to measure activity by photobeam crossings[11]. Food was available on the cage floor and tap water could be obtained from a drinking tube. Just before the lights were turned off, each rat was injected and a fresh quantity of food was provided. Food intake was measured after 30, 60, 90 and 120 min by weighing the remaining food and subtracting this value from its initial weight. Activity was monitored continuously but, for purposes of data analysis, was grouped into 30-min intervals.

Separate three-way analyses of variance (group × dose × time), followed by Tukey's *post hoc* tests, were done on the food intake and activity measurements. Amphetamine caused a dose-related anorexia ($F(5,70)=8.31$, $P<0.001$): during the first 90 min after injection, the food intake of SHM rats was significantly depressed by all doses of amphetamine. However, GAN rats showed no decrease in consumption in response to amphetamine at either 0.2 or 0.4 mg per kg ($F(5,70)=2.42$, $P<0.05$; see Fig. 1*a*). During the same interval, both groups showed a comparable dose-related hyperactivity ($F(5,70)=28.59$, $P<0.001$; see Fig. 1*b*). Thus, the feeding dose–response curves of SHM and GAN rats differed, but their activity responses were the same. Disrupting the sympathetic innervation of the viscera caused an attenuation of anorexia that was independent of the hyperkinetic action of amphetamine. This sympathetic mechanism accounted for a relatively large proportion of the anorexia at low doses of amphetamine, and relatively little at higher doses.

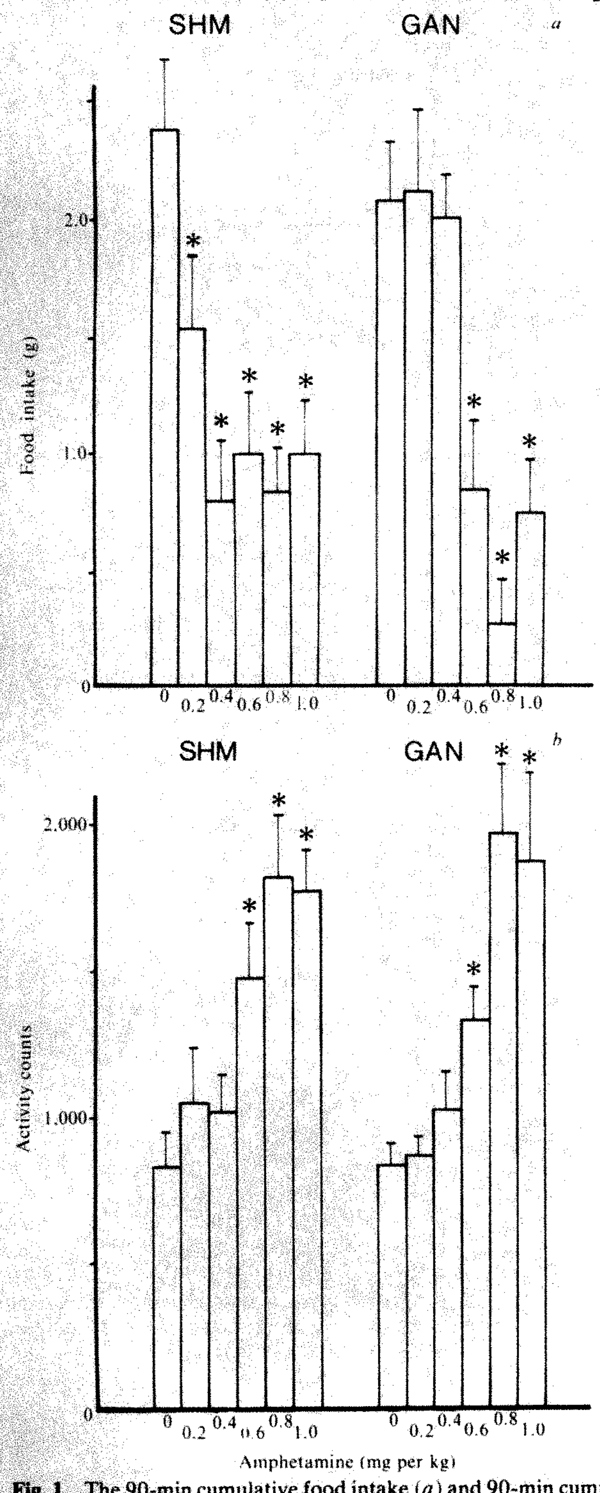

Fig. 1 The 90-min cumulative food intake (*a*) and 90-min cumulative activity (*b*) of sham (SHM) and coeliac ganglionectomized (GAN) rats were measured after administration of various doses of amphetamine. * $P<0.05$ compared with saline-injected controls (Tukey's test).

It is unlikely that nonspecific effects of the coeliac ganglionectomy affected the results. The food intake of SHM and GAN rats after injections of saline was statistically indistinguishable, as was activity after all injections. Furthermore, GAN rats ate more food than controls after low doses of amphetamine, which suggests there was no general debilitation.

The coeliac ganglion innervates most of the abdominal viscera. However, we consider the most likely site for the peripheral anorexic action of amphetamine to be the liver. The liver has considerable sympathetic innervation[12] and is involved in the glucostatic regulation of feeding. Russek[9] postulated that hepatic receptors sensitive to glucose or one of its metabolites respond to the liberation of glucose from glycogen, so that promotion of glycogenolysis stimulates hepatic receptors, which inhibit feeding. In support of this hypothesis, glucose, 2-deoxy-D-glucose and adrenaline have greater effects, with shorter latency, when administered intraportally or intraperitoneally than systemically[8,13,14]. In addition, vagotomy attenuates the anorexia induced by glucose, glucagon, adrenaline and amphetamine[14–17]. Both electrical stimulation of hepatic sympathetic fibres and i.p. injection of amphetamine induce glycogenolysis[8,18]. Finally, glucagon and amphetamine are more potent in rats with high rather than low glycogen levels[8,17]. A possible mechanism for peripherally-induced amphetamine anorexia could therefore involve the stimulation of sympathetic hepatic nerve fibres, hence inducing glycogenolysis and subsequent activation of metabolic receptors capable of inhibiting feeding[19,20].

Because the coeliac ganglion has both efferent and afferent hepatic innervation, including a large component of the vagus nerve, this study did not determine whether amphetamine acts either directly on the liver or its local innervation, or indirectly via a sympathetic discharge which originates in the CNS and which activates sympathetic fibres that travel to the liver. However, recent evidence suggests that direct stimulation of the liver by amphetamine may be relatively unimportant, as amphetamine-induced anorexia was more effectively blocked by coeliac ganglionectomy than by subdiaphragmatic vagotomy but adrenaline-induced anorexia was attenuated to the same extent by these two surgical procedures[16]. As adrenaline is a sympathomimetic which, unlike amphetamine, does not easily enter the brain, and because the coeliac ganglion provides hepatic sympathetic innervation, the additional protection from amphetamine anorexia afforded by coeliac ganglionectomy may reflect interruption of sympathetic discharge of CNS origin.

Blundell and Burridge[21] suggested that amphetamine anorexia consists of additive noradrenergic and dopaminergic components. In their model, the anorexia attributable to noradrenaline (NA) increases over low doses of amphetamine but reaches a maximum ~0.5 mg per kg. The anorexia attributable to dopamine (DA) has little effect in this range, but increases rapidly for doses >0.5 mg per kg. Although there is evidence which seems to contradict the Blundell and Burridge model[22–24], it is tempting to speculate that the dual anatomical (brain and periphery) and neurochemical (DA and NA) mechanisms may correspond. One might represent a centrally-mediated dopaminergic factor, and the other, a peripherally-mediated noradrenergic sympathetic discharge factor. Our

finding that GAN and SHM animals showed differences only with doses of amphetamine <0.5 mg per kg provides support for such a speculation, as the Blundell and Burridge model predicts this to be the dose where the major contribution to amphetamine anorexia changes from NA to DA.

Previous reports have negated the possibility of a peripheral locus for the anorexia induced by amphetamine, but these studies have used large doses, food-deprived animals or insensitive measuring techniques[2,3]. We have found that these conditions are the reverse of those required to observe differences in feeding between sympathetically denervated subjects and their controls. This suggests that the usual techniques for screening anorexic drugs using large doses and food-deprived rats may be inappropriate, because such tests would not recognize active anorexigens that had sympathetico-hepatic effects.

Effect of chloroform on charge movement in the nerve membrane

J. M. Fernández*, F. Bezanilla* & R. E. Taylor*†

It is generally accepted that membrane-bound charges or dipoles moving under the influence of the transmembrane electric field produce conformational changes that result in the opening and closing of ion-selective channels[1]. The location of these charged groups or dipoles is unknown but it has been speculated that they are sited either inside the channel macromolecule or embedded in the lipid bilayer[2]. We report here that in the squid axon membrane, the general anaesthetic chloroform reduces the magnitude of the gating currents but has no effect on their kinetics. In contrast, chloroform increases the rate of charge translocation of the lipophilic ion dipicrylamine (DpA⁻). These results indicate that the gating charges responsible for the opening and closing of the Na^+ channel do not move in the bulk lipid of the membrane as do DpA^- molecules, but that they move in a physical domain where their kinetics are unaffected by changes in the structural parameters of the lipid matrix. It is therefore unlikely that general anaesthetics act to modify the kinetics of the opening and closing of ionic channels via modifications of the structural parameters of the lipid matrix[3].

Experiments were performed on internally perfused and voltage-clamped squid giant axons using the methods of Bezanilla *et al.*[4] to record Na^+ and gating currents. Figure 1*a* shows that perfusion of the axon with a solution containing 60 mM chloroform reduced dramatically the magnitude of the inward Na^+ current. To observe sodium and gating currents simultaneously, the axon was bathed in a reduced Na^+ concentration (Fig. 1*b*, trace 1). In these conditions, 43 mM of chloroform added to the internal perfusion solution reduced the Na^+ current in parallel with the gating current (Fig. 1*b*, trace 2). Both effects were reversed on removing the chloroform (Fig. 1*b*, trace 3). The effect of chloroform on the Na^+ and gating currents was not reversed by hyperpolarizing prepulses, suggesting that these effects are not related to the mechanisms of inactivation.

To analyse the effects of chloroform on gating currents, the Na^+ current was eliminated by substituting the external Na^+ with the impermeant ion Tris and by the addition of 300 nM tetrodotoxin (TTX). Figure 1*b*, traces 4, 5, shows that

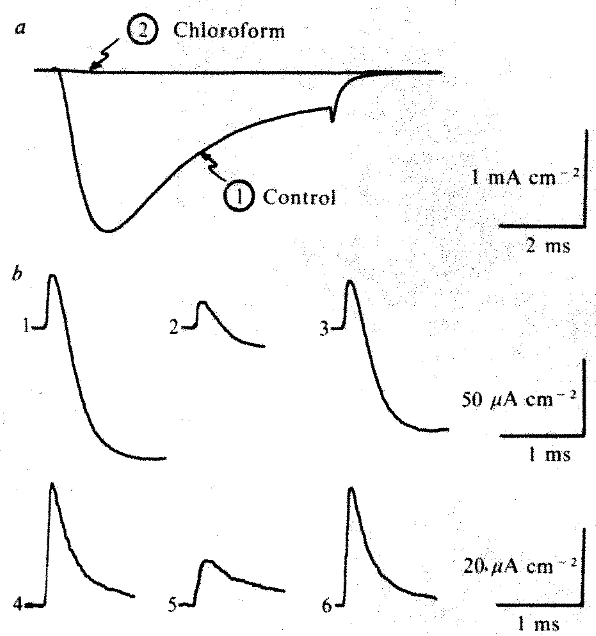

Fig. 1 Effect of chloroform on the Na^+ inward current and the gating currents. *a*, Trace 1, inward Na^+ current before treatment with chloroform; trace 2, abolition of the Na^+ current when the axon was internally perfused with a solution containing 60 mM chloroform. Traces 1 and 2 were obtained under voltage clamp by pulsing to −10 mV from a holding potential (HP) of −70 mV. Leakage and linear capacitive currents were subtracted using the P/4 technique with a subtracting holding potential (SHP) of −140 mV (for details of the technique see ref. 4). The external solution was 440 mM NaCl, 50 mM $MgCl_2$, 10 mM $CaCl_2$, *p*H 7.2. The internal solution was 100 mM *N*-methylglucamine(NMG) glutamate, 100 mM NMG fluoride and ~400 mM sucrose adjusted to make the internal and external solution isosmotic, *p*H 7.2, 5 °C. *b*, Trace 1, axon with low external Na^+ allowed measurement of the ON gating current as well as the Na^+ inward current. Trace 2, when perfused with a solution containing 43 mM chloroform, a significant reduction in the Na^+ current was paralleled by a reduction in the gating current. Trace 3, on removal of chloroform, both effects were reversed. Trace 4, ON gating currents measured in the same axon as in traces 1–3, after eliminating the Na^+ current with an external solution containing Tris and 300 nM TTX. Trace 5, partial decrease in the size of the ON gating current when the axon was perfused with the same solution as in trace 2. Trace 6, after removing chloroform, the gating current was almost completely recovered. The full effect of chloroform on the Na^+ and gating currents occurred within seconds of beginning the perfusion with chloroform-containing solutions; recovery was complete within <1 min after removal of chloroform. Traces 1–6 were obtained by pulsing to 30 mV from HP = −70 mV using the P/4 procedure with a SHP of −140 mV. The external solution (traces 1–3) was 88 mM NaCl, 360 mM Trizma 7.2, 50 mM $MgCl_2$, 10 mM $CaCl_2$. Traces 4–6 were obtained using an external solution containing 450 mM Trizma 7.2, 50 mM $MgCl_2$, 10 mM $CaCl_2$ and 300 nM TTX. The internal solution in each case was 100 mM NMG fluoride, 100 mM NMG glutamate and ~400 mM sucrose, *p*H 7.2, 5 °C. Where indicated, chloroform was added to the internal solution, which was stirred for 30 min in a closed glass cylinder. The chloroform concentrations correspond to the fraction (v/v) added. In the experiments reported here we did not add chloroform to the external solution because the experimental chamber consisted of acrylic plastic (Perspex).

0028-0836/82/190150—03$01.00

chloroform reduced the size of the gating current. As expected, this effect was reversible (Fig. 1*b*, trace 6).

Gating currents during a depolarizing or hyperpolarizing pulse (ON gating) can be described by the sum of two voltage-dependent exponential relaxations[5] (Fig. 2*a*, trace 1); the solid line indicates a two-exponential fit with time constants $\tau_F = 126\ \mu s$ and $\tau_S = 571\ \mu s$. When the axon was internally perfused with a solution containing 60 mM chloroform, the remaining gating current (Fig. 2*a*, trace 2) could again be fitted with two exponentials having time constants $\tau_F = 112\ \mu s$ and $\tau_S = 587\ \mu s$ which, within our resolution, are identical to those obtained in the fit of trace 1. However, the amplitude of the fast exponential component was reduced by about half but there was no significant change in the amplitude of the slow exponential component. This effect was seen for both depolarizing and hyperpolarizing pulses. The difference record between the gating current before addition of chloroform (Fig. 2*a*, trace 1) and during chloroform (trace 2), shown in Fig. 2*b*, is fitted by a single exponential (solid trace) with a time constant $\tau_F = 126\ \mu s$. Figure 2*b* represents the fraction of the fast component eliminated by chloroform. A more dramatic reduction of the fast exponential component is shown in Fig. 2*c*.

The main effect of chloroform was to decrease the amplitude of the fast component of gating with no significant effect on the kinetics of either the remaining fast or slow components. These results were qualitatively reproduced in several experiments, with variations only in their magnitude (see Fig. 2*a*, *c*) due to our present inability to control accurately the concentration of chloroform. The magnitude of the effect obtained was dependent on internal and external perfusion rates, therefore the actual concentration of chloroform reaching the membrane was probably significantly smaller than the values given throughout this paper. The concentrations given were estimated from the fraction of chloroform (v/v) added to the internal perfusion solution.

Several models have been proposed for the action of general anaesthetics such as chloroform on the structure of lipid bilayers. These include modifications of such structural parameters as thickness, dielectric constant, dipole potential and the degree of order (for example, fluidity) of the lipid hydrocarbon chains (see refs 3, 6). Lipophilic ions such as DpA^- and tetraphenylboron have proved useful in elucidating these structural parameters of lipid bilayers[3,7]. The general behaviour of lipophilic ions in membranes is phenomenologically similar to that of gating currents, because they bear a charge but are trapped inside the membrane[7]. It has been shown that changes in the structure and composition of the bilayer greatly affect the transport of these lipophilic ions. For example, Reyes and Latorre[3] demonstrated that pharmacological concentrations of the neutral general anaesthetics chloroform and benzyl alcohol significantly increase the translocation rate of the hydrophobic ion tetraphenylborate in lipid bilayers, indicating that these anaesthetics change the dielectric constant of the lipid matrix. As these physical changes should affect the movement of any membrane-bound charge, a similar effect would be expected for the charge movement of the gating particles responsible for the opening and closing of Na^+ channels. However, the results presented here show that this is not the case. The gating current kinetics of the fast and slow components were unmodified by chloroform, which indicates that the mechanism of action of chloroform on gating currents is very different from that on the charge movement induced by lipophilic ions.

To confirm that chloroform has the same general effect on the membrane of squid giant axon as it does on lipid bilayers, we incorporated the lipophilic ion DpA^- into the squid giant axon membrane and measured the effect of chloroform on the induced charge movement. As shown in Fig. 3*a*, DpA^- produced a very large charge movement having characteristics similar to those described by Benz and Conti[8] (details of these results will be published elsewhere). When the axon was

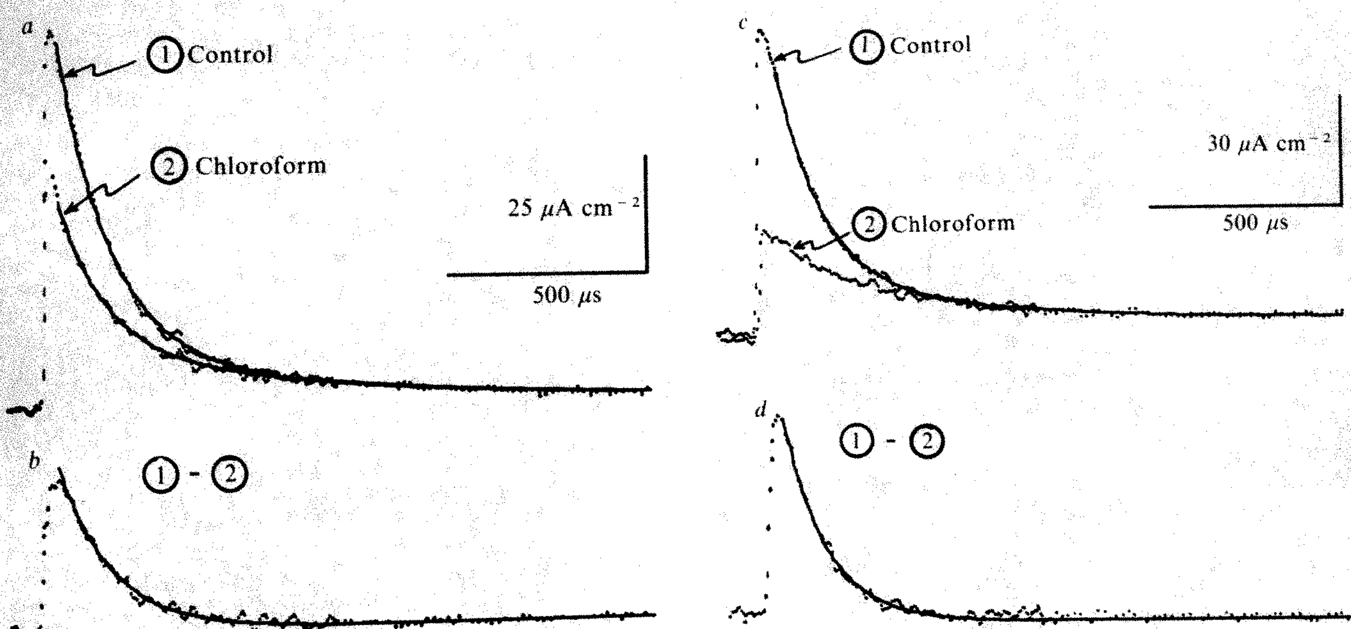

Fig. 2 Effect of chloroform of the ON gating currents. *a*, Trace 1 shows an ON gating current measured using the P/4 procedure in the absence of ionic currents for a test pulse of +100 mV from a holding potential of −70 mV (SHP = −150 mV). The solid line represents a two-exponential fit with a fast time constant, $\tau_F = 126\ \mu s$ and a slow time constant, $\tau_S = 571\ \mu s$. Trace 2 shows the effect of internally perfusing the axon with a solution containing 60 mM chloroform; this trace could again be fitted with two exponentials having time constants $\tau_F = 112\ \mu s$ and $\tau_S = 587\ \mu s$. Chloroform reduced the amplitude of the fast component to about half without altering the kinetics of the remaining fast and slow components. *b*, Numerical difference between traces 1 and 2 of *a*, which corresponds to the fraction of the fast component eliminated by chloroform. The solid line represents a single exponential fit with time constant $\tau_F = 126\ \mu s$. *a*, A more dramatic reduction of the fast component for a different axon internally perfused with a solution containing 60 mM chloroform. Trace 1 corresponds to the ON gating current for a test pulse of +110 mV from a holding potential of −70 mV (SHP = −140 mV). A two-exponential fit (solid line) gave the time constants $\tau_F = 108\ \mu s$ and $\tau_S = 508\ \mu s$. Trace 2 shows the gating current remaining when the axon was perfused with the chloroform-containing solution; in this case the fast component of trace 1 was reduced by ~85%. *d*, The numerical difference between traces 1 and 2 in *c*; the solid line corresponds to a single exponential fit with a time constant $\tau_F = 111\ \mu s$.

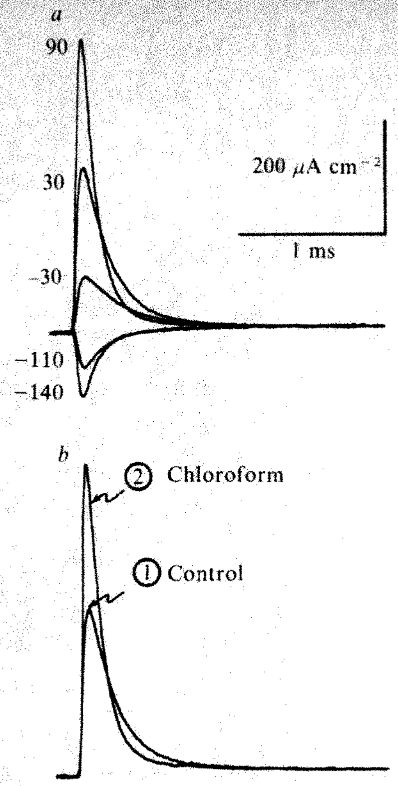

Fig. 3 Charge movement induced by the lipophilic ion dipicrylamine in the absence of ionic currents measured using the P/4 procedure. *a*, Charge movement measured after perfusing the axon internally and externally with solutions containing 10^{-5} M DpA^- for ~5 min. The currents correspond to pulses applied, from a holding potential of −70 mV, to the indicated membrane potential. As the induced charge movement was so large, correction for the normal gating charge movement was unnecessary. *b*, Effect of internally perfusing the axon with a solution containing 43 mM chloroform on the kinetics of the DpA^--induced charge movement. In contrast to the effect observed for the ON gating current, the rate of DpA^--induced charge movement was increased by chloroform (traces 1 and 2 were obtained by pulsing to +30 mV from a HP of −70 mV with a SHP of −140 mV). The effect was reversed after removal of chloroform. The data shown are for the same axon and solutions as used for the axon of Fig. 1*b* (traces 4–6), and demonstrate that the contrasting effects of chloroform on the Na^+ gating currents and the DpA^--induced charge movement can be observed in the same axon in identical conditions.

perfused with a solution containing 43 mM chloroform, the translocation rate of DpA^- was increased significantly as indicated by a larger initial current and a faster decay (Fig. 3*b*). The voltage dependence of the DpA^- charge movement was unmodified by chloroform, indicating that the observed change in the translocation rate represented a reduction in the activation energy that the DpA^- molecules must overcome to cross the membrane, in good agreement with the observations of Reyes and Latorre[3] for artificial bilayers. Thus chloroform has similar effects on the structural parameters of squid axon and lipid bilayer membranes.

These experiments therefore indicate that Na^+ channel gating charges do not diffuse through the bulk lipid matrix of the membrane as the DpA^- molecules do. It is therefore questionable to use hydrophobic ions as analogues of the Na^+ gating charge movement. This conclusion has important implications as it renders unlikely those classes of model in which the gating charges of the Na^+ channel move freely in the lipid matrix and in which gating is due to the aggregation of several charged proteins that are oriented by the field to form an operational channel[2]. These experiments also rule out models in which the action of general anaesthetics is to enhance the rate at which the Na^+ gating charges move between closed and open states, subsequently altering excitability[3]. The results suggest that chloroform decreases the number of operational channels by preventing the movement of the charge that produces the fast component of gating current.

The major difficulty in the study of gating currents has been the inability to examine the various components separately. Our experiments suggest the possibility of using chloroform as a tool to dissociate the fast from the slow component and to study the correlation between these components and the Na^+ conductance to elucidate further the gating processes of voltage-dependent channels.

We thank Drs S. Krasne, J. Vergara and M. White for helpful comments on the manuscript. This work was supported by a Grass Fellowship to J.M.F. and by USPHS grant GM 30376.

Regulation of muscarinic ligand binding sites by nerve growth factor in PC12 phaeochromocytoma cells

J. E. Jumblatt* & A. S. Tischler†

* Department of Biochemistry and Pharmacology and
† Department of Pathology, Tufts University School of Medicine, 136 Harrison Avenue, Boston, Massachusetts 02111, USA

The rat phaeochromocytoma cell line PC12 (ref. 1) possesses many characteristics of adrenal chromaffin cells, including the ability to synthesize, store and release catecholamines in response to acetylcholine and other depolarizing agents[2–4]. When exposed to 2.5S nerve growth factor (NGF), PC12 cells cease to divide, and exhibit a number of neurone-like characteristics, including the extension of neurites, development of voltage-sensitive ion channels and electrical excitability, and increased capacity to synthesize and release acetylcholine[3–8]. Biochemical and pharmacological evidence indicates that both adrenal chromaffin cells and sympathetic neurones contain, in addition to ganglionic-type nicotinic receptors, muscarinic cholinergic receptors proposed to modulate catecholamine release[9–13]. Catecholamine release from PC12 cells is directly stimulated by nicotinic, but not muscarinic, cholinergic agonists[3]. Although ion flux through acetylcholine-activated channels in PC12 cells is inhibited by high concentrations of the potent muscarinic antagonist quinuclidinyl benzilate (QNB)[14], the possibility that these cells may contain functional muscarinic receptors has been largely overlooked. We show here that PC12 cells contain saturable, high-affinity binding sites for ^{3}H-(−)-quinuclidinyl benzilate (^{3}H-QNB), which seem pharmacologically comparable with muscarinic receptors described in rodent brain[15,16], smooth muscle[17,18] and adrenal medulla[12]. Moreover, treatment with NGF produces a marked elevation of specific ^{3}H-QNB binding. PC12 cells thus may provide a useful system for investigating the biochemical mechanisms, cellular distribution and regulation of muscarinic receptors by hormones and trophic signals.

PC12 cells (passages 23–32) were derived from the clone originally isolated by Greene and Tischler[1]. Cells were cultured in collagen-coated 10-cm polystyrene dishes as described previously[1,6]. To treat cells with NGF for binding experiments, replicate cultures were inoculated at a density of 4×10^4 cells per cm^2 (except where otherwise indicated), and cultured for

0028–0836/82/190152—03$01.00

12–16 days in control medium or in medium supplemented with 50 ng ml^{-1} 2.5S NGF (ref. 19). The medium was changed every third day. To collect cells, the culture medium was replaced by 5 ml Ca^{2+}, Mg^{2+}-free phosphate-buffered saline[20] (CMF-PBS) containing 1 mM EDTA, and cells were gently removed using a rubber policeman. Complete detachment of cell bodies and neurites was monitored by phase microscopy. Cells were washed twice by centrifugation (1,000*g*, 10 min) and resuspension in 0.1 vol. of 320 mM sucrose, 50 mM phosphate, 0.1 mM EDTA *p*H 7.2 (SPE buffer) at 4 °C, and counted using a haemacytometer. To prepare membranes, cells were homogenized for 30 s with a Potter-Elvehjem homogenizer and centrifuged for 10 min at 1,000*g* to pellet the nuclei. Homogenization and centrifugation were repeated on the nuclear pellet, and the combined supernatants were centrifuged at 120,000*g* for 60 min to obtain a crude membrane (mitochondria + microsomes) fraction. The membrane pellet was resuspended in SPE buffer (3–5 mg protein per ml) and used within 12 h for the binding measurements. All fractionation steps were performed at 0–4 °C.

The concentration dependence of ^{3}H-QNB binding at equilibrium to PC12 cell membranes was determined in the absence and presence of 10^{-6} M atropine (Fig. 1). Scatchard analysis[21] of specific ^{3}H-QNB binding (Fig. 1*b*; total minus nonspecific binding) indicated a single, high-affinity class of binding sites having a $K_d = 0.146 \pm 0.07$ nM, $B_{max} = 32.7 \pm 7.2$ fmol per mg protein. These results are in close agreement with the reported affinity of QNB binding to muscarinic cholinergic receptors in rat brain[15], smooth muscle[17,18] and adrenal medulla[11,12]. Interestingly, the density of QNB binding sites in PC12 cell membranes is comparable with that reported for rat adrenal medulla membranes[12], but more than 10-fold higher than in bovine adrenal medulla[11]. Assuming 100% recovery of receptor-containing membranes, PC12 cells have ~1,400 specific QNB binding sites per cell. By comparison, Patrick and Stallcup[22] reported these cells to contain 5,000 binding sites per cell for

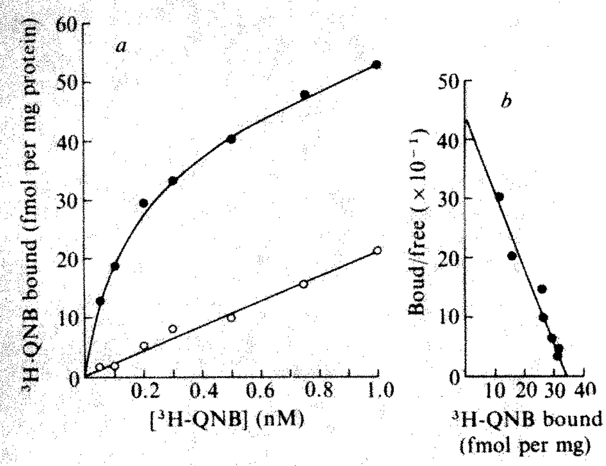

Fig. 1 Binding of ^{3}H-QNB to membranes from untreated PC12 cells as a function of ^{3}H-QNB concentration. PC12 cell membranes (100–160 μg protein) were preincubated for 10 min at 30 °C in microfuge tubes containing 0.9 ml of 50 mM $Na^+ + K^+$ phosphate buffer *p*H 7.2 plus or minus atropine sulphate (10^{-6} M final concentration). A volume of ^{3}H-QNB (NEN; 31.2 Ci mmol^{-1}) was then added to each tube to give the indicated final ^{3}H-QNB concentrations. Following incubation at 30 °C for 60 min, 0.8-ml aliquots were removed from each sample and filtered under suction through 25 mM Whatman GF/F glass fibre filters. Each filter was washed four times with 5 ml of ice-cold 50 mM phosphate, then dried and counted in 10 ml Beckman Ready Solv HP scintillation fluid using a Packard Tri-Carb liquid scintillation counter. All points are the means of duplicate determinations, which deviated by <15% from the indicated values. The protein content was determined by the Lowry method[24]. *a*, Total binding of ^{3}H-QNB (●); nonspecific binding in the presence of 10^{-6} M atropine (○). *b*, Scatchard plot of specific ^{3}H-QNB binding from the experimental data shown in *a*.

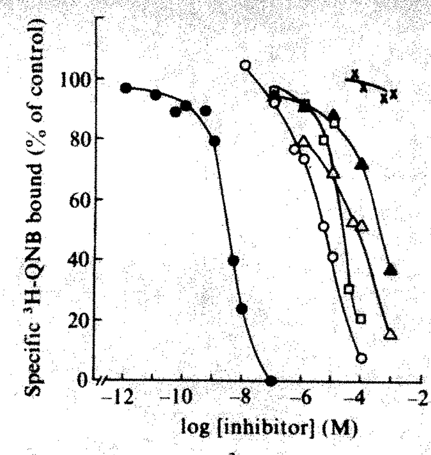

Fig. 2 Competition for specific ^{3}H-QNB binding to PC12 membranes by different concentrations of cholinergic drugs: atropine (●), oxotremorine (○), pilocarpine (□), (+)tubocurarine (▲), carbamylcholine (△), nicotine (×). Binding assays were performed essentially as described in Fig. 1 legend except that different concentrations of competing ligand were present during the initial preincubation and a single concentration of ^{3}H-QNB (0.2–0.6 nM) was present during the final incubation. Nonspecific binding has been subtracted from total binding and per cent of maximum specific binding in controls without inhibitor has been plotted. All points represent the means of duplicate or triplicate measurements, which ranged within 15% of the means.

^{125}I-α-bungarotoxin—a selective probe of nicotinic cholinergic receptors at neuromuscular junctions. The relationship of α-bungarotoxin binding sites to functional nicotinic receptors in PC12 cells is unclear, however, because the toxin fails to block the nicotinic receptor-mediated responses in these cells[22].

To evaluate the pharmacological specificity of ^{3}H-QNB binding, various cholinergic agents were tested at several concentrations for inhibition of specific QNB binding at a fixed concentration of radioligand (Fig. 2). Corrected IC_{50} values obtained from these data are listed in Table 1. The order of potency (atropine > oxotremorine > pilocarpine > carbamylcholine > (+)tubocurarine > nicotine) and the IC_{50} values for these agents correspond closely to the pharmacological selectivity of ligand binding to muscarinic cholinergic receptors in brain and other tissues[11,15–18].

Muscarinic receptors exhibit complex binding characteristics for agonists (Hill coefficients < 1), whereas binding of antagonists usually conforms to a simple mass action isotherm (Hill coefficients ~1)[23]. The basis for this complexity is unknown, but may reflect receptor heterogeneity or conformational shifts[23]. Hill analysis (not shown) of the inhibition data in Fig. 2 suggested similar complexity for agonist but not antagonist binding to PC12 membranes. Estimated Hill coefficients were 0.55 for carbamylcholine, 0.74 for oxotremorine, 0.81 for pilocarpine and 1.06 for atropine.

NGF treatment of PC12 cells is known to induce choline acetyltransferase, increased synthesis, storage and release of

Table 1 Relative abilities of cholinergic drugs to inhibit specific ^{3}H-QNB binding to PC12 cell membranes

Drug	IC_{50}*(M)
Atropine	1.2×10^{-9}
Oxotremorine	1.6×10^{-6}
Pilocarpine	7.4×10^{-6}
Carbamylcholine	2.6×10^{-5}
(+)Tubocurarine	1.5×10^{-4}
Nicotine	$> 10^{-3}$

Values are derived from the data presented in Fig. 2. IC_{50}* is the concentration of inhibitory drug which reduced specific ^{3}H-QNB binding by 50%, corrected for the shift in radioligand occupancy using the formula $IC_{50}^* = IC_{50}/1 + [L]/K_d$ where K_d is the measured equilibrium dissociation constant for ^{3}H-QNB (0.146 nM) and $[L]$ is the concentration of radioligand present (0.2–0.6 nM).

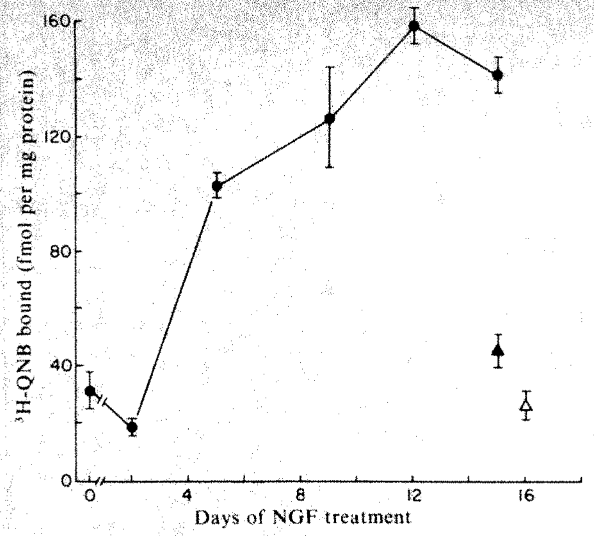

Fig. 3 Effect of NGF treatment on specific ^{3}H-QNB binding. Parallel cultures were plated and maintained in medium with or without NGF (50 ng ml^{-1}). Medium was changed every third day. Specific binding was determined as described in Fig. 1 legend, using 10^{-9} M ^{3}H-QNB in the presence and absence of 10^{-6} M atropine. Values represent means ± s.e.m. of triplicate determinations. NGF-treated cells plated at a density of 4×10^4 cells per cm^2 (●); untreated cultures plated at a density of 4×10^4 cells per cm^2 (▲); untreated cultures plated at 2×10^3 cells per cm^2 (△).

acetylcholine, elevation of acetylcholinesterase activity and the appearance of clustered vesicular structures resembling cholinergic synaptic vesicles[1,6-8]. When we investigated the effects of NGF, on QNB binding, we found that the level of specific ^{3}H-QNB binding sites in PC12 membranes increased markedly during 15 days of NGF treatment, following an apparent lag of 2–5 days (see Fig. 3). Mean values for specific QNB binding were 156.5 ± 7.1 fmol per mg protein after 12–15 days of NGF treatment compared with 28.3 ± 6.9 fmol per mg for untreated cells. The increase depended on the presence of NGF and was absent in untreated cultures maintained for the same period at high cell densities (Fig. 3). Interestingly, the major increase in binding, evident by day 5 (Fig. 3), preceded extensive neurite outgrowth.

This study using PC12 cells provides the first evidence for upward regulation of muscarinic ligand binding sites by a chemically defined, developmentally important, neurotrophic substance. These binding sites appear pharmacologically equivalent to muscarinic receptors in normal neural tissues. Their physiological functions both in PC12 cells and in normal tissues, however, require further study. Muscarinic receptors are proposed to influence adrenal cells and sympathetic neurones in several ways[9-13], but the most extensive physiological data are derived from the mammalian heart *in vivo*, where presynaptic muscarinic receptors on sympathetic nerve endings augment the effects of vagus stimulation by inhibiting release of catechol- amines[9]. PC12 cells thus may provide a useful system to study the biochemical aspects of muscarinic receptor function *in vitro*, as well as the effects of hormones and trophic substances on the expression of these receptors.

Adenosine diphosphate induces binding of von Willebrand factor to human platelets

Takayoshi Fujimoto & Jack Hawiger*

Departments of Pathology and Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee 37232, USA

Blood platelets seal off leaks in the vessel wall to prevent haemorrhage by a mechanism involving their activation, adhesion to the zone of vessel injury and aggregation[1]. This physiologically important haemostatic process requires Factor VIII/von Willebrand factor (vWF), a plasma glycoprotein missing in the genetic, haemorrhagic disorder called von Willebrand disease, in which platelets cannot adhere to the subendothelial layer of the vessel wall[2]. Thus vWF is necessary for anchoring platelets to the vessel wall, and it mediates platelet–platelet interaction. This interaction requires an appropriate receptor on the platelet surface. Until recently, the antibiotic ristocetin was used to induce *in vitro* receptor-mediated binding of vWF to platelets and to cause their aggregation or agglutination[3-7]. But although a useful laboratory tool[8], ristocetin is clearly non-physiological, so we turned our attention to thrombin, which appears in venous blood within 45 s of venipuncture and is a very potent physiological inducer of platelet aggregation. Thrombin causes platelets to change shape from discoid to spiny spheres, and alters the platelet membrane resulting in release of ADP, serotonin and other constituents of platelet storage granules[9]. We recently showed that low concentrations (0.1–0.5 nM) of thrombin, attainable in blood, induce binding of vWF to a specific platelet receptor[10]. We now report that the binding of vWF to platelet receptors is also induced by ADP on its addition to platelets. Moreover, ADP released from platelet storage granules by thrombin is, at least in part, responsible for subsequent binding of ^{125}I-labelled vWF.

Platelets from human blood were separated from plasma proteins by stepwise albumin gradient centrifugation and Sepharose 2B gel filtration as described earlier[11]. All experiments were performed with platelets suspended in HEPES buffer, pH 7.35, containing 0.1% dextrose and 0.35% albumin. Human vWF was purified and labelled with ^{125}I, as before[10]. This preparation was rendered essentially free of fibrinogen and fibronectin by passage through an anti-fibrinogen antibody Sepharose 4B affinity column and a gelatin–Sepharose 4B column. Purified vWF gave negative results for fibrinogen content in immunodiffusion and in the staphylococcal clumping test having a detection limit of 0.5 μg fibrinogen per ml[12]. By the use of an even more sensitive radioimmunoassay, we found that 1 mg of purified vWF contained < 60 ng of fibrinogen, that is, < 0.00006% (w/w).

Binding of ^{125}I-vWF to platelets occurred in 0.5 ml reaction mixture containing 1×10^8 platelets with 5 μM ADP or 0.5 nM

thrombin, to which hirudin and then ^{125}I-labelled vWF had been added. Incubation was at room temperature (22 °C) in polypropylene tubes (12×75 mm) without stirring. Incubation was terminated by rapid centrifugation (15,000 r.p.m., 2 min) of platelet suspension through 9:1 (v/v) mixture of dibutylphthalate and Apiezon Oil C (ref. 13) at 60 min, by which time binding had reached equilibrium (see below). The supernatant was sampled for free radioactivity, and bound radioactivity was measured in the platelet pellet which was cut off together with the tip of the tube after rapid freezing of its contents in a mixture of dry ice and acetone. Aggregation of platelets was measured photometrically in a Payton (Buffalo, New York) dual-channel aggregometer at 37 °C with constant stirring (900 r.p.m.) according to Born's method[14].

Intact resting platelets, separated from plasma proteins, bound little ^{125}I-vWF. After stimulation with 5 μM ADP, at least three times more ^{125}I-vWF was bound (Fig. 1); this binding approached saturation at 2.8–5.6 μg ^{125}I-vWF, and equilibrium binding was achieved within 30 min. Whereas approximately 75% of the bound ^{125}I-vWF could be displaced by a 100-fold excess of unlabelled vWF, a similar excess of unlabelled fibrinogen or fibronectin had no effect, suggesting that binding was specific for ^{125}I-vWF.

Induction of binding of ^{125}I-vWF to ADP-stimulated human platelets could be effectively abolished with either the ADP-splitting enzyme, apyrase (5.4 U; see Fig. 1), or an ADP-converting system comprising creatinine phosphate (7.5 mM) and creatinine phosphate kinase (3.0 U) (results not shown).

In the above experiments, exogenous ADP was added to platelets before ^{125}I-vWF. However, the dense granules of platelets are a rich source of ADP which is easily releaseable by thrombin[9]. We had earlier shown that thrombin (0.5 nM) induces binding of ^{125}I-vWF to human platelets[10] and so we decided to determine whether there was any relationship between thrombin-induced release of ADP and thrombin-induced binding. The finding that addition of the ADP-splitting enzyme apyrase to thrombin-treated platelets reduced binding by 73% showed that endogenous ADP, released from platelet dense granules and present in the platelet 'environment', was responsible in large part for inducing the binding of ^{125}I-vWF to thrombin-stimulated platelets. ADP-induced binding of ^{125}I-vWF required calcium as both EDTA and EGTA (2 mM) inhibited the interaction.

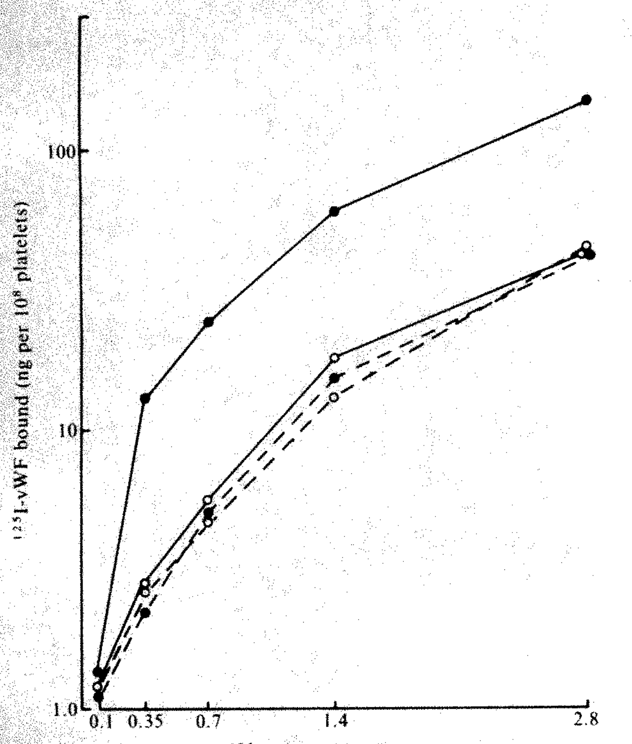

Fig. 1 Binding of ^{125}I-labelled human vWF to platelets treated with 5 μM ADP (●—●); 5 μM ADP plus apyrase (5.4 U; ●- -●), buffer (control: ○—○) and buffer plus apyrase (control: ○- -○). Platelets were treated with apyrase or buffer for 3 min followed by the addition of ADP. After 3 min ^{125}I-vWF was added. Binding was determined after 60 min incubation at room temperature without stirring.

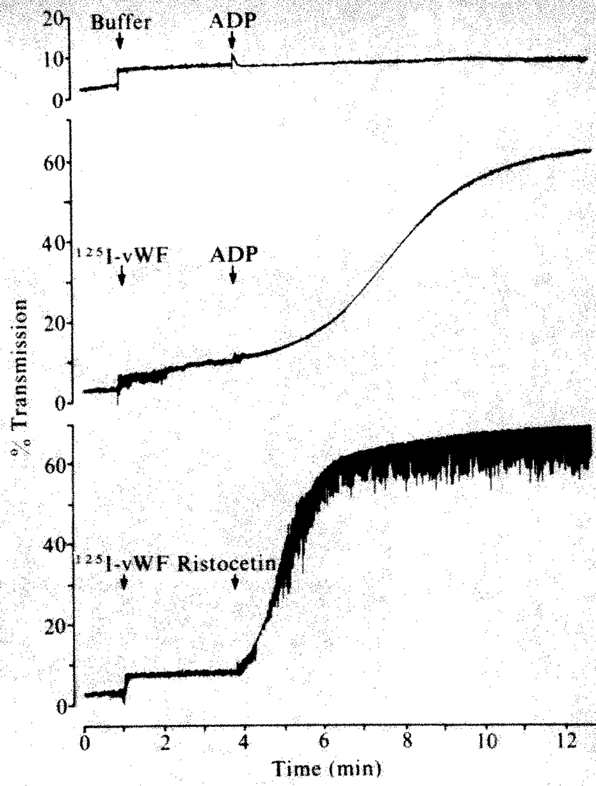

Fig. 2 Aggregation of platelets separated from plasma proteins by ADP and vWF (actual tracings). Upper panel, ADP (5 μM) without vWF; middle panel, ADP+vWF (30 μg); lower panel, ristocetin (1 mg ml^{-1})+vWF.

If binding of multimeric ^{125}I-vWF to the platelet surface is a prerequisite for their aggregation or agglutination, as postulated in the case of ristocetin-induced binding[7], then platelets stimulated with ADP in the presence of ^{125}I-vWF should also aggregate. Indeed, the induction of vWF binding to human platelets by ADP was paralleled by their aggregation. Human platelets, separated from plasma proteins, did not aggregate in response to either ADP or ristocetin[11]. However, addition of purified vWF (30 μg) induced aggregation of both ADP- and ristocetin-treated platelets (Fig. 2). As the fibrinogen content of our purified vWF preparation was <0.00006%, and since platelets were not responsive to ADP in the absence of added ^{125}I-vWF, we believe that the observed aggregation of platelets resulted from the induction of the specific receptor for vWF by ADP and the subsequent linking of platelets by bound multimeric vWF.

The previously observed interference by ADP of human vWF-stimulated platelet agglutination in the presence of EDTA and ristocetin[15] can be attributed to changes in the vWF receptor induced by a combination of ADP, ristocetin and EDTA. It is possible that this combinaton causes a downward shift in the affinity of the receptor for vWF, in contrast to the effect of ADP alone as observed in our system requiring divalent cations.

A major question pertains to nature of the trigger responsible for activation of platelets *in vivo*. Our results support the view of Born[1] that ADP is one such trigger, which by promoting interaction of vWF with platelets allows them to adhere to the vessel wall and to aggregate. *In vivo* activation of platelets by ADP administered intravascularly by microiontophoresis causes them to adhere to the vessel wall[16]. Although platelet activation *in vivo* may occur within 10–100 ms (ref. 17), results

obtained in the inherently slower *in vitro* system can still provide a useful new clue to the *in vivo* situation. According to the mechanism we propose here, as vWF is present at the interface between blood and the vessel wall, activation of platelets by ADP results in exposure of receptors for both vWF and fibrinogen[18-23]. The ADP-induced receptor for vWF binds this multimeric glycoprotein to form an anchor for the attachment of platelets to the inner zone of the vessel wall and to each other.

Bovine thrombin, hirudin, ADP, apyrase, creatinine phosphate and creatinine phosphate kinase were purchased from Sigma. This work was supported by USPHS grants HL-25935, HL-25107 and HL-27560.

Glicentin inhibits gastric acid secretion in the rat

P. Kirkegaard, A. J. Moody, J. J. Holst, F. B. Loud, P. Skov Olsen & J. Christiansen

Department of Surgery D, Glostrup Hospital and Institute of Medical Physiology C, University of Copenhagen, DK-2100 Copenhagen, Denmark
and Novo Research Laboratories, DK-2880 Copenhagen, Denmark

Gut glucagon-like immunoreactants (GLIs) are peptides of enteric origin, which have immunoreactivity in common with pancreatic glucagon. First reported in the intestine by Unger *et al.*[1], GLIs are concentrated in the L-cells of the lower small intestine and the colon[2]. The primary structure of gut GLI-1, glicentin, a highly purified form of the major component of gut GLIs[3], has recently been established. Glicentin contains 69 amino acid residues, has a molecular weight (M_r) of 8,128 (ref. 4) and contains the entire glucagon sequence[4,5], thus establishing it as a member of the hormone family which includes glucagon, secretin, gastric inhibitory polypeptide and vasoactive intestinal polypeptide. Until now there have been insufficient amounts of pure glicentin to test its proposed role in the intestinal phase of the body's response to a meal[6], but there is evidence which suggests that, like other members of the hormone family to which it belongs, glicentin can inhibit gastric acid secretion[7-9]. We confirm here that glicentin inhibits pentagastrin-stimulated acid secretion in the rat.

Female Sprague–Dawley rats (~200 g) were used. The rats were fitted with chronic gastric fistulas according to the method of Lane *et al.*[10] and allowed a 2-week post-operative recovery period. The day before the first experiment, the rats were lightly anaesthetized with ether, and a thin polyethylene catheter was placed in a jugular vein for infusion of glicentin, glucagon or saline. The rats were fasted for 24 h before each experiment, but allowed water *ad libitum*. They were kept in raised mesh-bottom cages to prevent coprophagy.

Ten rats were studied on two separate days. For experimental manipulation, the rats were placed in restraining cages and the stomachs were rinsed out by infusing warm saline through the fistula. After 1 h of spontaneous secretion, pentagastrin (25 μg per kg; Peptavlon, ICI) was given subcutaneously (s.c.). A bolus injection of either 2 ml saline or 3 μg per kg glicentin in 2 ml saline was given intravenously (i.v.) followed by infusion of either 0.9% saline (2 ml h^{-1}) or glicentin (600 ng h^{-1}) in 2 ml saline in random order. Another 8 rats received glicentin (120 ng h^{-1}) and 10 rats received glucagon (1,000 ng h^{-1}). All solutions contained 2% human albumin (Behringswerke). The concentration of glucagon-like immunoreactivity in plasma sampled at the end of the infusion were measured, after ethanol-extraction of the plasma (61%), with a radioimmunoassay specific for the glucagon sequence 6–15, which is also present in the glicentin molecule[5]. Gastric juice was collected continuously and sampled at 30-min intervals. Acid output was determined using an autotitrator (Radiometer ABU 13).

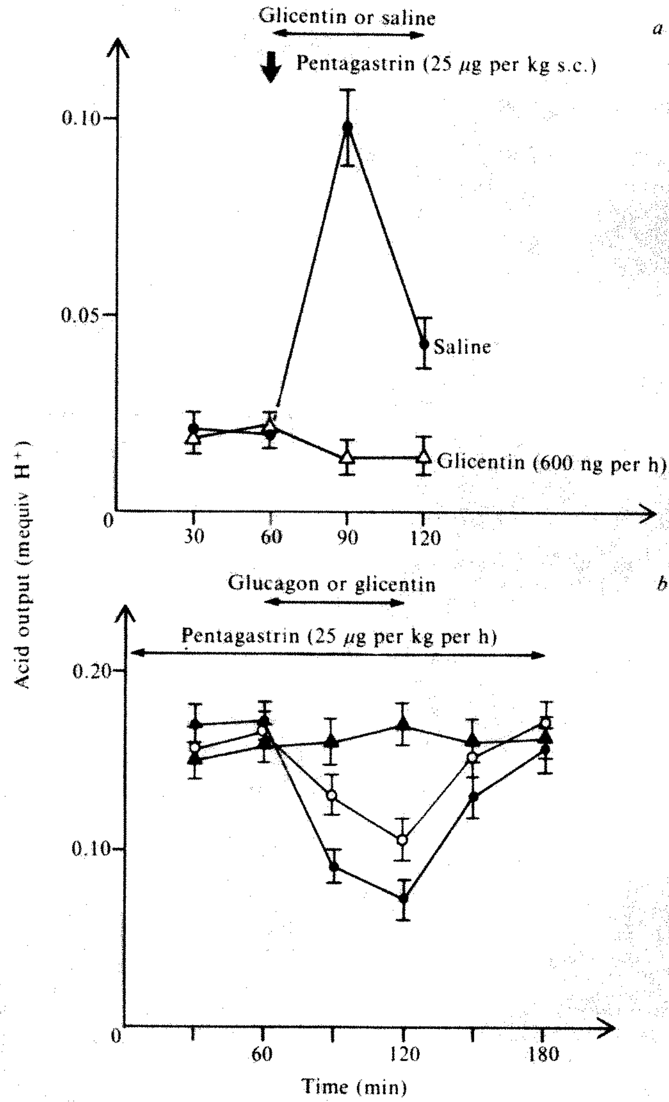

Fig. 1 *a*, Effect of i.v. glicentin infusion on submaximally stimulated gastric acid secretion in the chronic-fistula rat. Acid output (milliequivalents H^+) did not exceed baseline values. Control rats were treated with saline. *b*, Effect of i.v. infusion of glicentin (○, 120 ng h^{-1}; ●, 600 ng h^{-1}) and glucagon (▲, 1,000 ng h^{-1}) on maximally stimulated gastric acid secretion in the chronic-fistula rat. During infusion of glicentin (both doses), acid output decreased significantly. Glucagon had no effect on acid secretion. For *a* and *b*, each point represents 30 min acid secretion (mean ± s.e.m. of 10 rats).

0028-0836/82/190156—02$01.00

In another 10 chronic-fistula rats, pentagastrin (25 μg per kg per h) was infused i.v. for 3 h. After 1 h, a bolus injection of 0.6 or 3 μg per kg glicentin was given and for the next hour, 120 or 600 ng glicentin was infused together with the pentagastrin. For the last hour, pentagastrin alone was infused. The same experiment was performed with glucagon (1,000 ng per h) after a bolus injection of 5 μg per kg. Gastric juice was collected and acid output determined as described above.

The porcine glicentin used was isolated as previously described[3] and gave a single band on analytical isoelectrifocusing and polyacrylamide gel electrophoresis. The content of gastric inhibitory polypeptide was <100 p.p.m. (ref. 11) and that of vasoactive intestinal polypeptide was 70 p.p.m. (Moody, A. J. M., unpublished data) as determined by radioimmunoassay.

We observed a marked effect of glicentin on gastric acid secretion. After submaximal stimulation (pentagastrin, 25 μg per kg s.c.) the acid response was completely abolished by the infusion of glicentin (Fig. 1*a*). After maximal stimulation (continuous i.v. infusion of pentagastrin, 25 μg per kg per h) the acid output decreased in a dose-dependent manner during simultaneous infusion of glicentin. When infusion of glicentin was stopped, there was an immediate increase in gastric acid secretion. Glucagon at 1,000 ng per h had no effect on acid secretion (Fig. 1*b*). The levels of glucagon-like immunoreactivity in plasma obtained after infusion of glicentin at 600 ng per h and glucagon at 1,000 ng per h, were 541±135 and 428±94 pmol-equivalents l^{-1}, respectively, compared with 72±27 pmol l^{-1} in rats receiving saline alone (mean±s.e.m.).

The present study demonstrates that glicentin is a potent acid secretion inhibitor and the fact that it is effective in low doses supports the view that GLI-1 may act as an enterogastrone in the intestinal phase of gastric acid secretion. As glucagon, given in doses greater than those of glicentin and giving rise to similar concentrations of glucagon-like immunoreactivity, was ineffective, it is unlikely that the action of glicentin is due to that part of its sequence which corresponds to the glucagon molecule.

A sequence of mitochondrial DNA is associated with the onset of senescence in a fungus

Corinne Vierny, Anne-Marie Keller, Odile Begel & Léon Belcour

Centre de Génétique Moléculaire, Central National de la Recherche Scientifique, 91190 Gif-sur-Yvette, France

In *Podospora anserina*, a strict aerobic fungus, senescence[1] (arrest of vegetative growth of the mycelium) is correlated with severe modifications of the mitochondrial DNA similar to those observed in the *rho*⁻ mutants of yeast[2]. Senescent cultures yield a specific DNA (SEN-DNA) consisting of small circular molecules arranged in multimeric series of sizes[3,4] and which results from the amplification of either one of two non-overlapping segments of the mitochondrial DNA[5,6]. One region 0.89 μm long [2.6 kilobases (kb)] is most frequently amplified, in different strains of *P. anserina* and also in subcultures of a strain reaching senescence independently[6]. In 'young' cultures of the mating type-minus wild-type strain s (*s mt*⁻), the 2.6 kb region exists both as an integral part of the mitochondrial chromosome and as rare free sequences[6]. The results presented here show that (1) the free form is absent from two strains, *s mt*⁺ and *s mt*⁻ *cap*ʳ*1*, which both display increased longevity and which differ respectively from the *s mt*⁻ strain by a nuclear allele at the *mt* locus and by a mitochondrial mutation conferring resistance to chloramphenicol; and (2) in the mutant *mex1*, which develops beyond the edge of arrest of a senescent mycelium, that is, escapes senescence, the mitochondrial DNA precisely lacks the 2.6 kb region. The results suggest that excision and/or amplification of the 2.6 kb sequence is the cause of senescence.

We previously reported that senescent cultures of *P. anserina* contain one of two types of SEN-DNA differing by their density[6]. The first type has a density of 1.694 g cm^{3} (identical to that of the normal 'young' mitochondrial DNA) and exhibits a variable monomer unit comprising 4–6.3 kb. Cross-hybridization revealed that all SEN-DNAs of density 1.694 g cm^{-3} so far obtained share a sequence of mitochondrial DNA of ~2.3 kb and thus belong to the same family. The second type of SEN-DNA has a density of 1.699 g cm^{-3}, a size of 2.6 kb and a sequence that has been reproducibly recovered from independent senescent cultures grown in this and other laboratories[4,6,7]. Hybridization of SEN-DNAs with the mitochondrial DNA of a young culture of the *s mt*⁻ strain digested by *Hae*III (see Table 1 for a description of the strain) shows that both types of SEN-DNAs result from the amplification of particular regions of the mitochondrial chromosome[5,6]. However, whereas the 1.694 g cm^{-3} SEN-DNA hybridizes only with fragments of the 'young' mitochondrial DNA visible on the gel, the 1.699 g cm^{-3} SEN-DNA hybridizes to a 2.6 kb position as well, at which no visible fragment is found (see Fig. 1*a* and its legend). We have therefore assumed that the 2.6 kb sequence is present in young *s mt*⁻ cultures not only as an integral part of the mitochondrial chromosome but also as rare free molecules[6]. Three properties of the 1.699 g cm^{-3} SEN-DNA—its specific density, its peculiar pattern of hybridization with the 'young' *s mt*⁻ mitochondrial DNA and its repeated appearance in senescent cultures of independent origin—distinguish it from 1.694 g cm^{-3} SEN-DNAs and suggest that it has episome-like properties. In any case, whatever the basis for the difference between the two types of sequences, it is clear that senescence is always correlated with the amplification of one of these types of sequence. This correlation raises the question of the cause-effect relationship between senescence and the presence of the amplified sequences, and it is tempting to assume that the circular amplified molecules constituting the SEN-DNAs correspond to the infectious cytoplasmic factor responsible for senescence and identified by Marcou[8].

Two sets of new data on the 2.6 kb sequence provide good support for the idea that senescence actually results, at least in some cases, from the amplification of this sequence. (1) The *Hae*III-digested mitochondrial DNAs extracted from young cultures of the two strains *s mt*⁺ and *s mt*⁻ *cap*ʳ*1* (whose life spans are longer than that of strain *s mt*⁻; Table 1) were hybridized with the 1.699 g cm^{-3} SEN-DNA. In both cases, no

Table 1 Life spans of the different strains used

Genotype: Nuclear	Genotype: Mitochondrial	Life span (cm)
s mt⁻	*cap*ˢ	14
s mt⁺*	*cap*ˢ	40
s mt⁻†	*cap*ʳ*1*	100
s mt⁻	*cap*ˢ *mex1*	>110

* Strain *s mt*⁺ is isogeneic with strain *s mt*⁻ except for the mating-type locus and the two strains are cytoplasmically identical.

† Strain *s mt*⁻ *cap*ʳ*1* is strictly isogeneic with strain *s mt*⁻ from which it derives, except for the mitochondrial mutation *cap*ʳ*1*.

0028–0836/82/190157—03$01.00

labelled material was recovered at the 2.6 kb position (Fig. 1*A*, parts *b* and *c*). This indicates that in the strains *s mt*$^+$ and *s mt*$^-$ *cap'1*, the 2.6 kb sequence does not exist in a free form but is present only as an integrated sequence. (2) A mutant *mex1*, having a modified lifespan, was obtained and studied. This mutant was selected as a sector of growing mycelium that developed beyond the arrested edge of a *s mt*$^-$ senescent culture. Such revertants of the senescent state are uncommon. The mutant *mex1* exhibits a slow growth rate but since its isolation it has been growing steadily and has shown no symptoms of senescence. Preliminary genetic analysis of mutant *mex1* indicated that it segregates in a non-mendelian way, which suggested that the mutation might be located in the mitochondrial DNA. Restriction analysis of the mitochondrial DNA of this mutant confirmed this hypothesis. Figure 2 shows the restriction pattern (after digestion by *Bgl*II) of the mitochondrial DNA of mutant *mex1* compared with that of the wild-type strain

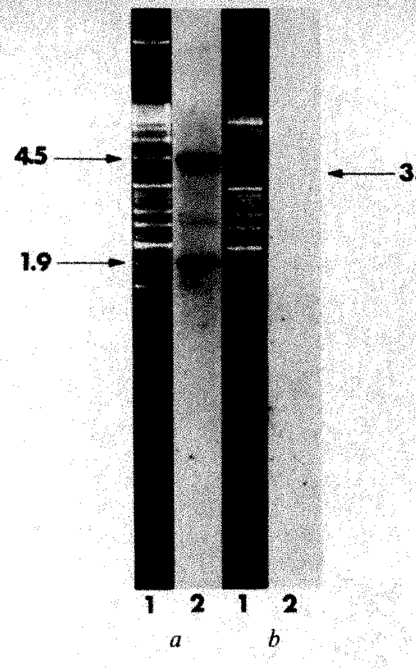

Fig. 2 Lanes 1, electrophoretic patterns of mitochondrial DNA of strains *s mt*$^-$ (*a*) and *s mt*$^-$ *mex1* (*b*) digested by *Bgl*II. Lanes 2, autoradiographs after transfer of the fragments to nitrocellulose filter and hybridization with a ^{32}P-labelled 1.699 g cm^{-3} SEN-DNA obtained by nick-translation (*a*, strain *s mt*$^-$; *b*, strain *s mt*$^-$ *mex1*). Note the monomer unit of the 2.6 kb SEN-DNA possesses one site for the restriction enzyme *Bgl*II. Sizes in kb.

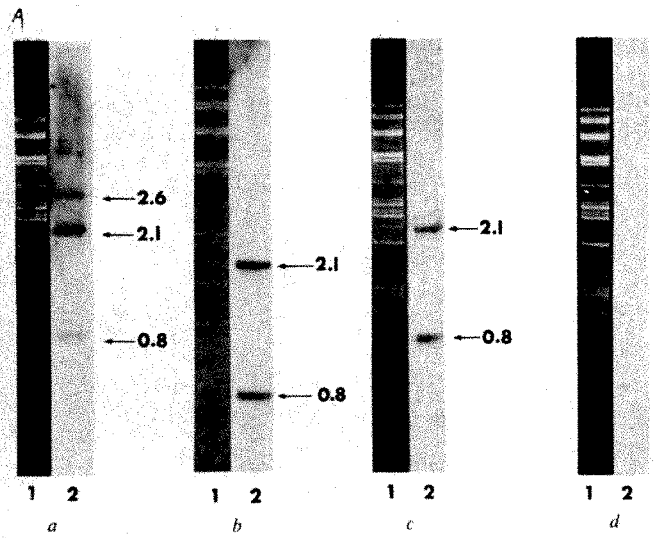

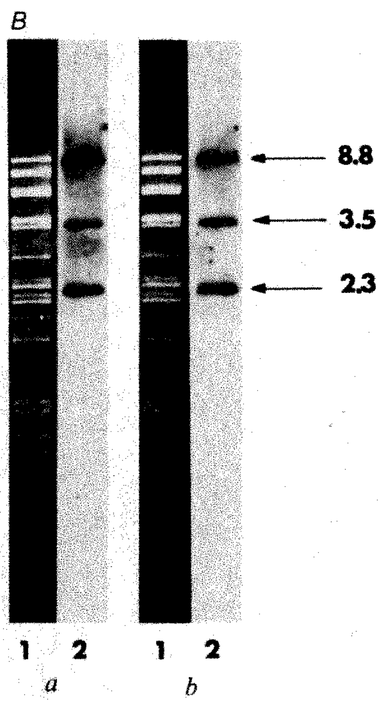

Fig. 1 *A*, Southern hybridizations between *Hae*III-digested 'young' mitochondrial DNAs of different strains and ^{32}P-labelled 1.699 g cm^{-3} nick-translated SEN-DNA. The conditions for preparation and endonuclease digestion of DNA, gel electrophoresis and transfer of DNA to nitrocellulose filters were as previously described[5]. The labelling of DNA by nick-translation was performed as described in ref. 12. For each DNA studied, the electrophoretic pattern and the autoradiograph of the filter after hybridization are shown in lanes 1 and 2 respectively. Sizes in kb. *a*, Strain *s mt*$^-$; *b*, strain *s mt*$^+$; *c*, strain *s mt*$^-$ *cap'1*; *d*, strain *s mt*$^-$ *mex1*. Note that the molecules which constitute the 2.6 kb SEN-DNA are circular and that the monomer unit of this SEN-DNA has a single *Hae*III site. Only one fragment of 2.6 kb is thus recovered after digestion of this SEN-DNA by *Hae*III. *B*, Southern hybridization between *Hae*III-digested 'young' mitochondrial DNAa of strains *s mt*$^-$ (*a*) and *mex1* (*b*) and ^{32}P-labelled 1.694 g cm^{-3} nick-translated SEN-DNA (monomer unit = 6.3 kb). In each case, the electrophoretic pattern and the autoradiograph of the filter after hybridization are shown in lanes 1 and 2 respectively. Sizes in kb. Note that the monomer unit of the 6.3 kb SEN-DNA possesses two *Hae*III sites.

from which it derives. The *mex1* mitochondrial DNA lacks two bands of respectively 4.5 and 1.9 kb and presents an additional band of 3.8 kb, thus *mex1* has a deletion of ~2.6 kb. Interestingly, the missing fragments are precisely those previously shown to hybridize with the 1.699 g cm^{-3} SEN-DNA. The number and the nature of the fragments missing in *mex1* and the estimated size of the deleted fragment obviously suggested that the mutation *mex1* corresponded to the deletion of the 2.6 kb sequence which is often amplified in senescent cultures. This was confirmed by hybridization experiments on the mitochondrial DNA of both young wild-type and *mex1* cultures after digestion by *Bgl*II, using a 1,699 g cm^{-3} nick-translated SEN-DNA as ^{32}P-labelled radioactive probe. The results of this experiment (Fig. 2) show that the mitochondrial DNA of mutant *mex1* does not exhibit any homology with the 1.699 g cm^{-3} SEN-DNA. Similar hybridization experiments in which the mitochondrial DNA *mex1* is digested by *Hae*III (Fig. 1*A*, *d*) or *Bam*HI yield the same result. It can be concluded that in the mutant *mex1*, a sequence containing at least the monomer of the 1.699 g cm^{-3} SEN-DNA has been deleted. The electrophoretic pattern of the *Hae*III- (or *Bgl*II-) digested mitochondrial DNA of mutant *mex1* indicated the absence of any modifications in the region capable of giving rise to the 1.694 g cm^{-3} family of SEN-DNAs. This was confirmed by experiments in which *Hae*III-digested *mex1* and *s mt*$^-$ mitochondrial DNAs were hybridized with 1.694 g cm^{-3} ^{32}P-labelled nick-translated SEN-DNA (monomer unit = 6.3 kb); the same hybridization pattern was obtained in both cases (Fig. 1*B*).

The data presented above show clearly that the 2.6 kb sequence has a central, although perhaps not unique, role in the determination of senescence. The existence of a mutant missing this sequence, which after more than 1 m of growth (see mean life span of the corresponding wild-type strain in Table 1) had not yet become senescent, suggests that excision and/or amplification of the 2.6 kb sequence are the cause of senescence or at least necessary for its onset. This hypothesis is supported by hybridization experiments which reveal that the state in which this sequence exists in young cultures (free and integrated in strain *s mt*$^-$, integrated only in strains *s mt*$^+$

and *s mt⁻ cap'1* and absent in strain *mex1*) seems correlated with the longevities of the strains; the higher the probability of appearance of the free 2.6 kb sequence, the shorter the longevity of the strain. The fact that the strains *s mt⁺* and *s mt⁻ cap'1* are isogeneic except for a nuclear (mt^+/mt^-) or a mitochondrial (cap^r1/cap^s1) gene implies that these might act on, for example, the probability of excision or the efficiency of amplification of the 2.6 kb sequence. Nothing is yet known about the mechanisms responsible for the appearance of the 1.699 g cm^{-3} SEN-DNA. However, the presence of a population of molecules lacking the 2.6 kb sequence in the residual mitochondrial DNA of senescent cultures displaying this amplified sequence[9] (our results, in preparation) suggests that excision rather than replication is the primary event necessary for further amplication of this sequence. The existence of a mutant lacking the 2.6 kb sequence indicates that the sequence does not code for a product essential for cell survival. The reduced growth rate of mutant *mex1* suggests, however, that the sequence is physiologically important, perhaps, as already postulated[6], in initiating the replication of the mitochondrial chromosome. As more than one replication origin is likely, as demonstrated in yeast[10,11], the mitochondrial chromosome would still be able to replicate in the absence of the 2.6 kb sequence but at a slower rate.

The phenomenon of amplification during senescence is not exclusive to the 2.6 kb sequence. Another family of sequences sharing a common region can also be amplified and, depending on the senescent culture, this second type of sequence is amplified either alone[5,6] or in association with the 2.6 kb sequence (our unpublished results). In the latter case, it is not yet clear whether the amplification of the two types of sequence is related, although preliminary results of other senescence-resistant mutants suggest that the absence or rearrangement of the second family of sequences also prevents the appearance of senescence.

Structural analysis of insertion sequence IS*5*

Manfred Kröger & Gerd Hobom

Institut für Biologie III der Universität Freiburg, Schänzlestrasse 1, D-7800 Freiburg i.Br., FRG

Among the transposable DNA elements that have been detected in bacterial genomes and plasmids[1–3], the small insertion sequence (IS) elements have been recognized as a class of autonomous, basic units of transposition. IS elements are not only fully competent of transposition and able to cause several other related chromosomal aberrations such as deletion of adjacent DNA segments[4,5] and integration of circular plasmid DNAs[6], but have also proved to be the active units of transposition in the larger composite transposon (Tn) elements[1–3,7–9]. In addition, IS and Tn elements interfere with local transcription patterns in the host genome by causing polarity [10,11]. Structural and functional analysis of the IS elements should therefore elucidate both the basis for autonomy of a genetic unit as small as 1,000 base pairs (bp), and the transposition mechanism, including its inherent step of DNA duplication[12]. We have now determined the 1,195 bp sequence of the transposable DNA element IS*5* in phage λKH100. Near-terminal signal structures appear to protect the central region from outside-in transcriptions and translations, and render IS polarity as a direct consequence of IS autonomy. The nucleotide structure shows an unusual, highly compact organization of two completely overlapping, antiparallel genes and correlated control sequences.

IS*5* was first identified among clear plaque mutants of bacteriophage λ (λKH100), and was accordingly localized to the C-terminus of the *c*I repressor gene[13,14]. IS*5* was estimated to be 1,200–1,250 bp long, and electron microscopy revealed short inverted sequence repetitions at its ends. The IS*5* unit of λKH100 seemed different from IS*1*–IS*4*, but identical with two other insertions respectively in the bacterial *arg*B gene of specialized transducing phage λ13d*arg*B2 and in phage Mu DNA[15]. Both ends of IS*5* are known to be deletogenic[15] and to stimulate general recombination within adjacent DNA segments[16]. IS*5* also appears to exert polar effects in at least one orientation[17,18].

We have used λKH100 DNA as a primary source of IS*5*, and have constructed a hybrid plasmid pHL118 by cloning a 1,720 bp *Hin*dIII fragment into a pBR313-derived vector plasmid (see ref. 12). The λKH100 *Hin*dIII fragment contains all of the IS*5* DNA as well as 564 bp of λDNA (λ: 37,727–38,291), and it was used for DNA sequencing according to the Maxam and Gilbert method[19] (see Fig. 1). Mapping of the resulting restriction fragments has provided independent proof of the existence and location of a large number of endonucleolytic recognition sites (see Fig. 2). Both junctions and the λKH100 DNA sequences adjacent to IS*5* have also been sequenced and found to be consistent with published data[20,21] obtained from other λ phage or plasmid DNAs. IS*5* is only slightly smaller than was estimated by electron microscopy[15], and the position of IS*5* in the λKH100 sequence (codon 207 of the 232 codon *c*I gene, see Fig. 2*a*) is only slightly to the left of two genetic determinations[13,16].

When IS*5* is inserted into λ*c*I DNA, 4 bp of the wild-type sequence (target site TTAG; λ:38,150–38,153) are directly duplicated to the left and right of both IS*5* ends, and are connected to the two IS*5* terminal inverted repeat sequences of 16 bp (with a single mismatch at position 13) (see Fig. 2*a*). No internal repetition of the inverted repeat sequence has been detected. It is now clear that a partial sequence of phage Mu445-8 DNA[22] includes an identical 99 bp fragment from the right *Eco*RI end of IS*5* (with a single deviation at IS*5*:1,171), followed by an identical target site sequence in opposite orientation (CTAA). A 4 bp target site duplication has not previously been observed for the integration of prokaryotic transposable elements, but has been reported in the integration of Moloney strains of murine leukaemia and sarcoma viruses in eukaryotic DNA[23,24].

Most of the internal sequence of IS*5* is dominated by a very long open reading frame, which extends in right to left direction from position IS*5*:1,127 to IS*5*:147 and codes for a 326 amino acid, predominantly basic protein of molecular weight $37{,}831^{+60}_{-38}$. The IS*5* large gene coding region is preceded by a Shine–Dalgarno[25] initiation sequence (the most likely fit is shown in Fig. 2*f*). A computer analysis also identified potential promoter and terminator signals[26] before (IS*5*:1,175–1,139)

0028–0836/82/190159—04$01.00

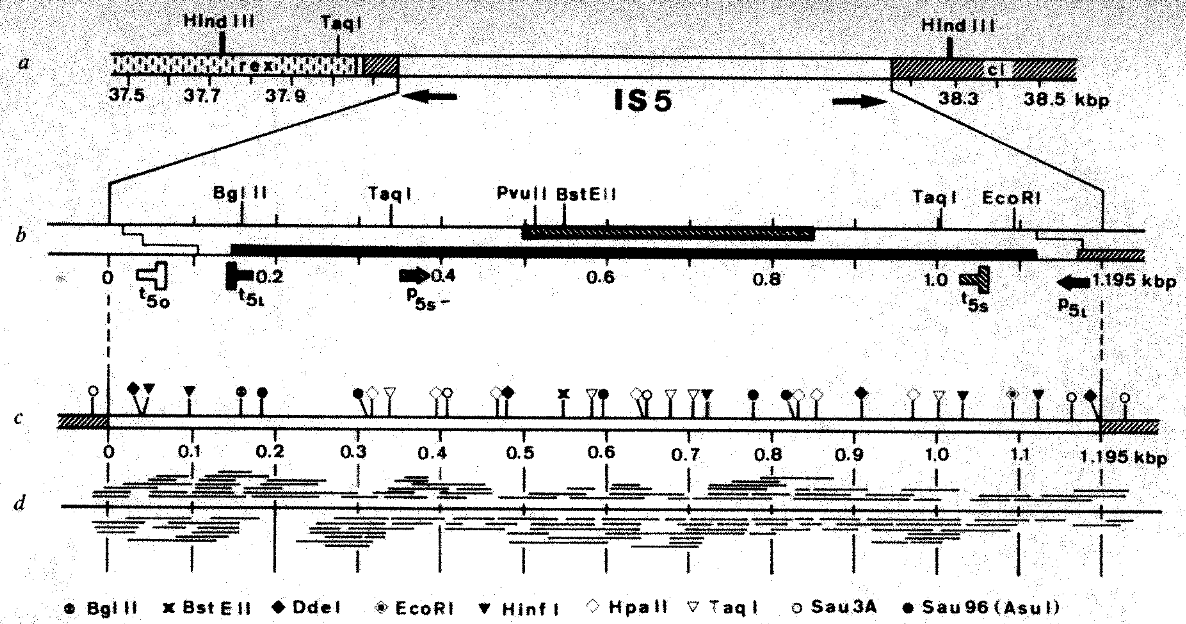

Fig. 1 Restriction map of the *rex-c*I region of λKH100 DNA and sequencing chart for insertion element IS*5* DNA. *a*, Position of insertion IS*5* in the *c*I gene of λKH100. Hatched regions represent IS*5*-adjacent λ DNA; sequence positions in λ DNA refer to the *Eco*RI restriction site located at the origin of replication (position 40,000). The marked *Hin*dIII fragment was cloned into a pBR313-derived vector plasmid and propagated as described previously[33]. *b*, Genetic map of insertion element IS*5* from the complete nucleotide sequence in Fig. 2 and from a functional analysis of its terminator and promoter signals of transcription (see Fig. 3 and text). The black bar indicates the coding region for the large IS*5* protein, the hatched bar corresponds to the IS*5* small protein reading frame. Outside-in translation according to the diverted λ*c*I reading frame is indicated as a lightly hatched bar at the right IS*5* boundary, and the near-terminal stop codons for the other five reading frames are indicated at the left and right termini respectively. Three transcriptional terminator signals (t_{5o}, t_{5l}, t_{5s}) and two promoter sequences (p_{5l}, p_{5s}) are indicated in their tentative locations. The restriction sites used during functional studies (see Fig. 3 legend) are shown above the genetic map. *c*, Restriction map of IS*5* DNA, indicating the restriction sites used in generating 5'-labelled fragments for DNA sequencing: *Bgl*II, *Bst*EII, *Dde*I, *Eco*RI, *Hin*fI, *Hpa*II, *Sau*3A, *Sau*96 and *Taq*I. A key for restriction site symbols is given at the bottom of the figure. *d*, Summary of DNA sequence results obtained for IS*5* DNA. Every stretch of independently determined DNA sequence is indicated by a single horizontal bar covering the corresponding region of unequivocal reading; segments of *l*-strand DNA are given above, *r*-strand segments below the central line. Note that almost the entire element has been sequenced using both strands, and large sections have been sequenced repeatedly, from different endonuclease cuts, as indicated by piles of horizontal bars. DNA sequencing was by the Maxam–Gilbert method, using the A > C reaction to determine adenine positions[19]. All isolated fragments were purified by butanol extraction[34] before both the kinase reaction and chemical degradation steps.

and after (IS*5*:166–143) the large gene coding sequence respectively.

Although none of the other two reading frames in right to left direction is open for any considerable length, the IS*5* DNA sequence appears to have the coding potential for a second protein in left to right direction, from position IS*5*:525 to IS*5*:851. The second open reading frame, which is in register with the sequence coding for the larger IS*5* protein, is predicted to code for a 108 amino acid, predominantly apolar protein of molecular weight $11{,}069^{+11}_{-10}$. Analogous to the IS*5* large gene, the IS*5* small gene also is preceded by a ribosome recognition sequence (see Fig. 2*g*; an alternative AUG start codon in the same reading frame, at IS*5*:495, is not affiliated with a recognizable Shine–Dalgarno sequence), and , according to computer search, has correlated promoter and terminator signals (at IS*5*:355–401 and 1,019–1,054) before and after the coding sequence.

To measure IS*5* promoter and terminator activities *in vivo*, we and Rak *et al.*[27] have individually subcloned into hybrid plasmids certain fragments containing IS*5* signal elements. Our analysis of the IS*5* terminator fragments (Fig. 3) confirmed computer-predicted locations and orientations, within the present limits of minimization. In addition to the large gene and small gene terminators (t_{5l} and t_{5s}), a termination signal has been detected near the left terminus of IS*5* in outside-in orientation (t_{5o}; IS*5*:31–71) which is consistent with the observed polarity of the element[18]. No analogous terminator has been found near its right end, however. The position of the IS*5* large gene promoter (p_{5l}) has been confirmed by Rak *et al.*, while the IS*5* small gene promoter (p_{5s}) was located at IS*5*: 460–495 in their cloning analysis. Expression of IS*5* large and small proteins has also been detected in minicells[27].

No other example of the IS*5* type of DNA dual coding capacity has been reported. Computer screening of published IS DNA sequences—IS*2* (ref. 28), IS*4* (ref. 29) and IS*903* (ref. 30) has, however, revealed quite similar reading frame organizations. In addition to a dominating large reading frame of more than 300 codons, there is always a second reading frame of 108–143 codons in the opposite orientation. Note that the large and small reading frames are consistently found in register, and that the (presumptive) small gene is always completely covered by the large gene. The sequence of IS*1*[31,32] shows a similar pattern, although both the large and small reading frames are short: 167 and 89 codons respectively. Similar to IS*5* (Fig. 2*g*), the small gene Shine–Dalgarno recognition sequences always appear as part of mRNA hairpin structure covering the smaller reading frame initiation region, and may be indicative of a generally reduced expression. There is no evidence, however, in any other element of promoter or terminator transcription signals or of dual protein expression. The role of such a compact antiparallel arrangement in genetic regulation or other functions is unknown.

An IS element preserves its autonomy by a genetic organization which avoids regularity dominance by adjacent genes or transcription units on the host DNA. There are therefore near-terminal stop codons in all six reading frames (marked in Fig. 2*b*) to avoid formation of fusion proteins under foreign control. In addition, near terminal termination signals of transcription, and therefore polarity, may be a direct consequence of IS autonomy. Whereas the structure of IS*4*, which has two outside-in termination signals[29], fully agrees with this prediction, IS*5* does not carry a termination signal at its functionally rather crowded right-hand end. IS autonomy may be protected in other ways, however (compare Fig. 2*f*). The biological significance of the different organization of the two ends of IS*5* is not known.

We thank B. Rak for communicating and discussing results before publication, and B. Traub and G. Schlingmann for technical assistance. λKH100 was kindly provided by W. Szybalski.

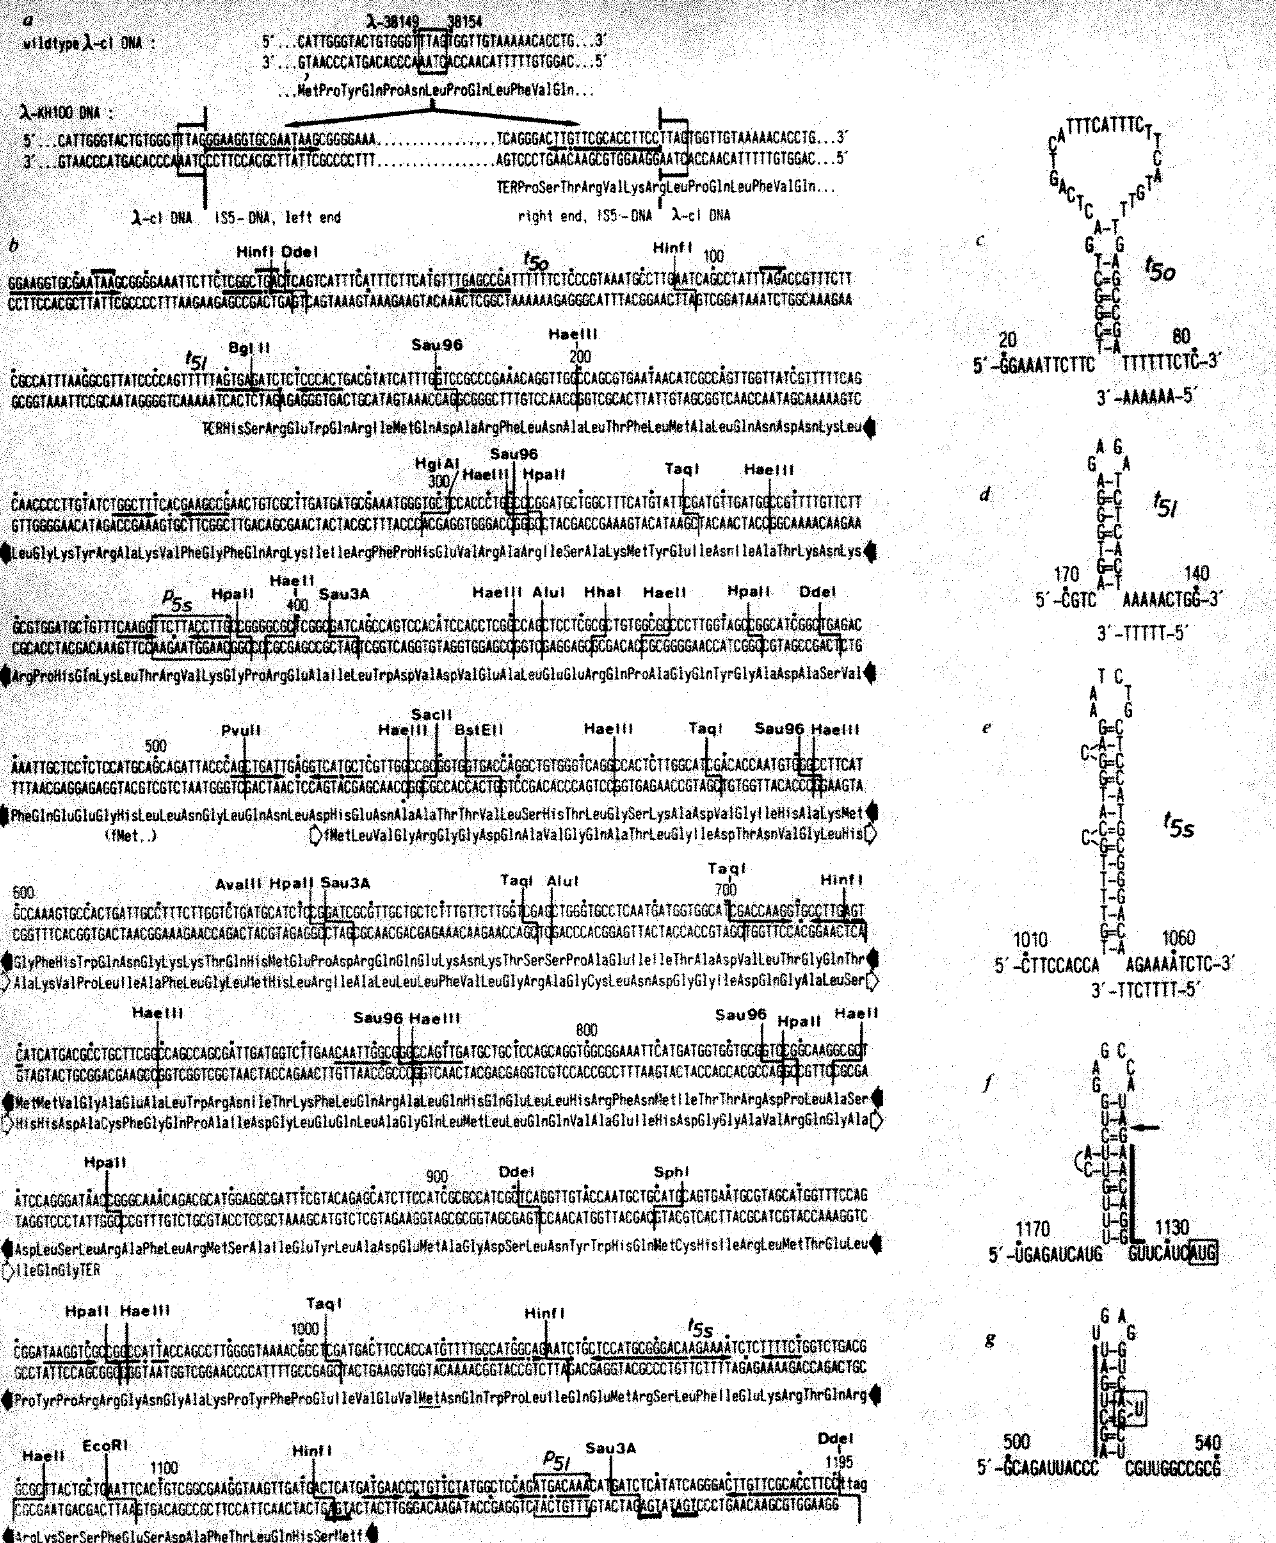

Fig. 2 DNA sequence of insertion element IS*5* in λKH100 DNA. *a*, Identification of the IS*5* integration site in the coding sequence of the *c*I repressor gene of phage λKH100. The 4 bp target site duplication is boxed, and the 16 bp terminal inverted repeat sequences (with a single mismatch) indicated by arrows. A proportion of the λ wild-type and of λKH100 *c*I protein sequences are shown below the DNA sequences. According to the genetic map of phage λ, the termini of IS*5* have been named left and right end respectively. *b*, Complete nucleotide sequence of IS*5*. Numbering starts from the left end. Amino acid sequences predicted from the DNA sequences of the large (right to left; closed arrows) and small (left to right; open arrows) genes of IS*5* are given in separate lines below the DNA sequence. Two potential alternative initiation sites for the large and small genes are indicated at positions 1,019 and 495 respectively. Cleavage sites for a collection of restriction enzymes that have been used for fragment mapping or DNA sequencing are marked at the respective nucleotide position above the DNA sequence. (In addition to experimentally proved restriction cuts, the recognition sequences for *Ava*III, *Hae*II and *Sph*I are also indicated.) Arrows between the DNA strands designate inverted sequence repetitions. Brackets refer to near-terminal stop codons with only the one closest to the terminus indicated for each of the six reading frames (excluding those in the target site duplication). Both rightward and leftward promoters are indicated by boxes at their tentative locations. Methylated cytidine *Eco*RII/*Bst*NI recognition sequences are indicated by squares; cleavage at the *Sau*96/*Hae*III restriction site at IS*5*:310 occurred in low yields, apparently due to an overlap with a methylated C residue. *c–e*, DNA secondary structures predicted for transcription terminator signals of IS*5*. Terminators for rightward outside-in transcription, for the IS*5* large gene (leftwards) and the IS*5* small gene transcription (rightwards), respectively, are drawn in a non-coding strand hairpin/coding strand 'tail' sequence manner (see refs 33, 35). Numbers refer to the respective positions in the IS*5* DNA sequence. *f*, *g*, RNA secondary structures predicted to occur at the initiation regions for the IS*5* large and small gene proteins respectively. The RNA hairpin structure in *f* can only be formed in a (long) outside-in transcription messenger and not within a (short) mRNA started at p_{5l}. According to a best fit with a bacterial promoter consensus sequence [26], the 5′ end of the p_{5l} mRNA is located at the position marked by an arrow (IS*5*:1,142), which would preclude formation of an initiation region hairpin structure. AUG initiator codons are boxed; bars along the sequences refer to Shine–Dalgarno recognition sequences[25].

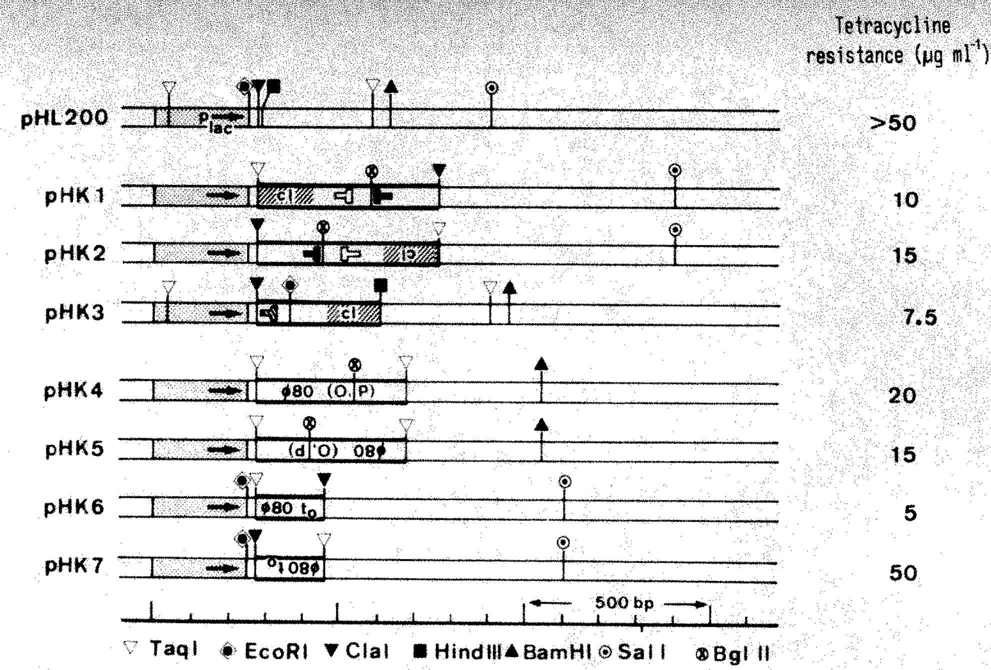

Fig. 3 Hybrid plasmid functional analysis of IS*5* terminator fragments. For all cloning experiments the same vector DNA, pHL200, has been used. This vector is a derivative of pBR322 and carries to the left of the *Eco*RI site a *lac*UV5 promoter fragment ~286 bp long (stippled area with arrow pointing in direction of RNA synthesis). The starting material to construct pHL200, pEx(lac)UV5-150, was kindly provided by H. Weiher, B. Zink and H. Schaller. Insertion of foreign DNA fragments between the *lac* promoter and downstream tetracycline-resistance genes made use of the *Cla*I and *Hin*dIII cloning sites. The tetracycline promoter of pBR322 extends across these restriction sites, but is destroyed by insertion. Care had to be taken, however, not to reconstitute the tetracycline promoter sequence through insertion of sequences similar to the missing −35 region. The levels of tetracycline resistance have been measured on the same freshly prepared agar plates for the whole set of clones together with a pBR322-containing strain (>50 μg ml^{-1} tetracycline) and an 'empty' strain of *Escherichia coli* K-12−490A (3 μg ml^{-1} tetracycline) as controls. The respective limiting concentrations of tetracycline are given on the right. DNA fragments incorporated into pHL200 are shown in heavier lines. The cleavage sites of restriction enzymes used for cloning or plasmid analysis are indicated by symbols defined at the bottom of the figure. The λKH100 DNA IS*5* left terminal *Taq*I fragment (λ:38,000–IS*5*: 335) has been cloned into the *Cla*I site of pHL200 in both orientations which correspond to the outside-in (t_{5o}) and large gene terminator (t_{5l}) respectively. Two sets of clones with different tetracycline resistance levels have been obtained: pHK1 and pHK2. A λKH100 DNA IS*5* right terminus containing *Taq*I–*Hin*dIII fragment (IS*5*:1,005–λ:38,291) corresponding to the small gene terminator, t_{5s}, has been cloned into the *Cla*I–*Hin*dIII gap of pHL200. The resulting hybrid plasmid pHK3 showed a strong reduction of the tetracycline resistance level. The control clones have been constructed in a similar way using two φ80 DNA *Taq*I fragments for insertion into the *Cla*I site of pHL200:φ80:40,107–40,514 which contains no transcription signal, but two long φ80 − *O*, *P* reading frames either in sense or in antisense orientation (pHK4, pHK5), which extend into and probably interfere with the tetracycline resistance initiation region, and φ80:39,406–39,584 containing the t_0 signal in direct or inverse orientation (pHK6, pHK7). The position of the IS*5* transcriptional terminator signals and the adjacent λ sequences are indicated according to Fig. 1.

Note added in proof: Since submission of this paper two independent sequence determinations of IS*5* DNA from different isolates have been published. They gave an identical[36] or nearly identical[37] (two deviations) result.

Bacillus amyloliquefaciens produces a ribonuclease[1] (barnase), the function of which is probably the digestion of external RNA: it is excreted by the bacillus and within the cell its action is inhibited by a protein of ~89 residues to which it binds with high affinity[2]. Determination[3] of the amino acid sequence of the ribonuclease, which is a monomer of molecular weight 12,382 consisting of 110 residues, has revealed its homology with other prokaryotic and eukaryotic ribonucleases[4–6]. We have now determined the atomic structure of barnase by X-ray crystallographic analysis. We report that its structure includes a large central β-pleated sheet and two α-helices. The arrangement of these secondary structures is different from that found in bovine pancreatic ribonuclease.

Crystals of barnase have the space group $P3_2$ and the hexagonal unit cell dimensions: $a = b = 59.0$ Å, $c = 81.6$ Å. There are three molecules in the asymmetric unit. X-ray diffrac-

					Tyr 17 (2)	⟨EH⟩	—	134	126	98	80

$$R_1 = \frac{\sum||FHLE| - |FH_{calc}||}{\sum|FHLE|}; \quad R_2 = \frac{\sum||FPH| - |FP||}{\sum|FPH|}; \quad R_3 = \frac{\sum||FPH| - |FPH_{calc}||}{\sum|FPH|}$$

where $FHLE$ is the experimental value of the heavy atom contribution, FH_{calc} is the calculated heavy atom contribution[7], $|FP|$ is the observed structure amptitude of the protein, $|FPH|$ the observed structure amptitude of the derivative, and $|FPH_{calc}|$ the derivative structure amptitude constructed by combining the calculated heavy atom contribution and the protein structure factor. $\langle FH \rangle$, r.m.s. value of FH_{calc} in the appropriate range of $4\sin^2\theta/\lambda^2$; $\langle EH \rangle$, r.m.s. lack of closure.

* $|FPH_{calc}|$ was constructed using the symmetry-averaged phases.

† $|FPH_{calc}|$ was constructed using the isomorphous phases defined by the gold derivative.

tion data were collected to 2.5 Å spacing on a Hilger and Watts automatic 4-circle diffractometer using the native enzyme and one derivative, which was prepared by soaking the crystals in gold cyanide. This derivative crystal diffracted well and the anomalous scattering effects produced by the gold were recorded. Owing to differences in the gold substitution, the data for the two crystals used in the case of the gold derivative were treated separately throughout. A second heavy atom derivative was prepared by iodination of the crystals and a 2.2 Å data set collected photographically at LURE using synchrotron radiation selected at $\lambda = 1.40$ Å. The anomalous scattering in this data set was not measured.

Three gold atom positions were identified from the difference Patterson function with coefficients $(|F_P| - |F_{PAu}|)^2$ and their parameters were refined by least-squares minimization to the experimental heavy atom contribution (F_{HLE})[7]. Iodine positions were determined from the difference Fourier map (coefficients $||F_P| - |F_{PI}||$) phased by the gold derivative[7]. A phase set was calculated from the two derivatives using Blow and Crick's combination procedure[8]. Details of the heavy atom refinement and phase calculations are given in Table 1.

We were unable to interpret the electron density calculated with the combined isomorphous phases although there were regions in which the protein's main-chain and side-chain structure could be traced in detail. There was also an encouraging similarity in the electron density of each of the three independent molecules. The non-crystallographic symmetry relations between the molecules were first determined from the gold positions and then refined by correlating the electron densities within spheres centred approximately on each molecule, using

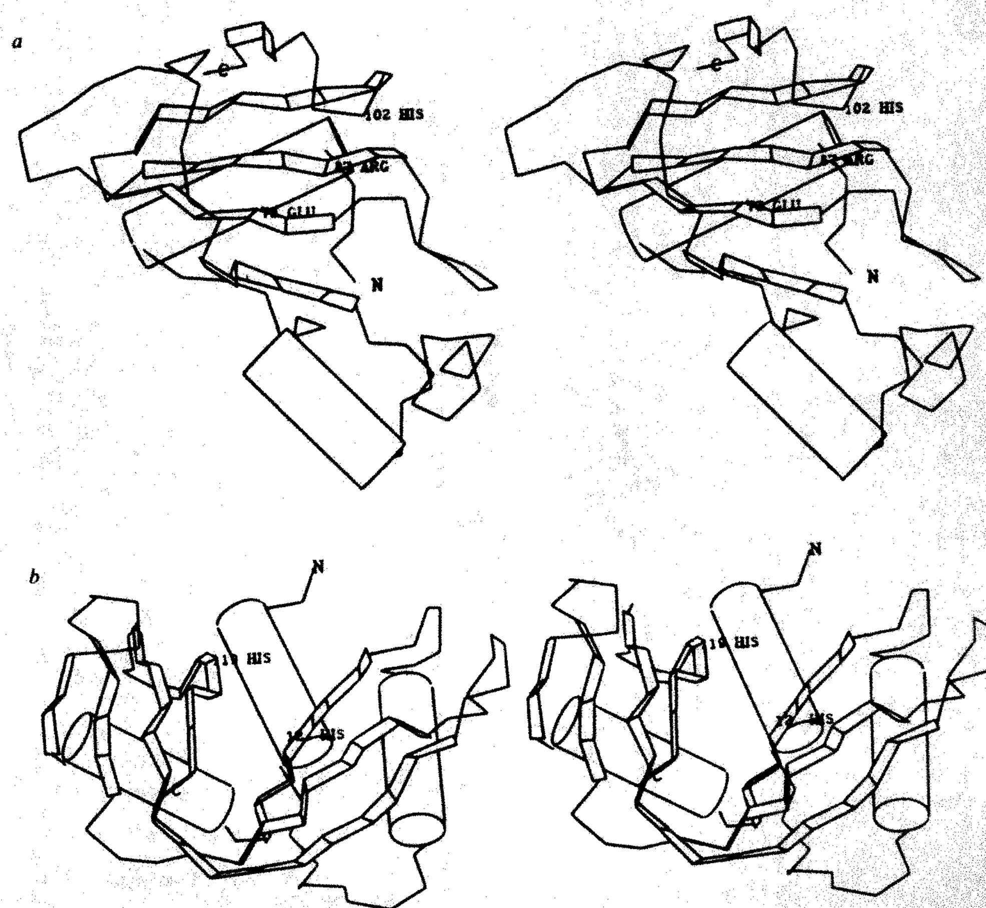

Fig. 1 Stereo pairs of schematic drawings of *a*, barnase and *b*, bovine pancreatic ribonuclease A. Each vertex represents the position of a $C\alpha$ atom; α-helices are shown as cylinders and the strands of the β-sheet as ribbons. The connecting loops are represented by lines. The active site of barnase includes Glu 73, Arg 87 and His 102 and is shown in more detail in Fig. 3. The active site of bovine pancreatic ribonuclease A includes His 12 and His 119. This figure was drawn from the atomic coordinates using the computer program of Lesk and Hardman[20].

a least-squares superposition method[9]. The mean of the correlation coefficients between the different molecules was 0.60.

The molecular envelope was defined from the isomorphous map, in which the electron density was averaged using the refined non-crystallographic symmetry operations. The map was sectioned in two perpendicular directions to ensure accurate tracing of the envelope. This was important to avoid the need for recalculating the envelope during the refinement calculations.

The electron density map produced with the symmetry-averaged phases[9,10] was readily interpreted. All but two residues have sensible density, which in some cases is very well defined, and their coordinates are now being prepared for refinement calculations.

The polypeptide chain of barnase is shown in Fig. 1*a*. The secondary structure of the enzyme consists of a central, five-stranded, twisted antiparallel β-sheet (residues 50–55, 70–75, 85–91, 94–101 and 106–108) and two α-helices (residues 6–18 and 26–34). The first helix packs against the face of the β-sheet in the normal manner[11] and the second helix packs against its edge. Bovine pancreatic ribonuclease also consists of a large central β-sheet with adjacent α-helices[12,13] but it differs from barnase in that its β-sheet is not only twisted but also bent in the middle, giving it a V shape (Fig. 1*b*). In addition, the residues that form the active site in the two molecules originate in parts of the structures that are not analogous (see below) and give different base specificities: barnase specific for purines[14] and pancreatic ribonuclease for pyrimidines[12].

Extracellular ribonucleases from *Bacillus intermedius*, *Streptomyces erythraeus* and from the fungi *Aspergillus oryzae* and *Ustilago sphaerogena*, have amino acid sequences that are homologous to that of barnase[4–6]. Figure 2 shows that residues 30–110 of barnase are between 82 and 20% homologous with the four other sequences. There are five positions at which the residues are invariant; in barnase these positions are occupied by Leu 42, Glu 73, Ser 80, Arg 87 and His 102 (Fig. 2). The residues at three of these positions have been shown to be involved in the ribonuclease activity of the proteins: the His in barnase and ribonucleases St and T_1, the Arg in ribonucleases St and T_1, and the Glu in ribonuclease T_1 (refs 6, 15, 16).

Fig. 2 An alignment of the amino acid sequences of the extracellular ribonucleases from *B. amyloliquefaciens*[3] (Ba); *B. intermedius*[5] (Bi); *S. erythraeus*[6] (St); *A. oryzae*[21] (T_1); and *U. sphaerogena*[22] (U_2). The numbering used here is that of barnase so that the positions of mutations, insertions and deletions can be seen in Fig. 1*a*, 3. Residues that are identical in two or more sequences are boxed and homologous residues that are part of the active site (see text) are indicated by asterisks. The regions that form secondary structures in barnase are indicated by 'α' for an α-helix and by 'β' for the strand in the β-sheet. The alignment shown here has been revised slightly from that given in ref. 4 in the view of the barnase structure. The residues that form the first part of the five sequences show little overall homology and large deletions. It has been shown that the alignment of such sequences derived by maximizing the match of the few similar or identical residues can give results that are structurally incorrect[23].

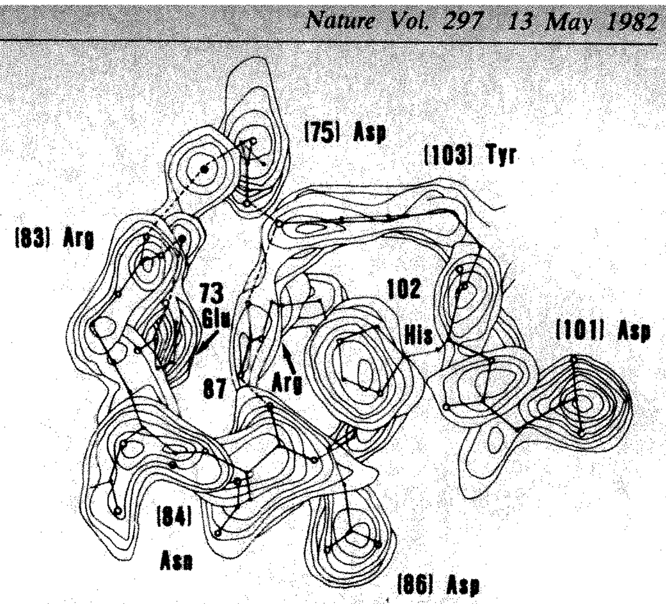

Fig. 3 A composite view of the electron densities at the active site, with the protein atomic coordinates superimposed. Two water molecules are indicated by solid circles.

Inspection of the barnase structure shows that residues Glu 73, Arg 87 and His 102 cluster in one region of the molecules, therefore this region must form the active site (see Figs 1*a*, 3).

The catalytic role of hisitidine 102 has been confirmed by the finding that gold cyanide, which reacts with imidazole N_D in the crystal, suppresses the enzyme's activity. Removal of the gold cyanide by dialysis restores fully the catalytic activity of the enzyme (R.W.H., unpublished results).

In barnase, the active-site residues are in a shallow depression and come solely from the C-terminal half of the molecule. Their chemical and structural organization differs from that at the active site of bovine pancreatic ribonuclease A, where the principal catalytic residues are two histidines, residues 12 and 119, which lie in a deep cleft (Fig. 1*a*, *b*).

Work is in progress to elucidate the catalytic mechanism of barnase and to provide a structural interpretation of previous experiments on its folding[16]. X-ray analyses of the ribonucleases T_1 and St are in progress elsewhere[17–19] and comparison of their structures with that of barnase should allow an understanding of how this family of ribonucleases evolved.

We acknowledge with gratitude the use of the synchrotron radiation facilities at LURE and the help given by Peter Moody, Federico Giordano and Christopher Hill during the analysis.

Note added in proof: Since submitting this paper we have learnt of the structure determination at 2.5 Å resolution of ribonuclease St (Yamamoto, Y. *et al.* 9th Symposium on Nucleic Acid Chemistry, Tokyo, October 1981) and of ribonuclease T (Heinemann, U. and Saenger, W., personal communication).

BOOK REVIEWS

From Kharkov to Tel Aviv

John M. Charap

Refusenik: Trapped in the Soviet Union. By Mark Ya Azbel. Pp.513. UK ISBN 0-241-10633-8; US ISBN 0-395-30226-9. (Hamish Hamilton/Houghton Mifflin: 1982.) £9.95, $17.95.

IF YOU look up *refusenik* in a Russian dictionary, you will not find it there. After all, it is not an official Russian word, but has been improvised to describe someone who has applied to emigrate from the USSR to Israel, and whose application for a visa has been refused. What the word does not convey is the anguish and the courage of those who wait, often for years, trapped in a situation in which as individuals they face the power of a state at best indifferent, frequently hostile.

Mark Yakovlevitch Azbel is probably best known to many readers of this journal for his work on cyclotron resonance in metals. He learnt his physics at "the cradle of Soviet physics", Kharkov State University, where Lev Landau had established a world-famous research institute. From Kharkov he went to Chernogolovka, to the Landau Institute for Theoretical Physics, where he continued to rise to a position of prominence and international repute. Yet in December 1972 he took the fateful step of applying for a visa to emigrate to Israel, and became a *refusenik*. It was not until July 1977 that he was finally permitted to leave the USSR.

This remarkable book tells how it was that, notwithstanding his success and prospects for continuing advancement as a Soviet physicist, he became convinced that he could not remain in the Soviet Union. And it tells of the hazards and torments which dogged his steps from Kharkov to Tel Aviv. Azbel has written a moving and sincere autobiography. Any such work from the Soviet Union must be of interest, because of the light it sheds, sometimes no less illuminating for being oblique, on life in that country. For readers of *Nature* it will be of particular interest because of the view it gives of Soviet science, and indeed of some individual Soviet scientists. But to my mind the real importance of this book lies in its exposition, from the stand-point of one who experienced and suffered from it, of the corrupting pervasion of anti-Semitism in the USSR.

Azbel's parents were both physicians, who graduated in Kharkov in the terrible days of 1931 when famine stalked the land, the man-made famine which followed forced collectivization, and Mark was born the following year. As a four-year-old, left unsupervised whilst his parents worked six days a week, Mark first found out that he was different, that he was a Jew. Lenin had tried to eliminate the anti-Semitism which was so deeply rooted in the USSR — nowhere more than in the Ukraine. Stalin, as first Commissar for Nationalities, had made it in a certain sense impossible to be a Russian Jew, or a Ukrainian Jew. To be a Jew in the Soviet Union is not a matter of choice or conviction; it is rather a question of nationality, and if it says "Jew" on an internal passport, it cannot say "Russian" or "Ukrainian". From his first day at nursery school when his teacher greeted him with "Another zhid! Where do they all come from?" to his last few hours in Moscow when the cold insulting indifference of the officials at the airport made his departure a nightmarish farce, Azbel was time and again reminded of his difference, of his Jewishness.

Of course there were times when this awareness could recede into the background. But with dramatic force public affairs would make him, along with the whole of the Jewish community, aware of the precarious — even dangerous — status of the Jews. As a student he felt the tension which prevailed throughout the country during Stalin's last years.

> The Lysenko catastrophe had repercussions all over the Soviet Union affecting biologists in even the smallest, most remote institutions, obscure little places of minor importance. Now the laws against Cosmopolitanism were threatening artists, composers, writers. Russians were not wholly exempt from these attacks; but nine out of ten of the criminals were Jews.

Confronted by the menace and threat of disappearance, arrest by the KGB or worse, Azbel asked himself: how could one survive in this atmosphere? The question was not about physical survival, but moral survival. There were several possibilities: concentration on personal life; devotion to a struggle with the system; escape into pure science. But

> I could not make any of these choices. I felt that my own way of life was to be in science, but as to friends: it seemed to me that it would be crippling, demeaning, to choose my friends on the basis of which friendships would be safe and which would not. To confine my loyalties to science, and to my fellow-scientists, for reasons of security; to cultivate indifference to everything and everyone else — I knew I couldn't do that. In a word, I simply made up my mind at that time that I would try to be a decent human being.

Stalin died, and the terrible threat implicit in the "Doctors' plot" receded. Azbel graduated, brilliantly, but not without politically motivated machinations against him which it required the intervention of Ilya Lifschitz to deflect — and not without his first encounter with the KGB, perhaps an attempt to obtain a hold on him for future exploitation. The heavy atmosphere lightened with Khruschev's short-lived thaw. Azbel married and moved to Moscow.

Also now in Moscow was Alexander Voronel, a close friend from student days in Kharkov and now a director of a laboratory in Dubna: they had much in common, and their mutual friendship and support for Andrei Sinyavsky, and especially Yuli Daniel, brought them both into the hands of the KGB when these two authors were put on trial in 1965. This brush with the authorities was more significant than the earlier one, and Azbel was lucky to avoid losing his post at the university.

The shifting attitudes within the Soviet Union during the late 1960s, responsive to events such as the Six-Day War and the Czech uprising, meant that when in 1970 news first began to filter through that some Soviet Jews had publicly expressed a wish to emigrate to Israel, Azbel was amongst those who began to recognize that to leave the Soviet Union was a real possibility. His

Contemporary Jewish Library

The start of active protest: four of the seven scientists who took part in the 15-day hunger strike, June 1973, in reaction to the refusal of the Soviet authorities to allow them exit visas. From left to right: Dan Roginsky, Alexander Voronel, Mark Azbel and Victor Brailovsky.

resolve was stiffened by the trial in Leningrad of Dymshitz and Kuznetsov and the demonstrations in the Visa Department offices in Moscow in 1971.

And so it was that in December 1972 he went to the Visa Department. He was not the first distinguished scientist to do so: that was probably Alexander Lerner who had applied a year earlier. Lerner is still a *refusenik* more than ten years later. Nor was he the last. Recent information suggests there are about 100 *refuseniks* with a scientific doctorate (roughly equivalent to DSc) in Moscow alone, another 200 with the degree of Candidate (roughly PhD). Voronel applied shortly before Azbel, and was allowed to leave at the end of 1974.

It must be understood that to apply to emigrate from the USSR is an act of the highest significance. It leads almost inevitably to social ostracism. And in most cases, certainly for scientists, it leads to dismissal from one's job. For a scientist this in turn means more than loss of livelihood (which can in turn lead to prosecution for "parasitism"); it means deprivation from contact with colleagues, from access to libraries and laboratories. It means "exclusion from science". To counter that exclusion, to provide mutual support and scientific sustenance, Voronel organized a seminar every Sunday noon at his apartment. These Sunday seminars continue to this day, despite a succession of attempts to disrupt or prevent them. They have multiplied: similar meetings are held in other Soviet cities, and in disciplines other than physics. The participants have received Western visitors in this way (a recent session learnt about Feigenbaum's work on frequency doubling and the transition to chaos): indeed they have held impressive international meetings. All of this has been under the watchful eyes of the KGB, and has been scrupulously within the law.

The legality (and to Western readers perhaps the normality) of private gatherings of scientists to discuss science has not prevented harrassment, and official attempts to disrupt their proceedings. These reached a climax when Voronel, Azbel and Victor Brailovsky decided in 1974 to hold an international scientific symposium, and again three years later when another international meeting, on collective phenomena in physics, was held to celebrate the fifth anniversary of the seminars. Both meetings were attended by numerous distinguished visitors from abroad. Both were heralded by oppressive KGB surveillance, questionings and indeed arrests — Azbel was himself imprisoned in 1974. After Azbel's emigration, Victor Brailovsky took over as chairman of the Sunday seminars from Azbel, who had succeeded Voronel. Brailovsky is now living in exile in Beineu, Kazakhstan.

Azbel's book speaks eloquently of the courage and resourcefulness of those scientists who persist in their legitimate aspirations to emigrate and of their motivation. It answers some but not all of the questions which must be raised about the reasons behind the Soviet policies towards them. It underlines their vital need for support from the international scientific community, which I believe to be an obligation upon us as scientists. The pursuit of science gives privileges and brings responsibilities: and it is not possible to separate those responsibilities from the wider relations between the pursuit of science and human affairs. This book should be read by all those who profess an interest in international scientific activities, and I would hope that would mean all scientists. □

John Charap is Head of the Physics Department at Queen Mary College, University of London. He attended the Moscow Sunday seminar in 1978, and is Chairman of the European Physical Society Advisory Committee on Scientific Freedom.

The quantum theory of space and time

C.J. Isham

Quantum Fields in Curved Space. By N.D. Birrell and P.C.W. Davies. Pp.340. ISBN 0-521-23385-2. (Cambridge University Press: 1982.) £27.50, $49.50.

THE problem of quantizing the gravitational field commands the attention of an increasing number of theoretical physicists who are attracted by the importance of the subject to studies of the early Universe, gravitational collapse, grand unification of all fundamental forces, and the Planck length structure of space and time. In spite of much effort a successful resolution remains elusive, and it seems natural to tackle first the simpler problem of the quantization of a field propagating in a curved, but fixed, background spacetime. It had been known for many years that a time dependent metric would transmute part of its energy through the medium of quantum particle production, but the subject became of widespread interest only after Hawking's announcement in 1974 of the production of particle pairs by the event horizon of a black hole.

The subsequent effort devoted to quantum field theory in a curved space has spawned a considerable literature of research papers, conference proceedings and review articles, but the text of Birrell and Davies is the first attempt to present the subject in a more permanent form. I can think of at least three quite different types of book that might be published under this title with the contents reflecting the individual approaches that have been developed by different researchers. The present authors have made a determined and commendable effort to cite most of the important papers that have appeared, but the final treatment sharply reflects their own personal contributions and methodology. Quantum field theory is introduced with heuristic methods involving mode function expansions; there is no discussion of the mathematical problems associated with such sums or of their resolution via the operator algebra techniques that form the backbone of most rigorous investigations into quantum fields with external sources. This simpler approach does however have the asset of rendering the book accessible to a postgraduate student who has attended any standard first course on quantum field theory, and the assumed knowledge of general relativity is no more demanding.

A significant application of the subject is to the physics of the early Universe; for example it has been suggested frequently that an initial anisotropy could be removed by the quantum production of particle pairs. Birrell and Davies are especially interested in this problem and provide a comprehensive discussion of quantum field theory in various cosmological backgrounds. Of particular value here is the careful account of the resolution, using model particle detectors, of the conceptual problems that arise concerning the operational status of a quantum particle.

Almost all work in quantum field theory is plagued by the infamous ultraviolet divergences and the addition of a curved background tends, if anything, to make matters worse. A particularly disturbing feature is the appearance of infinities in the matrix elements of the energy momentum tensor which, in a semiclassical limit, forms the source of the gravitational field. The regularization and renormalization of these divergences is a subtle problem and is discussed at length with most of the established techniques being given a respectable hearing; applications include an authoritative account of the Hawking effect and of the ensuing use of the stress tensor to isolate the origin of the particle pairs.

Professor Davies has rightfully earned a high reputation as an author of informative and well written semi-popular science books and this research monograph is presented in a similarly clear and attractive style. Quantum gravity is an active subject and it would be difficult to predict that all sections of the text will seem equally relevant in ten years time; nevertheless, the authors are to be congratulated on producing a timely work that should help to stimulate interest in this fascinating branch of theoretical physics. □

C.J. Isham is Reader in Theoretical Physics at Imperial College, University of London.

Mycology: a successor to Cochrane

John D. Weete

Fungal Physiology. By David H. Griffin. Pp.383. ISBN 0-471-05748-7. (Wiley: 1981.) £25.45, $43.25.

DURING the past few years several excellent, advanced-level monographs have appeared on aspects of the biochemistry and physiology of fungi, reflecting some 20 years of continual advance in our understanding of these subjects. Yet there has been no successor to Cochrane's general introductory text, *Physiology of Fungi,* published by John Wiley in 1958, and long out of date. Professor Griffin has now provided such a text with *Fungal Physiology.* His coverage emphasizes those physiological processes typically associated with fungi, and stresses the experimental rather than historical aspects of the subject.

The opening three chapters, reviewing the fungal thallus, and the chemical composition and structural organization of fungus cells, are followed by an outline of the major processes occurring within fungal cells. On balance I believe more emphasis could have been given in this latter chapter to metabolism and the treatment strengthened by greater coverage of the relationships between metabolic change, growth and reproduction. The author then turns to various aspects of vegetative growth, and in the next three chapters considers the uptake of nutrients, the chemical requirements for growth and the relation of the physical environment to growth. Chapters 9 to 12 deal with sporogenesis (environmental factors, biochemistry), dormancy and germination, and the role of hormones in sexual reproduction. Here, Professor Griffin has chosen *Dictyostelium discoideum* rather than a yeast or filamentous fungus to illustrate the biochemistry of spore formation. He provides ample evidence indicating that fungi of different classes seem to have developed different hormonal systems for regulating sexual reproduction. The chapter on syngamy (Chapter 12) is organized on the basis of fungal groups and the specific hormones associated with each group are discussed.

Understanding specific biochemical processes can be aided by the use of inhibitors; in this context, inclusion of a chapter devoted to fungicides is noteworthy because of the significance of many of these compounds in the agrochemical and biomedical fields as chemical agents for controlling pathogenic fungi. The final chapter, "Fungal Attack Mechanisms", is concerned with fungal toxins, exoenzymes, fungal responses to environmental stimuli and fungal interactions (non-pathogenic) with other living systems. Fungal genetics *per se* is not covered, but genetic studies are discussed where they are relevant to other topics, particularly fungal symbiotic relationships. The importance of using mutants in mycological research is implied by the citation of examples throughout the book.

The book is well organized; each chapter begins with an introductory statement which puts the subject under consideration into perspective, ends with a brief summary, and is appropriately referenced. Topic discussions are well illustrated with light and electron micrographs, tables and, where pertinent, graphs and chemical structures. *Fungal Physiology* is suitable as a text for a general course serving advanced undergraduate and graduate students, and also provides a handy reference work for researchers seeking general background information. The appearance of this book is both significant and timely; I highly recommend it. □

View of laser fusion

David W. Forslund

Physics of Laser Driven Plasmas. By Heinrich Hora. Pp.317. ISBN 0-471-078880-8. (Wiley: 1981.) £28.95, $49.15.

THE field of laser fusion and the physics of laser driven plasmas has developed rapidly in the past decade and it has proven difficult for research workers to keep up with progress. Particularly lacking have been good reviews and good textbooks which would help introduce new people to this extremely complex subject. In this recent attempt to meet such a need, Professor Hora has sought to derive the basic physics of the interaction of intense laser light with matter from first principles. He attempts to lead the reader through the derivation of the fundamental plasma physics, kinetic theory, hydrodynamics and an expression for the nonlinear force arising from intense laser light, and follows this with discussion of the numerous applications of the nonlinear force from its role in parametric instabilities to its use in the implosion of pellets.

The book suffers from a number of flaws, however, which prevent it from being useful either to the student or as a handbook for the research worker. First, the discussions of most of the phenomena are unduly complex, confused and full of errors, making the text extremely difficult to read. As a typical example, the derivation of the plasma frequency and Debye length on pages 22–25 introduces

the unclear and irrelevant ideas of "cell distance", "refractive index" and "electrostatic explosion of ions".

Throughout the book Professor Hora seems to be forcing his own conceptions on the reader rather than trying to properly survey the field. As a consequence the book gives a very unbalanced view. For example, only one paragraph is devoted to the production of high energy electrons, which continues to be such a major difficulty in laser fusion. Consistent with this neglect, the major problem of electron transport is totally ignored.

More than one-third of the book is spent on calculating the ponderomotive force and its effects on hydrodynamics, which leads, in the conclusion of Chapter 13, to the claim that all the problems of hot electrons in experiments can be removed by utilizing "the nonlinear force". As an alternative to the usual ablative compression approach which suffers from electron preheat, Professor Hora suggests

> . . . the very fast nonlinear force pusher will accelerate the plasma before the hot electrons can be generated. This has been confirmed by extensive numerical studies and can be the way out of the present difficulties of laser fusion.

Apparently, Professor Hora genuinely believes that a short pulse intense laser at the upper limit of already achieved intensities will not produce energetic electrons. It is remarkable that, although this simple target approach is at least five years old, no major experimental programme has sought to make use of it. Evidently, of the many proposals to reduce the preheat problem, Professor Hora's has been judged to be the least likely to succeed. □

Seismologists look at arms control

Peter D. Marshall

Identification of Seismic Sources — Earthquake or Underground Explosion. Edited by Eystein S. Husebye and Svein Mykkeltveit. Pp.876. ISBN 90-277-1320-0. (Reidel: 1981.) Dfl. 195, $98.

In 1958 a Committee of Experts met in Geneva to study the possibility of verifying a treaty to ban the testing of nuclear devices. Under the treaty, eventually signed in 1963, the USA, USSR and UK stopped all but underground testing — although underground explosions could be detected by their seismic effects, uncertainty in discriminating between explosions and the many earthquakes of equivalent magnitude meant that a treaty to ban them was politically unacceptable. This uncertainty in discrimination has occupied forensic seismologists for over 20 years. Their latest views are aired in these proceedings of a NATO-sponsored Study Institute, convened to assess progress since systematic research began with the Vela Uniform programme in the USA and Tabor Pluto in the UK.

These programmes led to instrumental improvements and to the use of digital computers to increase the accuracy of detection and hypocentre location. Many more earthquakes could then be distinguished from explosions because of their greater depth; in addition, the spectral differences between earthquake and explosion signals led to identification by their body to surface-wave ratios. These improvements opened up the possibility of teleseismic rather than the short-range monitoring available in 1958, thereby allowing a potential reduction in the number of stations required to verify a treaty. However problems continued to arise: the increasing number of explosions in both seismic and aseismic regions brought differences in transmission paths to the attention of seismologists and provided much of the impetus for modelling seismograms. This in turn highlighted the loss of information suffered by the narrow recording bands in common use, and thought and effort was successfully brought to bear on digital recording and processing in much wider bands.

By 1976 many countries had initiated seismological discrimination studies and the UN Committee for Disarmament took advantage of this wider interest to set up a multinational Ad Hoc Group of Scientific Experts to make recommendations on how a Comprehensive Test Ban Treaty (CTBT) might be monitored. Soon afterwards, CTBT negotiations were re-opened between the USA, USSR and UK; these demonstrated a need to supplement teleseismic stations with regionally sited stations in order to achieve the verification levels required.

At this point, groups in the USA and Norway proposed a discussion of recent developments in discrimination studies under NATO sponsorship. The resulting proceedings of the Study Institute provide seismologists with a reference book of 45 papers, 20 by invited key lecturers.

The scene is set by Douglas's objective review which includes a comprehensive account of diagnostic criteria. Effective and stable diagnostic criteria depend on a knowledge of earthquake and explosive sources. Not surprisingly little is known about the earthquake source but strangely, as Rodean shows, much the same applies to nuclear explosions even after 20 years of underground testing. Any technique which defines their parameters thus becomes a significant diagnostic aid. One in which the seismic moment tensor is used to represent the source is discussed, among others, by Doornbos, clarifying what was becoming a rather confused topic and one turning out to be well worth further exploitation even though the method is bedevilled by transmission path effects. Waveform synthesis, discussed by both Harkrider and Kennett, may however one day lead to a solution of the problem of path effects. Of the seven papers on the influences of attenuation and scattering (both path effects) on the waveforms, that by Aki demonstrates the dramatic effects of even small velocity fluctuations within the lithosphere beneath a recording station.

In spite of the uncertainties, a seismologist must ultimately make a decision: earthquake or explosion? Much may depend on his decision, so the more independent observations available to him the better and Tjostheim reports on how multidimensional discrimination techniques may be applied to teleseismic data. The technique can also be applied to regional diagnostic data of the type described by Blandford. Finally, an indication is given of the kind of network which would need to be established with the appropriate instrumentation, automatic processing, data transmission facilities and data centres capable of promptly handling enormous quantities of data.

In 1958 Sir William (later Lord) Penney described seismology as a "stone-age science". The contents of this book demonstrate that this is no longer true, and the organizers of the meeting are to be congratulated on their initiative. Nonetheless problems remain. Seismic decoupling of explosions, explosion-like earthquakes, the detection of small explosions among earthquake signals and, above all, inadequate knowledge of the structure of the Earth all contribute to the difficulties of concluding a CTBT. Seismologists and physicists anxious not to rediscover the wheel will find in this volume the sources on which to build their new research programmes. □

20 May 1982

Good start on strategic arms

President Ronald Reagan's proposals for a new bilateral negotiation on strategic arms control are welcome. Will the Soviet Union listen? And will the Administration follow through?

President Reagan appeared to take a stride towards serious strategic arms control on 9 May when he made his first strategic arms control proposal to the Soviet Union and called for deep cuts in each side's arsenals. While the proposal deserves applause as a first step, it is like the proverbial horse that has been led to water but has not yet drunk. The Soviet Union has yet to respond. And unless it is followed by clear, realistic and consistent effort by the Administration in the coming months, even years, the progress Reagan has made will be undone.

The proposal, transmitted to the Soviet Union in detailed form at the same time as the President outlined it in a speech at his *alma mater*, Eureka College in Illinois, focuses on reducing the Soviet advantage in long-range intercontinental ballistic missiles (ICBMs) by asking that each side should reduce to 5,000 the number of its ballistic missile warheads, no more than half of which could be on land-based ICBMs. At the latest count, the Soviet Union may have 6,300 ballistic missile warheads, of which 5,100 are on land-based ICBMs. The United States has 7,500 ballistic missile warheads, of which only 2,154 are on land-based ICBMs. One effect of the proposal is that the Soviet Union would have to reduce its land-based ICBM warheads from 5,100 to 2,500, and so forgo all or most of its force of SS-18 giant "heavy" missiles, which could have up to 3,000 high-precision warheads and which could now, in theory, knock out most of the US force of land-based ICBMs in a single blow. The United States, which invests a smaller fraction of its strategic forces in land-based ICBMs, is at present below the 2,500 warhead ceiling in the President's proposal and could comply merely by retiring some of its older ICBM-carrying submarines without sacrificing much in force capability. So much for phase one.

The President also proposed a second phase of negotiations in which both sides would strive for equality by another measure, ballistic missile throw-weight, "at less than current American levels". Throw-weight is the weight of a missile's payload including warhead. This notion has grown out of an argument (backed by Eugene V. Rostow, director of the Arms Control and Disarmament Agency, and by Defense Secretary Caspar Weinberger) that an aggregate index of throw-weight would be a better basis for measuring current and future force levels than merely counting holes in the ground or launch tubes on submarines, as in Salt II. The President apparently resisted using this formula for the first phase of negotiations because the joint chiefs of staff felt that weight-counts are less verifiable than actual warheads. Rostow now says that the connection between phase one and phase two will depend on the Soviet Union's reaction and counter-suggestions, but that phase one alone would achieve substantial reductions in throw-weight on the Soviet side, the area where its forces have an advantage.

So far, the plan has only been sketched in public, and the Soviet side has just received it. More details may not be forthcoming for some time, but the plan has some obvious weaknesses and some curious strengths. One weakness is that the proposal does not include nuclear warheads carried by aircraft in its warhead ceiling of 5,000. Instead, the proposal is said to put a separate ceiling on bombers, limiting each side to between 350 and 400. On the US side, this would include the long-range older B-52 bombers and the new B-1 but also the intermediate range FB-111s based in Europe, armed with nuclear weapons and capable of striking at targets in the Soviet Union. The Soviet Union has long insisted that the FB-111s should be counted as strategic weapons, a view which the United States has rejected in the past. In return for including the FB-111s under the bomber ceiling, the United States would now insist that the Soviet Union includes the "Backfire" bomber under its bomber ceiling. The range and deployment of the Backfire bomber was a contentious issue in Salt II — and its exclusion from the Salt II ceilings was one reason why that agreement was never ratified. In this connection, domestically, the Reagan plan could give the Administration a respectable way to back out of building large numbers of MX missiles, which have been touted as — but not proved to be — a way to reduce the vulnerability of land-based ICBMs, although the obvious way for the United States to reduce its total number of ballistic missile warheads from 7,200 to 5,000 would be to scrap some older submarines, another could be to cancel part of the MX programme. The Administration is already embarrassed that its promise a year and a half ago to set the MX issue straight forthwith has not yet borne fruit.

The Reagan plan therefore deserves a fair wind. It is to be hoped that the Soviet Union will not reject it outright, as it rejected President Carter's proposal for deep cuts in missile forces in 1977. But advocates of a nuclear freeze in the United States (see *Nature* 29 April, p.790) and Europe should not delude themselves that the President has taken a step towards their version of arms control. A curious fact about the politics of arms control in the United States is that both the left and the right favour deep cuts in nuclear forces, but for different reasons. The left favours cuts (and the extreme left favours unilateral cuts) as part of the continuing process of negotiation. The right, in the United States, favours proposals for deep cuts on the grounds that they are a way of limiting Soviet striking power substantially — and that they also challenge Soviet protestations of good intentions on arms control. At the worst, it is always possible to say "See, we told you so. They don't mean what they say".

As it happens, it is not yet clear how sincere even the Reagan Administration is about arms control, no matter what the President said in Eureka. In their 18-month partnership, Secretary of State Alexander Haig and Secretary of Defense Caspar Weinberger have shown that they have radically different views of the US–Soviet military balance. As a result of these and other differences, often aired publicly, the Administration has yet to convince countries abroad (and even itself) where it stands on some key issues. Yet what is critical to the success of the strategic arms negotiations is not this opening flourish but whether, in following up, the Administration can speak with one voice and settle down to serious talks, taking Soviet rhetoric in its stride and keeping policy on a single course, rather than zigzagging and confusing the Soviet leadership. In short, it remains to be seen whether the horse will take a drink.

Unfortunately it will be several months before these issues can be clarified. Mr Brezhnev, having had the Soviet Union complain that President Reagan was "warmongering" by choosing to attend the NATO meeting planned for June and not the opening session of the Special Session on disarmament of the United Nations Assembly, has now ducked the United States offer (or challenge) of a meeting on that occasion. Instead, the two men may now meet on neutral ground sometime in October. The delay

0028-0836/82/200169-02$01.00

is probably to be welcomed. It will give the US Administration a chance to put its act together, and the Soviet Union a chance to resolve the delicate problem of continuity in strategic arms negotiations during the period when Mr Brezhnev will be succeeded by somebody else. And the delay will also be a chance to decide how the negotiations now proposed should be linked with those formally under way, but almost stalled, on the limitation of nuclear weapons in Europe. The United States has always intended that the two processes should be merged, as it is sensible that they should be. For only then will President Reagan's "zero option" seem secure. By October, the Soviet Union should be ready to soften the negotiating position it has repeated since last November — that it will withdraw some of its mobile missiles if the United States will agree not to introduce the Pershing II and cruise missiles.

French new world?

France wants next month's economic summit to talk technology. It should not expect too much.

The summer now begun in the Northern Hemisphere will be metaphorically long and hot. Several important issues fall to be decided, or at least to be given an airing. Strategic arms control (see above) is one. The South Atlantic (where it will be winter) is another. Next month, there will also be the Special Session of the United Nations on Disarmament in New York. Before then, President Reagan will have made the rounds of several West European capitals and will have sat in on two crucial if lesser summit-meetings — one (in Bonn) of the North Atlantic Treaty Organization (NATO) and another (at Versailles) of the members of the sub-set of the Organization for Economic Cooperation and Development (OECD) considered to deserve a seat at gatherings where senior politicians contemplate the future of the world. President François Mitterrand of France, who will not be at Bonn because France does not belong to NATO, has characteristically done his best to ensure that the Versailles summit, under the wing of OECD, will be enlivening. He has hatched a plan that the economic summit should begin with a discussion of governments' responsibilities for the development of technology. If he were not the host, the *rentier* in the public cause of the splendid palace at which the meeting will take place, it is improbable that his subject would have reached the head of the agenda. But the subject cannot be the emollient of fellow feeling that he calculated it to be.

President Mitterrand may in retrospect be thought to have captured the allegiance of those who voted for him a year ago by his simplicity; he seems to believe in what he says. This phenomenal habit appears also to be the reason why he has also won the affection, even respect, of European politicians ideologically at odds with him. But President Mitterrand also believes in the future — a future fashioned by technology. Why else would he have given such encouragement to his buoyant colleague, M. Jean-Pierre Chevènement, minister for research and technology? Together, they appear to be convinced that the future of France can be assured by the intelligent direction and the generous support of research and development. They may well be right. But President Mitterrand is also now bent on propagating this hopeful message in a wider circle, among France's industrial partners and competitors. The objectives may again be admirable, but it is important that President Mitterrand should understand why his advocacy next month at Versailles of the case that science and technology are a means of making up for economic recession will cause many of those present to shuffle uneasily in their seats. For the French argument, while half right, is three-quarters wrong.

The case that science and technology are too much neglected by those who look for a way out of present economic troubles is, of course, beyond dispute. If the present recession is caused by the fivefold increase of the world price of petroleum in the past decade, then something like a ten per cent increase of productivity in the oil-consuming states would suffice to ensure that nobody would notice. That, of course, is well within the immediate grasp of people in research and development. And a fivefold increase of productivity, by no means out of court, would ensure that the cost of buying oil would at some point in the future seem as unimportant as in the early 1960s, but with the difference that average prosperity would be five times greater. So, by putting money into research and development, the governments of industrialized states can realistically hope to work their way towards a more stable world, one in which not merely their electors but the people who live elsewhere will have a sense of being better off. Would that President Mitterrand's colleagues at next month's meeting at Versailles more openly shared his view.

The weakness of the French case is that it is almost certain to be an exaggeration. For at least the past two decades, successive French governments have worked deliberately at the improvement of science and technology. And not before time. The old republic was uncongenial for research. President de Gaulle, concerned though he may have been with the paramountcy of the identity of France, and of its place in the world, nevertheless provided an opportunity for those who sought to remedy the earlier neglect of the universities and of research. It tends, however, to be forgotten that even the young turks who took up that challenge made several disastrous mistakes. While the development of the petrochemicals industry in the early 1960s was an immense success, a proof that technology can spell prosperity, the nuclear power industry of that time was swiftly overtaken by events (and by the superior designs put on offer by United States manufacturers) while the efforts of those early governments to build a domestic computer industry were no more successful than later attempts have been. The still new government of France has inherited a much stronger base for the conduct of research and development than any of its predecessors; the universities are mostly in good shape, as are the grant-making agencies. But the government seems not to have learned from the hard experience of earlier decades. Its political persuasions, indeed, tell it that it need not learn. Yet mistakes will happen, and governments are especially prone to them.

This is why the unexpected French agenda item for the Versailles summit meeting will not be the uncontentious matter that President Mitterrand seems to hope. While some among the governments of the United Kingdom, the United States and West Germany may have ideological reasons for believing that too much government intervention in the shaping of the pattern of technology is mistaken, each of them also has vivid illustrations of how such efforts can go wrong. Sir Harold Wilson's technological revolution (1974) is only the most memorable error. Even the Japanese experience is not the proof that sufficiently clever governments can act wisely that the French will be hoping to claim at Versailles. For while the Tokyo government's support of successful manufacturers is the envy of manufacturers elsewhere (and properly a cause for complaint by luckless importers in other countries), nobody suggests that the government of Japan plans in advance whether next year's wonder product will be a new hi-fi set or a new space invaders game. The principle seems to be that the market will define what technology should do — if the market is given half a chance.

The French, in their present mood, are unconvinced. And it is certainly the case that if President Mitterrand could win the agreement of other industrialized nations to some coordinated plan for the development of technology, it would be possible to create both rising prosperity and a proof that the technological prophecy had come true. The agreement will not be forthcoming, but the proof would in any case be false. For to ordinary people, governments' electors, what matters about technology is not that it should be successful but that it should be wanted. Even the belief (to which the French government holds) that science and technology should be harnessed to the needs of development overseas is likely to run foul of the now well-established truth that developing countries do not like being told what is good for them. Sooner or later, Frenchmen will come to hold the same opinion if President Mitterrand pushes his view of the management of technology down their throats.

US sours on foreign graduates

Job prospects clouded by immigration bill

Washington

US high technology industries and scientific organizations are just waking up to a little-noted, devastating change in US immigration laws which, if enacted, could change the face of Silicon Valley and university engineering faculties. The proposed change would prohibit foreign students from taking jobs in the United States on graduation. Instead, they would have to go home for two years before they could apply to work in the United States.

Under present law, they may apply for a change in visa status without leaving the country, and often do so.

The new provision may well become law before Congress adjourns. Identically worded provisions are in both the House and Senate versions of the bill. Neither has yet emerged from committee, but the provisions are unlikely to change before Congress acts.

Nobody knows how many students would be affected partly because many are either in the country illegally or do not report their work status.

At Stanford, for example, 50 per cent of all students studying for a PhD degree are foreign. Nationally, in 1980, 20.4 per cent of all science and engineering graduate students were foreign. In engineering, one-third of all PhD recipients are not US citizens. Engineering is the most popular field for the 311,000 foreign students, graduate and undergraduate, estimated to be in the United States (see Table).

Civilian high technology companies have come to rely increasingly on newly qualified engineers and scientists who are not US citizens, says Pat Hubbard of the American Electronics Association, because the US defence build-up has caused defence industries to hive off many of the American graduates. William Cagney of the National Foreign Trade Council which represents 650 major companies adds: "When DuPont goes looking for a PhD in chemical engineering, it more often than not hires a foreigner; there simply aren't that many Americans to go around. These people are vital to US industry." Both trade groups are opposing the proposed change in the law, as is the Semiconductor Industry Association, representing many Silicon Valley firms.

The provision in question is Section 212 of a bill that changes the Immigration and Nationality Act, the umbrella law that governs US immigration policies. Reform of the act has long been a public issue in the United States, where many thousands of Mexicans cross the southern border to work on ranches, illegally, and where the plight of the Cuban and Haitian refugees drew world attention to the problems of assimilating still more people from abroad. A blue-ribbon study was made by the Select Commission on Immigration, headed by Father Theodore Hesbergh of Notre Dame. The Reagan Administration proposed its own views of how to tighten US immigration laws, but the bill that has received the most support is that proposed by Romano L. Mazzoli (Democrat, Kentucky) in the House and Alan K. Simpson (Republican, Wyoming) in Senate. That part of the bill involving foreign students did not appear in Father Hesbergh's recommendations nor in the Administration bill, and so went unnoticed until a few weeks ago.

At present, most foreign students in the United States have visas allowing them to stay as long as they are studying, but they are not allowed to work. On graduation, they may apply for permanent resident status — a step towards citizenship — if they have a job offer. They usually remain in the United States (working) until this change occurs. A minority of foreign students are in the United States on so-called J visas, having been sent by their government or on exchange programmes, and they must return home on completion of their studies. Under Section 212, all students would have the equivalent of J status.

A House staff member explained that far

Setback for Chevènement

The second constitutional airing of the prospective science and technology bill (*loi*), on which the French science boom depends, has led to a bloodbath. For the Senate, the conservative French upper house, last week voted amendments which amputate most of its effective clauses.

The law, in the tattered form approved by the Senate, will now go to the National Assembly (the lower house), probably in June. Although the government has the majority there, the law will have to go through a lengthy process in which clauses deleted by Senate are reintroduced as amendments, adding to an already packed parliamentary session.

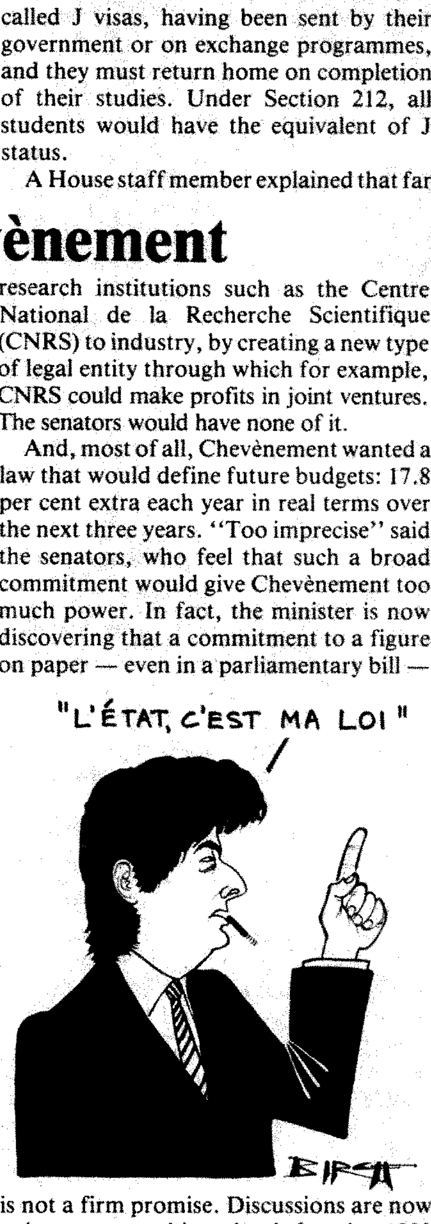
The Senate is an indirectly elected body, a third of its members being appointed each year on the basis of regional (departmental) elections. Electors consist of mayors and other such dignitaries, and amount to some 500 from each department. The Senate remains firmly conservative despite last year's election of the socialist Mitterrand government, and so is a source of constant irritation. But this is the first time it has behaved quite as badly towards government legislation.

The government explanation is that the science and technology bill gave the opposition an excellent opportunity to put a major dent in the plans of a senior minister, Jean-Pierre Chevènement, who is also the leader of the most left-wing element of the socialist party, the Ceres group. Ceres is of an intellectual and loosely Marxist tendency, and a favourite target of the conservatives. The fact that science and technology were involved in the Senate debacle is incidental.

Chevènement wished to devolve power to the regions, setting up regional councils for science and technology with their own budgets. The senators wished to "put off" that reform.

Chevènement wanted to open up research institutions such as the Centre National de la Recherche Scientifique (CNRS) to industry, by creating a new type of legal entity through which for example, CNRS could make profits in joint ventures. The senators would have none of it.

And, most of all, Chevènement wanted a law that would define future budgets: 17.8 per cent extra each year in real terms over the next three years. "Too imprecise" said the senators, who feel that such a broad commitment would give Chevènement too much power. In fact, the minister is now discovering that a commitment to a figure on paper — even in a parliamentary bill —



is not a firm promise. Discussions are now going on at cabinet level for the 1983 budget, and Chevènement is having to fight as hard this year as he did last.

Chevènement was impatient with the Senate's reaction to his well-laid plans. He described the Senate majority as "reactionary" and "cut off from the people". But he now faces a long struggle against the conservatives and against those of his cabinet colleagues who resent his scientific imperialism. **Robert Walgate**

0028-0836/82/200171-02$01.00

too many foreigners arrive in the United States saying they are going to study, but really plan to stay afterwards and work. This is a "backdoor immigration policy", he said, which must be reformed as part of a general tightening of US immigration.

The provision may have originated with an engineering activist, Irwin Feerst. Feerst says there was no consideration of a change in the old law regarding students, until he sent out a special issue of an independent newsletter he publishes to engineers around the country. Three hundred responses he received, he says, indicated that professional US engineers want to "throw the foreign students out". Feerst spoke to Senator Simpson and testified to this effect in December. According to Feerst, there is no shortage of engineers in the United States, only a "cabal" of academic engineers and corporate executives who are publicizing the alleged shortage so they can hire foreign graduates at lower pay.

Nationality of foreign students in the United States 1980–81

Regions	Selected sub-totals	Totals
Africa		38,180
Nigeria	17,350	
Europe		25,330
UK	4,440	
Greece	3,750	
FRG	3,310	
France	2,570	
Eastern Europe + USSR	1,670	
Latin America		49,810
Middle East		84,710
Iran	47,550	
Saudi Arabia	10,440	
North America		14,790
Oceania		4,180
South and East Asia		94,640
Taiwan	19,460	
Japan	13,500	
India	9,250	
		311,640

Source: Institute of International Education

However, the Institute of Electrical and Electronic Engineers (IEEE), the engineers' umbrella society in the United States (where Feerst has often run as an "alternative" candidate for president) does not favour the change in Section 212 as it is now written. Richard J. Gowen, chairman of IEEE's manpower task force and a candidate for president of IEEE, says that foreign engineers are being offered jobs at salaries that may be as little as 25 per cent of the salaries paid to US-born engineers. Gowen wants the proposed Section 212 to be changed to allow only "professional" hiring of foreign graduates. That is, a foreign graduate would have to go home unless his prospective employer certifies that he will be paid at least 75 per cent of what a US citizen would be paid in the job.

So far, Congress has been mainly concerned with getting the immigration reform bill through, and seems little disposed to tinker with the minor provisions. On the other hand, organizations like IEEE are becoming very active on the issue, as they begin to realize its implications. **Deborah Shapley**

EEC budget

Windfall ahead

Brussels

An unexpected shortfall of £280 million (500 million European Currency Units) in the European Economic Community's agricultural expenditure has resulted in an extra £19.6 million (35 million ECUs) becoming available for the European Community's research programmes in 1982. The strength of the dollar, favourable prices on the world market for agricultural goods and good weather have all helped to reduce the EEC's agricultural subsidies. Most of the extra money will be allocated to the joint research centres and in particular to nuclear safety research, but around £3.7 million will go to the indirect action programmes.

The budgetary revision highlights the degree to which the European Commission's ability to meet its goal of revitalizing scientific research and development in Europe, and thus create new jobs for scientists, is linked with the long-standing quarrel over agricultural prices, the British budgetary contribution, the reform of the Community's budget and the Common Agricultural Policy and even the Falklands crisis. If an agreement could be reached on lower agricultural prices for this year, as the British are demanding, an even greater sum could be set free for other areas of expenditure. The cooperation shown by the other member states over the Falklands crisis has now made it more difficult for Britain to push for budgetary reform. But if Britain achieves its objectives in the Council meetings this week, not only will its contributions be reduced, but it should lead to greater Community outlays in other areas including research.

The Commission's preliminary draft budget for 1983 reflects the hope that the other nine member states will agree to shift the emphasis of Community spending. Thus, the text emphasizes a "significant reinforcement of financial resources for energy policy, innovation and research and development". This includes increasing expenditure on energy research by 120 per cent although the total sum for payment appropriations will still be small, at £58.4 million.

Most of the extra money for this year will go towards the Supersara project on reactor safety at the joint research centre at Ispra in Italy. An extra £4.2 million will be needed this year as the project is overshooting its budget and will probably continue doing so until 1990 to the tune of £168 million.

The entire programme for the joint research centres is, in fact, now being reviewed and some changes are certain to be reflected in the 1984–87 research programme. Under consideration is a temporary increase in staff by 161, to provide replacements for scientists expected to retire in the next few years. Apart from streamlining research on nuclear safety, the handling of radioactive wastes and the control of fissile materials, a new institute for developing countries is planned at Ispra for training in energy planning, new energies, remote sensing techniques and the inventoring of resources. The Commission is also hoping to increase staff for research into solar energy, fusion, the rational use of energy and the study of high temperature materials.

Again, the success of these proposals will depend on the attitude of the member states, who will be influenced by the amount of money in the budget left over after provisions have been made for agricultural subsidies. **Jasper Becker**

Polish arrest

Expel and detain

The expulsion from Poland, last week, of two US diplomats and the arrest of Dr Ryszard Herczynski bodes ill for the resumption of normal academic exchanges between Poland and the West. The two diplomats, Scientific Attaché John William Zerolis and First Secretary for Cultural Affairs, James Daniel Howard, found in Dr Herczynski's flat, were accused by the Polish ministry of foreign affairs of "pursuing activity conflicting with their diplomatic status". Their presence in the flat appears, however, to have been entirely in the line of duty; they had gone there to confer with Dr Herczynski and with Professor Wladyslaw Fiszdon, a former pro-rector of Warsaw University, on the forthcoming joint US–Polish symposium on fluid mechanics.

Dr Herczynski, a mathematician specializing in fluid dynamics, is employed at the Polish Academy of Sciences' Institute for Fundamental Problems of Technology. Although now accused of having been "one of the inspirers of activity contrary to our *raison d'être* in the scientific milieu", he has never been associated with the dissident movement. In autumn 1980, however, he founded the "Society of the friends of science" — a semi-popular organization based on the then current principles of the liberalization of learning.

It was presumably for this reason that, during the night of 12–13 December 1981, he was taken into custody and interned for some two weeks. Although the authorities now claim that before being released, he signed an undertaking to cease such activities, Dr Herczynski's friends insist that not only did he never sign such an undertaking, but that at the time of his release there had been no mention of any such document.

The arrest of Dr Herczynski was, according to official sources, effected as he handed Mr Zerolis a packet of material "damaging to the interests of the Polish People's Republic", apparently com-

0028-0836/82/200172-02$01.00

prising a personal letter to his son, at present studying in the United States, an unidentified leaflet and an anonymous "Code of conduct during this testing time" addressed to Polish academics. Dr Herczynski now faces trial before a summary court. **Vera Rich**

NATO civil research

More wanted

Applicants for NATO (North Atlantic Treaty Organization) fellowships will have less chance of success this year than ever before. Applications have risen by 30 per cent, while the number of fellowships (about 800) remains constant. The NATO science committee will have to apply "new criteria" to make selections, a spokesman said last week. One possibility is that group applicants will be favoured over individuals.

NATO staff pinpoint four reasons for the increase in applications — financial difficulties among the 15 member countries, an increase in the number of papers now citing NATO as a supporting agency, a deliberate "willingness" on the part of NATO to expand the programme and a policy of greater visibility, including advertising in *Nature*.

The willingess to expand, however, is restricted to the NATO Science Committee, headed by Frenchman Professor Robert Chabbal (at present NATO's Assistant Secretary-General for Scientific and Environmental Affairs). The Civil Budget Committee, from which Chabbal draws his funds, is not so willing. To cope with the increase in applications for fellowships and for summer-school sponsorship, and for increased travel costs, the committee would have to increase its budget next year by 25–30 per cent in real terms, to $23–24 million. In fact, it may be lucky to get 15 per cent extra, just enough to cover the depreciation of the Belgian franc.

Pressing his case, Chabbal claimed last week that the NATO civil science programme (which completely avoids military research) is substantial and important. It accounts for half of all summer-school and training fellowships. Schools such as the Ettore Majorana at Erice, Sicily, and Les Houches in the Alps, get 60 per cent of their money from NATO, said Chabbal.

Meanwhile the committee will press ahead with new plans. It runs advisory panels which help to provide seed money for communications in new fields, largely by establishing "advanced workshops", and this year it will create two new panels: one on global transport mechanisms (in the atmosphere, ocean and mantle) and one on the selective activation of molecules (for example by laser). These panels would be expected to launch six workshops a year for a maximum of five years.

The committee is also experimenting with links between an industry in one country and a university in another, in a programme dubbed the "double jump". Finance will be *à la carte* — only interested countries need support it. So far only two such fellowships have been organized, but many more are planned — Dr Mario di Lullo, organizer of the "double jump" programme, believes that it will not run into the protectionist difficulties that sometimes face the European Commission — that one nation's industry does not reveal its secrets to nationals of another. **Robert Walgate**

British biotechnology

Out of the blue

In an unusual move, the British University Grants Committee is earmarking part of its annual budget to develop a specific topic — biotechnology. The committee plans that £800,000 will be spent in each of the next three academic years on fostering biotechnology in a handful of universities. The committee had previously been reluctant to earmark grants, preferring that universities should spend their income as they wished, relying on the research councils to encourage centres in particular topics by means of research grants.

The scale of the recent budget cuts seems to have prompted a change of heart. The committee, worried that universities may pare all their activities rather than cut them selectively, clearly hopes that earmarked grants will make the future pattern of university research more pointed. The £800,000 set aside for biotechnology will be taken from the money reserved for restructuring the reduced university system which in the next academic year (1982–83) will be £50 million. Most of that sum is expected to be spent on payments to redundant academics, leaving uncertain the amount available for fostering priorities.

So far, three centres — at University College London, the University of Birmingham and the University of Manchester Institute of Science and Technology — have been awarded annual grants of £100,000 each to develop biotechnology. Five other centres are expected to receive similar grants soon. The money will be paid as a separate item in each of the next three years, after which it will be incorporated in the recipients' recurrent grants.

The grants committee says that the recipients must decide for themselves how to spend their extra money. Nevertheless, it expects them to forge closer links with industry, chiefly by encouraging the process engineering side of biotechnology, to develop postgraduate rather than undergraduate courses and to appoint some permanent staff, thus fulfilling the recommendation of a Royal Society report which nearly two years ago called for twenty more university posts in biotechnology.

The research councils welcome the new grants, seeing no conflict between the grants committee's assessment of priority and their own. The Science and Engineering Research Council, in particular, welcomes the grants as a way of supporting staff and equipment which could not be paid for out of its research awards. **Judy Redfearn**

Development and drugs

More not less

The latest shot in the long-running battle between the pharmaceuticals industry and its detractors, in which the health problems of developing countries provide the battleground, has been fired by the Office of Health Economics (OHE). Despite its governmental sounding title and Whitehall address, the office is sponsored by the UK pharmaceuticals industry and its main task is to carry out research on the economic aspects of medical care. Its latest contribution, *Medicines, Health and the Poor World* by David Taylor, is a response to recent criticisms of the industry's marketing practices.

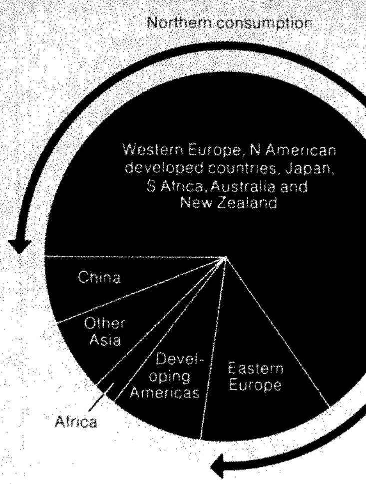
The large multinational companies have been accused of over-aggressively selling unsuitable drugs in the developing countries, leading to only a minimal improvement in the health of the population and sometimes proving positively harmful. Chief among the industry's critics have been aid organizations such as Oxfam and War on Want and the pressure group Social Audit.

The report acknowledges that some drugs have been "inappropriately" sold in the past but claims that the industry itself is now more capable of policing its methods of promotion and that the important role of drugs in improving health care in developing nations may be obscured by concentration on abuse in some areas.

Although a typical poor nation may spend around a quarter of its central government health budget on pharmaceuticals, the report says, 60–70 per cent of the people do not have regular access even to the most basic drugs. So while it is important that those drugs now being sold to the "wealthier" members of developing societies are properly advertised and correctly used, it is even more important to find ways of getting the basic drugs to the mass of the population deprived of them. Whether the past performance of the multinational companies has contributed to the weaknesses of governmental health services in the developing countries, or whether the unavoidable difficulties have limited the ability of the drug companies to act effectively, remains a point of conflict.

Better distribution of a limited range of medicines and vaccines, together with research aimed specifically at new pharmaceuticals for the developing world, are the urgent needs, says OHE. The World

0028-0836/82/200173-02$01.00



World pharmaceutical consumption for 1980 (total $76,000 million, manufacturer's prices.

Health Organization (WHO) has put considerable effort into work on new medicines and vaccines for diseases such as malaria, onchocerciasis, leprosy and leishmaniasis, but the report argues that the commercial companies cannot take on work on new drugs for these diseases because of the harsh economic realities of the marketplace — the return from sales of "Third World-oriented" drugs would not cover the cost of their development.

Thus OHE argues that the major drug companies should be used as contractors by WHO and governments to carry out the expensive first stages of developing drugs for diseases in developing countries. It is argued that this approach would be the most cost-effective way for the developed nations to help the poorer nations achieve better health standards.

To put the expenditure involved in finding new drugs into context, the total research and development spending by the UK pharmaceuticals industry is around £300 million per year, compared with the £1,000 million spent annually by the UK government on overseas aid. So an increase of just 5 per cent in this aid budget would provide £50 million, which if spent on contracted research could support a significant effort to find drugs important to developing countries.

On the supply of existing medicines to the developing countries, the OHE report is critical of the WHO programme on "essential" drugs. As for policing the marketing and advertising methods used to promote drugs in the Third World, OHE sees the international code of marketing practice drawn up recently by the International Federation of Pharmaceutical Manufacturing Associations as the best hope for the future. The federation, it is argued, would be well able to regulate the activities of the major international companies because it is in the companies' interest to be seen to be acting responsibly throughout the world. WHO is seen by the industry as being open to political pressures and therefore ineffectual as a controlling body.

Charles Wenz

US weather and ocean research

Outlook bleak

Washington

The major controversy in Washington this week has been the fate of the federal budget, as congressional leaders and the President joust with each other, leaving the outcome in doubt. No less concerned are the atmospheric scientists and oceanographers, especially those involved in international programmes, many of which have been cut back in the President's proposed budget. Ocean and atmospheric research has always had friends in Congress, and they are trying to have the funds restored. But whether the money can be put back, and then retained in a final budget package, is in doubt.

Marked for the axe are funds for joint US–Canadian efforts to clean up the Great Lakes, half of the satellite capability that provides weather data to nations in Asia, Africa and South America, funds to study and prevent ocean dumping (including radioactive waste), and the World Climate Program, the successor to the Global Atmospheric Research Program, which is a major international effort run from Geneva.

The Canadian government has been very upset about the proposed cut-back in US efforts to help study, monitor and clean up the Great Lakes, to which the US government is committed under several agreements with Canada. Under the proposed Reagan budget, two laboratories would be closed down and one programme office severely curtailed.

One laboratory is run by the Environmental Protection Agency (EPA) at Grosse Ile, Michigan, near Detroit. The other is run by the National Oceanic and Atmospheric Administration (NOAA) at Ann Arbor, Michigan.

The Administration justifies the cuts by claiming that most of the research needed to identify Great Lakes pollution has been done, and that cleaning up is a responsibility of the states that border them.

But the Canadian government's view is that still more pollution problems are being unearthed, such as the identification and reduction of such toxic substances as mirex and dioxin which have recently been found in "hot spots" in all the lakes except Lake Superior, and that the international commitments are federal, not state, issues. According to one Canadian official the cuts amount to "an attempt by the United States to renege on its water quality agreement of 1978" with Canada. This is strong language, given the historical close cooperation between the two countries — at least until the advent of the acid rain dispute and the Great Lakes budget cuts.

The Administration also wants to cut NOAA funds for ocean dumping research and marine pollution generally. NOAA runs most of the government's research in this area. The work concentrates on the area off the north-east coast of the United States which has the worst pollution problem, a major fishing ground and possible oil development. The rationale for the cut is that northeastern states should individually bear these costs. Congressmen seeking to restore the funds argue that these are national problems, especially in the light of renewed talk of disposing of radioactive and other forms of waste in the oceans.

For the second year in a row, the Administration has tried virtually to eliminate one of the ocean research programmes most popular on university campuses in the United States, the $35 million per year Sea Grant programme. For 1983, the Administration proposes only $1.7 million. However, as in 1982, representatives and senators are expected to get the funds restored. About half of the Sea Grant funds go for research, and the other half for community services related to the oceans issue.

The proposed Administration budget would also cut $6 million of the $7 million going to weather modification research, as part of a 40 per cent cut in atmospheric research funds. Likewise, a programme to upgrade the old weather radars on which continental US weather forecasting relies heavily is being slowed drastically. The Administration contends that weather is a local issue. Friends of NOAA counter, however, that weather modification and atmospheric research are important basic research programmes.

Of worldwide interest is a cut of $24 million that would decrease the launch rate of the NOAA series of polar-orbiting weather satellites, so that there would be one instead of two in orbit at any given time. These satellites complement the existing two GEOS geosynchronous satellites that provide "side views" of the Earth's weather, including the familiar television-screen images, to many countries that have receivers.

Representative James H. Scheuer, chairman of the House Science and Technology Committee's subcommittee on natural resources, agriculture research and environment, is trying to get the second NOAA satellite restored.

Scheuer argues that while the geosynchronous satellites indicate current weather, mostly in the middle and lower latitudes, the polar-orbiting satellites are essential to forecasting worldwide. Only they can acquire the quantitative data needed for modelling the Earth's weather, and only they can track the Arctic and Antarctic air masses moving towards the inhabited regions. The NOAA series satellites are thus crucial to weather prediction in parts of the world, such as Asia, Africa and Australia, that other satellites do not "look at" as often as at North America and Europe.

Two satellites provide twice as many passes over a region as one, and so improve

0028-0836/82/200174-02$01.00

daily forecasting. Two satellites also provide for redundancy. Scheuer says the Administration's cut will reduce the timeliness of forecasting and leave those parts of the world that are "neglected" by the rest of the system without any weather information at all when the remaining satellite breaks down — which happens often enough. Sometimes it takes a year to put a replacement for a broken satellite in orbit.

Finally, funds for the US contribution to the World Climate Program, a major international climatological effort run in cooperation with the World Meteorological Organization, have been cut from $1.8 million to $0.5 million.

Deborah Shapley

Lead in petrol

Clear risks

The British anti-lead lobby is flying high. Results now emerging from recent studies seem to be persuading scientific and medical opinion that the government should take further action on the lead content of petrol. Total elimination was advocated by many of the participants at an international conference organized last week by the Campaign for Lead Free Air (CLEAR).

Local councillors, civil servants and scientists from several countries heard evidence that children's IQ is impaired by low blood lead levels and that a significant contributor to lead burden is the lead in petrol. Des Wilson, chairman of CLEAR, is confident that the conference was given conclusive evidence that the position of the government is becoming increasingly isolated and untenable. The Lawther report, he said, had been completely discredited.

In 1980 a working party under the chairmanship of Professor P.J. Lawther advised that the evidence on danger from low blood lead levels was inconclusive. The Lawther working party also recommended that most effort be directed to reducing the lead in food and water, on the grounds that lead in petrol did not make the most significant contribution to the body lead burden.

The fear that blood lead concentrations of 300 $\mu g\ l^{-1}$ and below may have neurological effects represents a gradual shift of opinion over the past two years. The official government position is that harmful effects do not occur below 350 $\mu g\ l^{-1}$. The change of heart by the government which resulted in the decision last year to cut the legal amount of lead in petrol from 0.4 mg per litre to 0.15 mg per litre was in keeping with the Lawther case for a progressive reduction. Professor Lawther now says that the elimination of lead in petrol did not conflict with the findings of his working party and that "if there were damn all, nobody would be happier than me".

While there is no dispute about the toxic effects of lead at high levels, controversy persists about the level at which harmful effects occur. After the Lawther working party reported, two members, Dr Richard Lansdown and Dr William Yule of the Institute of Psychiatry and Great Ormond Street Hospital for Sick Children, produced results suggesting a link between blood lead levels and IQ performance in children of the London suburb of Greenwich and claimed a significant difference of IQ performance with blood lead above and below 120 $\mu g\ l^{-1}$ (*Devl Med. Child Neurol.* **23**, 567-576; 1981).

At last week's symposium, Yule and Lansdown gave new evidence (as yet unpublished) that children's behaviour is related to blood lead levels — 19 per cent of those with blood lead levels above the average (120 $\mu g\ l^{-1}$) were overactive compared with only 4.9 per cent of those with blood lead levels below the average. Bad conduct, nervous tension and lack of concentration increased with higher blood lead levels. Professor Herbert Needleman (Children's Hospital, Pittsburgh) also reported an association between classroom behaviour, IQ performance and lead burden.

Others say, however, that there should be extreme caution in moving from an observation of correlation between childhood lead exposure and impairment of intellectual development to postulating lead as the cause of extreme behavioural and psychological damage. The social environment is an extremely important factor in IQ performance.

The conference was also told of the significant contribution of lead in petrol to lead burden, making the Lawther estimate of 10 per cent seem too low. One recently completed study by the EEC Joint Research Centre at Ispra, Italy, suggests that as much as 30 per cent of the lead in blood is derived from petrol. The study determined the contribution of lead from petrol by relying on the known abnormal isotopic composition of lead in the petrol in one region of Italy. The conference also heard that in the United States in the four years since the phasing out of lead in petrol (1976–80), blood lead levels had fallen by 36.7 per cent. Dr Clair Patterson (California Institute of Technology) said that "exhausts from leaded gasolines are the most serious sources of lead in people".

While opinion is still divided and the need for further research acknowledged, Professor Michael Rutter (Institute of Psychiatry, London), a member of the Lawther committee, came down firmly in favour of the elimination of lead from petrol: "the level of probability is such that I think it is worth acting on".

CLEAR moves confidently into battle having already captured the support of the Labour party. The National Executive Committee pledged last month that a future Labour government would eliminate lead in petrol. CLEAR's sights are now set on the party conferences where it is confident of rallying support from the other opposition parties.

While much of the new evidence is not yet published, the Royal Commission on Environmental Pollution has now also launched an investigation into lead. It has heard evidence from the British Medical Association (BMA) supporting the link between low blood lead levels and impaired mental function. The BMA also appears to be convinced by the Ispra study.

The Royal Commission plans to investigate the sources of lead in the environment and its pathways to man. The commission also plans to "get to the bottom" of arguments about the technical and economic implications of reducing lead in petrol below that promised by the government last year. The commission may be confronted with strongly held opinions — Des Wilson described Associated Octel, the British company owned by Shell, BP, Chevron, Mobil and Texaco, which supplies the lead for petrol, as "the biggest mass child poisoners in the world today".

The oil companies say, however, that they will cooperate with the government if it calls for a ban on lead in petrol. The buck has now been passed.

Jane Wynn

Enter Exxon

New York

Cold Spring Harbor Laboratory on Long Island, New York, has agreed to a five-year "cooperative research agreement" with Exxon Research and Engineering Company. However, the financial terms of the deal are not being disclosed by Exxon, which is making its debut into the overcrowded world of biotechnology.

Under the terms of the agreement, up to six Exxon scientists will be assimilated into the Cold Spring Harbor staff to work full time on mutually agreed projects. In return, Cold Spring Harbor will select six postdoctoral fellows to participate in Exxon-funded research. In addition, Exxon's biosciences laboratory in New Jersey (which has never worked on molecular biology) may consult Cold Spring Harbor on various matters.

Exxon plans that its lawyers will visit the Cold Spring Harbor Laboratory regularly to keep abreast of latest developments. It will have exclusive rights to all patents derived from the research it funds, while Cold Spring Harbor Laboratory will retain rights to patents derived from work done by staff members not associated with Exxon projects.

Exxon will not ask those working on its Cold Spring Harbor Laboratory projects to defer publication of patentable inventions, as some industrial sponsors have requested of academic institutions relying on their funds.

0028-0836/82/200175-01$01.00

CORRESPONDENCE

Scientists who act

SIR — Sir Peter Medawar's review of Martin Gardner's book "Science: Good, Bad and Bogus" (*Nature* 28 January, p.351), criticizes people working in fringe science, scientists who step aside from their specialisms to apply their experience in other areas and the inexperienced whose opinions force them into a corner where they grimly hold on to their untenable theories. He paints a broad canvas of condemnation and thereby implies that most speculation is put forward by rogues motivated by profit or starved of recognition and that we on the receiving end are unable to distinguish between the possible, probable and downright foolish.

Sir Peter's attack questions the integrity of scientists whose imaginative speculations, right or wrong, stimulate action that eventually leads to the truth. He makes use of the reference to unnamed people — the astronomer, microbiologists — without stating his objections. Above all, Sir Peter forgets that absence of proof is not proof of absence. Truth prevails eventually and the speculations and experiments that lead to it are winnowed by time.

Sir Peter's preoccupation with the intellectual underworld does disservice to those who think as well as labour in their laboratories. Also to those who in these difficult times are without laboratories and who have only their thoughts to offer to the service of human understanding.

D.G. APPLIN

Leystonstone,

Doves in false garb

SIR — The leading article "Doves in false garb" (*Nature* 18 February, p.542) asks "What other justification is there for the Medical Campaign against Nuclear War except that physicians prefer hobnobbing with other physicians than with the hoi polloi?" This is a cheap shot unworthy of *Nature*. Let us hear some specific criticism of the physicians' proposals, let us hear some refutation of the plentiful justifications offered for the campaign by the physicians, but let us not hear "Nyah, nyah, nyah."

As the present American government considers a nuclear war ever more wageable and winnable, physicians must also begin ever more often to picture themselves crawling about on radioactive heaps attempting to dispense medicine in the aftermath of victory. The hope for curing anybody is less than small. Physicians claim that a nuclear war is a terminal disease for entire nations. When a doctor helps us to not catch a disease this is called preventative medicine. Such help is not only legitimate for a doctor to offer but may be felt required by the Hippocratic oath. Physicians involved in the aforementioned campaign are doing what they perceive is their duty to keep their patients alive. Does *Nature* doubt this prognosis? Do you share the opinion of the Federal Emergency Management Agency to the effect that society (at least that of the United States) will totally recover from a full-scale nuclear war within two to four years?

Nature concludes this commentary with the suggestion that if physicians, or any other professional group's members, seek to influence policy they should become members of parliament. This suggestion is nonsense. It is precisely because physicians are not politicians that they may help bring significant arms control into being. In past comment (*Nature* **294**, 197; **295**, 270) *Nature* has both stated the evident desirability of serious arms control negotiations and depicted the bumbling attempts of (US) politicians to initiate them. Atomic and hydrogen bombs now proliferate faster than ever before and members of parliament *et al.* have been as yet unable to inhibit this malignant growth. To stop and reverse the arms race will require the efforts of people in all walks of life acting in ways often without precedent, often compelled by personal, moral feeling.

Nature owes the living minds of its readers mature and honest evaluations of proposals from any campaign against nuclear war.

Mutualistic lives

SIR — In his News and Views article, "Mutualism: New Ecological Theories", May[1] asserts that ". . . conspicuous mutualistic associations tend to be tropical ones". May I suggest that conspicuousness is in the eye of the beholder? All the examples he cites involve animals. From ericaceous heaths of arctic–alpine regions, through vast acreages of boreal forest and temperate grasslands to tropical rain forests, the structure of the plant communities is governed, to those with the eye for them, by the conspicuous associations between plants and their mutualistic mycorrhizal fungi (see, for example, refs 2–6).

Mutualistic associations between plants and nitrogen-fixing prokaryotes and lichens are also important in tropical and non-tropical, especially sub-arctic, zones[7,8]. Harley[9,10], myself[11] and others have bemoaned the slow recognition by taxonomists and ecologists of the importance of mutualistic fungi and bacteria to plants in all terrestrial ecosystems. Let us hope that another of May's assertions[1] — that empirical and theoretical studies of mutualistic associations are likely to be one of the growth industries of the 1980s — will be world-wide and encompass interactions between all five kingdoms of organisms[12].

Kin to whom?

SIR — Kin selection is not normally used by students of mammalian social evolution to explain the sociobiology of a particular class[1,2]. Contrary to the assertions by Packer and Pusey (*Nature* 22 April, p.740), Boorman and Levitt[3] (p.250) derived the conclusion that "attempts to apply $k > (1/r)$ directly to the analysis of primate, carnivore or other mammalian societies should be evaluated very cautiously" from their thorough review of the literature on mammals.

Students of vertebrate social systems have recognized the importance of the "multi-male" group, selection for outbreeding, and reciprocal associations between unrelated males for social evolution in the mammals, and the implications of these classical features for the genetic and phenotypic structures of mammalian, including human, populations have been discussed[1,4-9]. It is the persistence of these features that leads some primatologists to conclude that macaques and baboons, rather than gorillas or chimpanzees, are the richest models extant of hominid evolution[10,11]. Further, numerous "theoretical analyses" have pointed out that "inclusive-fitness maximizing" and kin selection are not equivalent and that under certain competitive regimes, kin may be "ego's" worst enemies[12-14]. Packer and Pusey's appreciation that individual reproductive "games" may not often be explained by kin selection for the mammals follows from the literature on behaviour and social evolution in that class.

NEWS AND VIEWS

The garden path

from Beverly Griffin

PERHAPS *Pilgrim's Progress* should after long neglect once again take its place on the literary scene, as required reading for today's molecular and cell biologists, and immunologists, instructing us to tread warily into the unknown, encumbered as it is with the snares, crevices and hidden dangers afforded by our modern technology. Not that there is anything sinister in the technology itself. Rather, we understand it too little and often use it too glibly. With due apologies to a distinguished group of scientists, I wish to quote a sentence from one of their papers to illustrate my point: "These results unequivocally demonstrate that chicken DNA contains nucleotide sequences related to (the) transforming gene of Y73 and that these endogenous DNA sequences . . . are different from the endogenous *sarc* related to *src* of RSV and do not correspond to any endogenous viral sequences"[1]. (Both Y73 and RSV, Rous sarcoma virus, are RNA viruses capable of inducing fibrosarcomas in chickens, and their transforming genes are designated *yes* and *src* respectively.)

The data that indicated *yes* and *src* as being structurally unrelated were based on nucleic acid hybridization analyses in conditions that would generally be described as 'medium stringency'. They were said to "unequivocally demonstrate" and were no doubt correct, but nonetheless led to incorrect conclusions, as now shown in an article in this issue of *Nature* (p.205) by N. Kitamura and some of the authors of the above mentioned paper.

Kitamura *et al.* have sequenced the *yes* gene of Y73 and compared it with a (revised) sequence of *src*. Overall, the homology is about 70 per cent; but they find that, at the nucleotide level, the longest homologous stretch is only 17 residues, which explains why in the conditions used[1], no hybridization was previously observed. A great many of the non-homologies, however, prove to be third base changes, so the encoded protein structures are remarkably similar, allowing the authors to suggest that these two transforming viral genes were probably derived from a common prototype sequence. The two protein sequences, although differing at the N- and C-termini, are almost indistinguishable over about 80 per cent of their length. Notably retained is a polypeptide stretch of over fifty amino acids containing the phosphorylated tyrosine residue that now appears to be a common feature of transforming genes of both RNA and DNA viruses.

In this context, another interesting paper by Stoner and Schlief[2] questions whether the amino acid, but not the nucleotide, sequences of the *araC* genes in two strains of *Escherichia coli* have been conserved. Again, the data point to third base changes which would prevent hybridization but retain protein structure. Returning to the viral model, one can ask whether all the transforming genes of the class of viruses called retroviruses, when subjected to the same degree of scrutiny, might not prove to be similarly related. Take the *fps* gene in Fujinami virus (FSV), for example. Hanafusa *et al.*[3] state that "the results described convincingly exclude the presence of RSV-related *src* gene in the genome of FSV. The lack of *src* was shown by oligonucleotide fingerprinting, molecular hybridization and immunoprecipitation with antiserum to the *src* gene product". The question now arises, will these techniques survive the nucleotide sequence test, or have they, in this instance, proved false in the hands of undeniably eminent scientists? At this stage, the possible relationship between viral transforming genes and oncogenes[4,5] or that between the transforming genes of RNA and DNA tumour viruses seems a matter of conjecture. The question has to be raised of how much confidence one can put in negative data. With all the enthusiastic computing going on at many terminals, can a program be devised that will allow the accuracy of sequence relationships to be estimated, particularly with respect to hybridization?

Before this becomes possible, one presumably needs to understand what hybridization measures. Is it, for example, 90 per cent hydrogen bonding (G-C carrying more weight than A-T) and 10 per cent pi-electron interaction (purine–purine interactions more significant than pyrimidine–pyrimidine)? What effect does the location of imperfections in homologies have on the hybridization? How effectively does intramolecular hybridization compete with intermolecular hybridization and under what conditions? Since much weight is put on the data derived from hybridization between partly complementary sequences, shouldn't we know the answer to questions such as these? The future clearly will involve searching for specific cellular genes with the aid of this very powerful, but also less than well understood, technique.

The literature contains a smattering of good papers on the subject. To quote but a few that help to clarify matters, a start can be made with a paper by Howley *et al.*[6]. The authors chose three related and well defined (that is, sequenced) DNA viruses of different host origins to compare by hybridization — SV40 from monkey, BK virus from man and polyoma virus from mouse cells. Under stringent hybridization conditions, very little homology was observed, and this was assigned to the region encoding the viral capsid proteins, not a region of primary importance in the pathology of these viruses. By sequentially decreasing the stringency, however, homologies began to appear elsewhere, such that the coding regions of SV40 and BKV could be observed to be remarkably similar, and also similar to about 75 per cent of polyoma virus. The validity of these hybridization studies was confirmed by a direct comparison of their DNA sequences[7], and evolutionary relationships among the viruses were proposed[6,8]. What was the outcome of this less qualitative and rather more detailed approach to hybridization than is usually seen in the literature?

Beverly Griffin is in the Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London WC2A 3PX.

0028-0836/82/200177-02$01.00

One outcome was to suggest that immunological relationships should exist among some of the viral proteins other than the structural proteins. McCormick *et al.*[9] thus looked for, and (in contrast to previous negative reports) found, immunological cross-reaction between the large T(tumour) antigens of SV40 and polyoma virus. They conclude their paper with the warning note, "that a cross-reaction between two proteins of related function and extensively homologous primary sequences should prove so elusive sounds a note of caution in the interpretation of negative results when immunological techniques are used to search for homologies between polypeptides".

At a simpler level, but perhaps the one from which quantitative understanding of hybridization will ultimately come, Gillam *et al.*[10] have studied melting temperatures between duplexes of oligo(T) and oligomers such as A_5TA and A_5GA. A difference of several degrees in the relative stabilities of the duplexes was found, with the rather surprising result that the former mismatched double helix appeared to be more stable than the latter one. As the length of the oligomers was increased from the septamer to the nonamer, this difference diminished. (Among many interesting conclusions, they note that an oligodeoxyribonucleotide is less likely to form a mismatched structure with DNA than with RNA.) When homologies between dissimilar but related species are compared, is not hybridization essentially a result of a composite of melting out and reforming short duplexes?

A related approach has been taken in a series of stimulating papers by Wallace *et al.*[11], who investigated hybridization by using oligodeoxynucleotides as 'hybridization probes' for specific genes. By modification of the conditions under which hybridization was carried out, they could discriminate between the formation of perfectly matched and single-mismatched duplexes involving rabbit β-globin DNA and fourteen-long oligomers. To end on another 'perhaps', studies such as the elegant ones mentioned above may ultimately lead to a series of rules for the selection of the appropriate hybridization conditions that will allow interactions, whether between nucleic acids, or proteins, or even between the two, to be predicted accurately, even before detailed sequences become known. □

Fission, fusion and fracture

from Robert W. Cahn

CONFIDENCE in the intrinsic feasibility of an economically effective fusion reactor is now sufficiently widespread among those responsible for research policy that technological aspects of fusion reactor design are receiving detailed attention. One straw in the wind is the recent publication of the Proceedings of the Second Topical Meeting on Fusion Reactor Materials[1].

While about a quarter of the papers deal with such matters as tritium and deuterium recycling, breeding blankets and their constituent materials (especially lithium), and alloys for magnet windings, the central concern is the 'first wall' — the inner surface of the torus which is exposed to the full intensity of the 14 MeV neutrons resulting from the D-T fusion reaction. Schiller[2] surveys the various dangers that beset a first wall: swelling and embrittlement due mainly to helium generated *in situ* by a nuclear reaction due to neutrons, especially with nickel; erosion by sputtering due to neutral atoms escaping from the plasma, which might remove as much as 1cm from the surface during a 15-year reactor lifetime; and thermal fatigue because the operation of the reactor will be pulsed.

A number of alloys have been proposed for the first wall, including some exotic ones. Thus several investigators have seriously proposed the use of metallic glasses which typically crystallize at 350–600°C: Emmoth *et al.*[3] have shown that the familiar glass $Fe_{40}Ni_{40}B_{20}$ sputters three times more slowly than Fe-Ni-Cr (crystalline) stainless steel. (This is interesting from a fundamental point of view also since no rigorous comparative measurements have yet been made of sputtering yields from the same alloy in glassy and crystalline forms.)

However, the 'prime candidate materials' for the first wall appear to be an Al-Mg-Si alloy and variants of type 316 stainless steel (with ∿ 15 wt per cent each of Ni and Cr). A great deal of research on 316 steel was reported at Seattle: it is a familiar material, used for components of fast fission reactors as well. The most impressive of the papers on 316 steel variants are a group devoted to steels incorporating a fraction of a per cent of titanium carbide. One paper[4] from the very active research group at Jülich in West Germany compares the behaviour of 316 steel with and without TiC. The unirradiated creep rupture life at constant stress at 700°C and the reduction of creep rupture life due to helium ion implantation (which simulates what happens in a fusion reactor first wall) were very much better in the modified steel. This is plainly due to a fine distribution of TiC in grain interiors and the ability of these TiC particles to trap helium bubbles away from the grain boundaries where alone they produce creep embrittlement. This is an example of the increasingly common metallurgical ploy of setting one impurity trap to combat the effects of another.

A steel almost identical to that studied at Jülich is the American 'prime candidate path A alloy'. Arnberg *et al.*[5], of MIT, show that if this alloy is made by rapid solidification processing (flakes frozen at ∿ 10^5 K s^{-1} and then hot extruded), a fine grain size (∿ 10 μm) and extremely fine TiC particles result. This material, when helium-bombarded, proved to be very resistant to swelling at ∿ 600°C, even more so than the same alloy made by conventional methods. The TiC, according to the investigators' electron micrographs, nucleates numerous helium bubbles (especially the more numerous TiC particles in the rapidly frozen alloy) and these bubbles all remain very small, presumably under high pressure. Megusar *et al.*[6] (also at MIT) have prepared versions of this steel with triple the TiC concentration (only rapid freezing will give a uniform distribution of particles at this concentration) and this is expected to be even more resistant to swelling. The corresponding embrittlement tests have not yet been undertaken.

The 316 steels are austenitic (face-centre cubic in crystal structure). Ferritic (body-centred cubic) Fe-Cr steels without nickel have also been examined They have the advantage of generating less helium from (n,α) reactions than do 316 steels. These steels are hardened but also quite severely embrittled by irradiation[7], but Japanese work showed that a high Cr content (15 wt per cent) minimizes embrittlement[8].

An interesting German paper[9] shows that ordinary pressure vessel steel (without Ni or Cr) embrittles much less when irradiated at the service temperature of 290°C (in a PWR reactor pressure vessel) than when irradiated at ambient temperature, in the sense that the ductile-brittle transition temperature is less affected. However, if the steel contains a small amount of copper (a notorious source of contamination from recycled scrap steel), then embrittlement at service temperature is much more substantial. Here, an involuntary trace element, unlike the intentionally added Ti in 316 steel, has dangerous effects; but it is not difficult to control copper levels in high-grade steel.

Pressure vessel steels are currently being analysed in great detail in terms of linear elastic fracture mechanics, and the characterization of such steels goes a long way beyond a study of the effect of

Robert W. Cahn is Professor of Metallurgy at the University of Paris-Sud, Orsay 91405.

irradiation on ductile–brittle transition temperatures. It is possible, with a very high degree of confidence, to calculate for any part of a pressure vessel to what size a crack must grow before it can present any danger. The basis for these calculations have been outlined in technical terms by Nichols and Cowan[10] and, with his incomparable clarity of exposition, by Cottrell in his popular book on reactor safety[11]. While a failure of a fusion reactor first wall would certainly represent a far less serious accident than the fracture of a PWR pressure vessel (which, of course, has never happened), no doubt fracture mechanics will in due course be applied to the fusion situation as well, since it represents the guarantor of nuclear safety where the prevention of fracture is concerned. □

Star formation in galactic spiral arms

from Gerard Gilmore

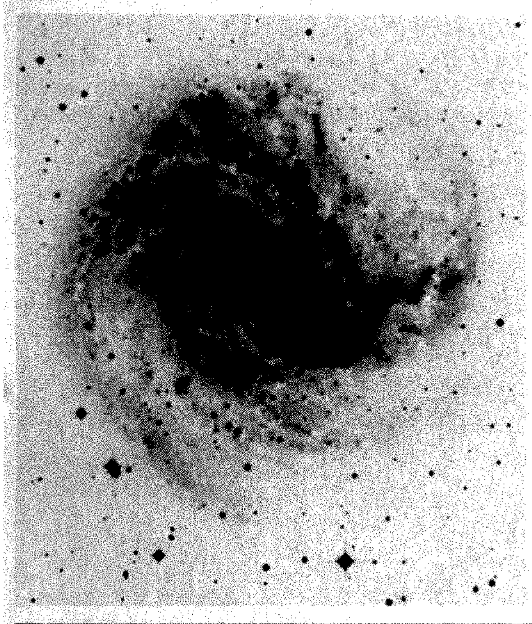
TWO-THIRDS of all bright galaxies show spiral structure, with the arms being made visible by young luminous stars and the giant gas clouds which are the sites of continuing star formation. The relation between the existence of the arms and the young stars which delineate them is analogous to the relation of the chicken to the egg. Do the galactic density waves which sweep material into the arms purely by chance create the ideal conditions for star formation, and thereby provide an optical tracer of the density enhancement, or is star formation a more fundamental requirement for the existence of the spiral arms? While current theories of galactic spiral structure suggest that the star formation is incidental, a recent numerical study of the effect of star formation on the appearance of a rotating galactic disk suggests that, in some cases at least, bursts of star formation may in fact generate the observed structure (Seiden, Schulman & Feitzinger *Astrophys. J.* **253**, 91; 1982).

Gerard Gilmore is at the Royal Observatory, Blackford Hill, Edinburgh EH9 3HJ.

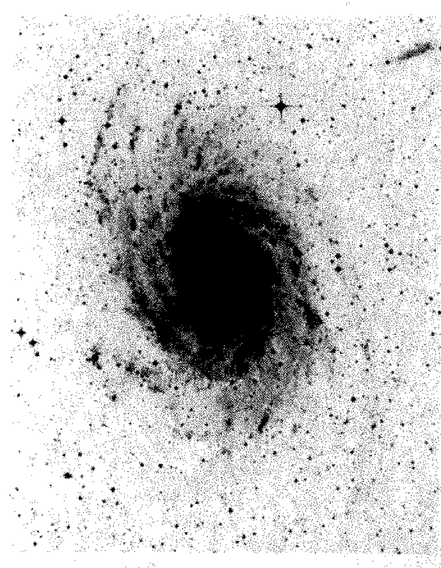
There are currently two widely discussed theories of galactic spiral structure. The first, originated by Lindblad in 1941 and developed extensively by C.C. Lin and associates, involves the response of a disk to an imposed spiral perturbation to the galactic gravitational field. As the stars and gas respond to this perturbation, they form a spiral density perturbation, which sustains the gravitational pertubation. The density wave is therefore self sustaining. The important difficulties with this theory are to find an origin for the perturbation, to maintain it against energy loss to resonances in the stellar orbits and to prevent its destruction by winding up. In general, the stars and gas outside the nuclear regions of galaxies have flat rotation curves, implying strongly differential rotation with distance from the galactic centre. This in turn will smear out any material structure in a few rotation periods. Spiral galaxies are, however, typically 50 rotation periods old. So what maintains the spiral structure?

In the second theory, extensively developed by Alar Toomre and collaborators, the spiral density perturbation is generated as a consequence of dynamical interactions with nearby companion galaxies. His numerical simulations of such interactions show a strong density wave propagating through the disk galaxy as a consequence of internal dynamical resonances (called 'swing amplification' by Toomre) initiated by quite small density perturbations. This model can generate density waves, but requires them to be transient. The high proportion of disk galaxies showing spiral structure is then a consequence of the high rate of dynamical interactions between galaxies. The spiral structure of our Galaxy becomes a consequence of the orbital properties of the other galaxies in the local group.

While proponents of both these theories are able to generate models in striking agreement with observation, what of isolated galaxies, where no obvious origin for the spiral density perturbation is apparent? It is here that the model of Seiden *et al.* is of interest. They have extended earlier work by Seiden and Gerola (*Astrophys. J.* **233**, 56; 1979; *Nature, News and Views* **283**, 133; 1980) modelling the effect of star formation on the appearance of a galactic disk by including a simple approximation to current ideas of self-propagating star formation (SPSF). In this model, a few very massive stars formed in a dense molecular cloud evolve rapidly, and generate strong shock waves from stellar winds or supernovae explosions. As these shocks propagate through the remaining dense cloud, they initiate further compression with consequent enhanced star formation, leading to more massive



Left, M83, a large, almost face-on spiral galaxy perhaps 10 million light-years away. The complex spiral arms are patterned with masses of dust, some of which seem to occur in giant shells many hundreds of light years across, and contain large numbers of young, luminous stars and masses of hot, glowing gas. At the centre of the galaxy is a source of radio waves. Right, one of the largest barred spiral galaxies, of visual magnitude 10.6 and an angular diameter of 9 arc min, in the constellation of Pavo.



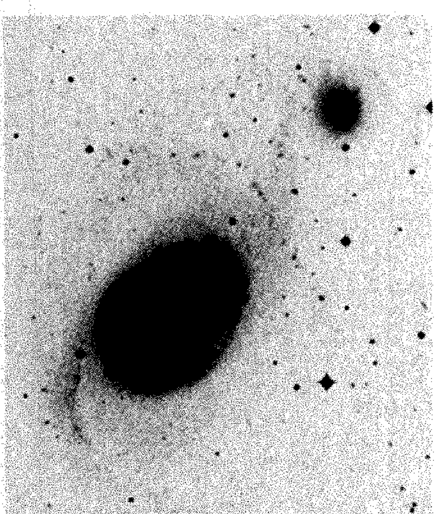
Photography by Photolabs, Royal Observatory, Edinburgh

0028-0836/82/200179-02$01.00

stars, and so on (Lada, Blitz & Elmegreen in *Protostars and Planets* ed. Gehrels, 341; 1978). The positive feedback rapidly destroys the conditions for further star formation, leaving a proportion of the cloud as gas. Eventually, this will cool and recollapse, ready for another burst of star formation.

Seiden *et al.* model this SPSF process by allowing random star formation to initiate bursts of subsequent formation, and explicitly including a cooling time for the remaining gas. As a burst of star formation propagates outwards, differential galactic rotation smears the expanding shell into an arc. The arc will then grow until it meets a region in which star formation occurred less than the recovery time before. With this simple view, the simulations are able to generate two-armed spiral galaxies allowing the initial star formation to occur randomly (hence their name: stochastic self-propagating star formation — SSPSF), and without having to impose an initial spiral density perturbation. They note that their process may in fact be an appropriate mechanism to stabilize a spiral density wave for many galactic rotation periods.

Gerola *et al.* (*Astrophys. J.* **242**, 517; 1980) have also pointed out a further important property of models of this type for small galaxies. If the recovery time for the gas is comparable to the galactic rotation period, the star formation will occur in delayed but periodic bursts. Large bursts of star formation have in fact been invoked by many authors for several years to explain the properties of small irregular galaxies and anomalously blue galaxies. While most of these bursts can be explained, as with spiral arms, by dynamical interactions of nearby companions, a few cannot. As Seiden *et al.* point out, it is not clear how to distinguish observationally between periodic bursts of star formation for the few isolated galaxies, as predicted by their model, and a non-periodic phenomenon.



The larger of the two galaxies is NGC1512, consisting of a cigar-shaped bar of stars surrounded by a bright ring from which the spiral arms trail. The small elliptical companion, NGC1510, contains many young stars and clouds of hot gas, features which are very rare in galaxies of this type. It is thought to have 'rejuvenated' itself by scooping up gas from the cloud around its larger companion; the newly acquired material has since formed stars.

Perhaps the best summary of the current state of spiral density wave theory is by Toomre (see *Structure and Evolution of Normal Galaxies* eds Fall & Bell, 111; 1981): "It seems clear now that the spiral structure of galaxies is a complex riddle, without any unique and tidy answer".□

The great Japanese IQ increase

from Alun M. Anderson

THE mean IQ of the Japanese has risen spectacularly this century and, among the younger generation, is now the highest in the world, some 11 points above the mean IQ of the United States and other Western populations, according to a report by Richard Lynn in this issue of *Nature* (p.222). Analysis of results from the American Wechsler Intelligence Scale for Children shows that more than three quarters of the Japanese younger generation have a higher IQ than the average American or European. Lynn points out that with this difference in mean IQ there will be a far greater proportion of the Japanese population with a high IQ — 10 per cent of the Japanese younger generation should have IQs above 130, the levels generally found among professional groups such as research scientists, engineers, lawyers and doctors, compared with only 2 per cent of the American population. If, indeed, any link between IQ and intellectual achievment is accepted then the future implication for societies which are becoming increasingly dependent upon technological innovation may be profound.

How can this remarkable increase be explained? The dramatic changes in Japanese society that have occurred in the last century — a mixing of previously isolated peasant communities in the massive post-war urbanization, rapid economic growth and accompanying improvements in welfare, health and education and exposure to Western culture and ways of thought — probably provide a large part of the explanation. By comparing the group of Japanese born in 1910–1945 (mean IQ 102–105, only a little above the American level) with that born between 1946 and 1969 (mean IQ 108–115) it is possible to find evidence of changes in that period in almost every factor, genetic, nutritional, educational and social, that has been supposed to affect IQ. Some of these can be documented by a few key measures of Japanese society.

Japan retained a feudal society much later than the West. Until 1868, when the Emperor was restored to power after nearly three centuries of rule by the military Shogunate, the great mass of the population were peasant farmers, tied to the land and marrying within the local

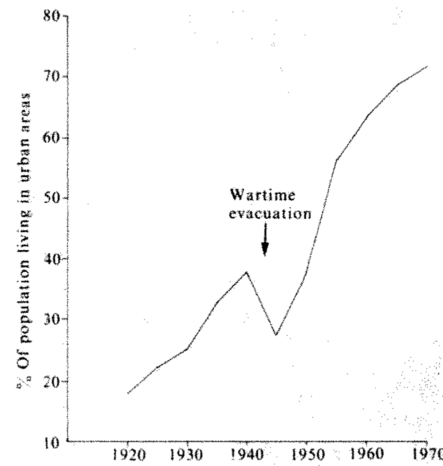


Fig.1 Increase in the urban population of Japan between 1920 and 1970 (from ref.1).

communities. In the late nineteenth and twentieth century a movement of the population towards the cities began, but it was not until the middle of this century that urbanization gained pace. In the period between 1930 and 1960 almost 40 per cent of the population moved from the country to the cities[1] (see Fig. 1). The remoter rural areas of Tohoku, Hokuriku, San'in, Shikoku and Kyushu were drained of their population, whole villages sometimes being abandoned, as Tokyo, Nagoya and Osaka emerged as massive industrial centres. In the new urban areas rural groups that had been isolated for many centuries now mixed and inter-marriage between individuals from different parts of the country became common. As a result the Japanese population has almost certainly become more outbred — a supposition supported by data on consanguineous marriages gathered in the exhaustive genetic studies of the populations of Hiroshima and Nagasaki carried out by the Atomic Bomb Casualty Commission[2]. The change is one factor that could have contributed towards the IQ increase; that inbreeding can reduce cognitive performance, including IQ scores, is well documented (see ref. 3, for example).

Raised nutritional standards are very likely to have had major effect on IQ. Lynn

Alun M. Anderson coordinates the News and Views columns of Nature.

0028-0836/82/200180-02$01.00

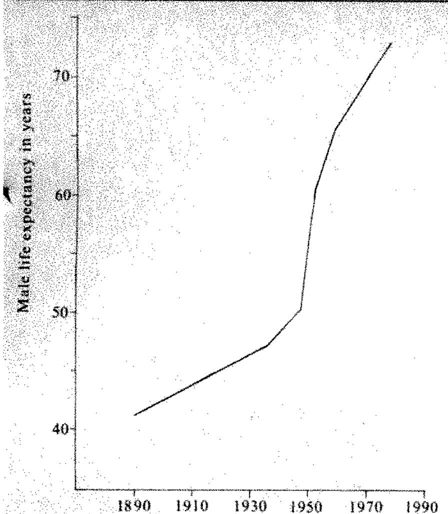

Fig.2 Male life expectancy in Japan between 1890 and 1977 (from ref.8).

points out their importance and documents them by noting the increase in birth weights. His conclusion is supported by the recent increases in the height of the Japanese and the rapid rise in life expectancy.

Japanese males born in 1960 are on average 5.2cm (2.1 inches) taller than those born in 1940. A similar increase was observed in Western Europe in the late 19th and early 20th century[4] and was closely linked to improving economic conditions. Interestingly, the change is not simply one of height but of proportion, for leg length has increased by 4.3 cm while sitting height (from base of spine to top of head) has increased by only 0.9cm in the same period[5]. (Thus the popular, but erroneous, Japanese view that they have grown taller by adopting the habit of sitting on Western chairs rather than sitting with legs folded underneath the body on a *tatami* mat.)

The rapid rise in life expectancy (to 72.7 years for men and 78.9 years for women in 1977 compared to 46.9 years and 48.6 years in 1935, see fig. 2) has produced yet another first for the Japanese. In 1977 they became the world's longest lived race and their life expectancy has continued to rise since then.

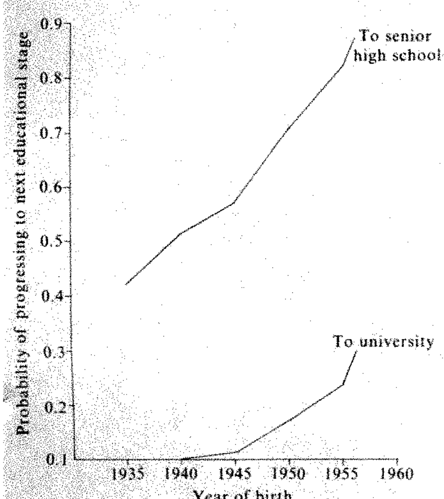

Fig.3 Fraction of middle school students going on to senior high school and to university or higher education college according to year of birth (from ref.9).

Of more obvious significance for the rise in IQ may be the very great increase in educational opportunities since the 1930s. School attendance is well known to have a substantial effect on IQ levels[6]. Among those born in 1948 and graduating from junior high school in 1962, only 51.5 per cent went on to senior high school and 10.3 per cent to college. By 1972, 87 per cent of junior high school students were progressing to senior high school and 30 per cent going on to college (see Fig. 3).

Nor, indeed, is this the first time that such a rise in IQ has been recorded. In the early days of American IQ testing many new immigrant groups were found to have low IQ (admittedly on much less sophisticated tests) but as they became accustomed to American life their IQs rose[7]. A similar effect may have occurred as the Japanese have become used to tests devised for a very different culture.

The change in IQ may, then, be explained in a multitude of ways. What remains a puzzle is why the rise should have been to a level significantly higher than that found today in the United States. Once again, given the massive cultural differences between the West and Japan and the difficulties of devising any test that does not favour one culture or another there would seem to be endless opportunity for speculation. Whether the difference in IQ represents a real difference in 'intelligence' or simply implies that the Japanese are better at IQ tests, remains open to question. At present, there is little more to say than that. □

The 'fold-back' elements of *Drosophila*

from D.J. Finnegan

GENOMIC rearrangements and DNA transposition have been observed in eukaryotes so often as to be a novelty no longer. Their significance and the various mechanisms by which they occur are far from clear, however, and at this stage all examples bear detailed investigation. The best characterized eukaryotic transposable elements are the '*copia*-like' elements[1-3] of *Drosophila melanogaster*. They are not the only transposable elements in *D. melanogaster* and in this issue of *Nature* (p.201), Potter presents the complete DNA sequence of a member of a striking different class of transposable elements — the 'fold-back' elements.

When DNA from any eukaryote is denatured and allowed to re-anneal at low concentration the first sequences to become double-stranded are those that occur as inverted repeats. The repeats may be immediately adjacent or separated by up to several thousand base pairs and, as the reaction is intramolecular, the structures formed are called 'snap-back' or 'fold-back' structures. Schmidt *et al.*[4] and Baker and Thomas[5] have estimated that there are 2,000–4,000 pairs of inverted repeats, or potential fold-back structures, in *D. melanogaster* which comprise about three per cent of the total genome. To study the properties of the fold-back structures Potter *et al.*[6] screened a library of cloned fragments of *D. melanogaster* DNA with a probe enriched for the stems of fold-back structures. They obtained one clone containing an inverted repeat and used it to select a number of others containing related fold-back (FB) elements. The sequence of one of these, FB4, is reported in this issue.

Potter *et al.*[6] also determined the chromosomal distribution of FB elements by hybridizing an FB probe to polytene chromosomes of larvae from different strains. About 30 hybridization sites were found in each case but their actual positions differed, indicating that FB sequences can move about the genome, that is, that they are transposable elements.

There are approximately 25 families of *copia*-like elements in the *D. melanogaster* genome. The members of each family are well conserved and are bounded by direct repeat sequences a few hundred nucleotides long, at the ends of which are short inverted repeats. The sequence of the direct repeats varies little within a family and, in all cases looked at so far, the repeats at the end of any one element are identical. In contrast, FB elements vary greatly in their inverted repeat sequences and the DNA separating them[6,7]. The inverted repeats have a sequence organization similar to that of satellite DNA[7] and those of FB4 are made up largely of tandemly repeated copies of a 155 base pair repeat unit which itself contains smaller sub-repeats[8]. Inverted repeats of different FB elements vary in length from a few hundred to a few

0028-0836/82/200181-02$01.00

thousand base pairs, presumably reflecting variation in the number of repeat units present[7]. The inverted repeats of FB4 differ in this way, with the right-hand repeat being longer than the left, and Potter points out that length variation of this type could be generated by mismatch recombination between repeats of different FB elements. In addition to these gross differences, the two repeats also differ by base substitutions and deletions/additions. The most highly conserved regions are at the extreme ends of FB elements. This is not surprising since these regions must presumably interact with any proteins involved in transposition.

The central region of most FB elements is made up of sequences related to the inverted repeats themselves[7]. FB4 is unusual in that its terminal repeats are separated by about 1,750 base pairs of unrelated DNA containing a potential gene coding for a 148 amino acid polypeptide. Most of this central region may itself be a transposable element since 33 nucleotides at its right-hand end occur as a near-perfect inverted repeat a short distance from the left-hand end (terminal inverted repeats are characteristic of all known prokaryotic and eukaryotic transposable elements).

The mechanism by which *copia*-like elements are able to redistribute themselves around the genome is by no means clear but the many properties they have in common with proviruses[3] suggest that it could involve circular intermediates[9] produced by a transcription–reverse transcription cycle. This is unlikely to be true of FB elements, however, and Potter (p.201) suggests that a transposase similar to those of bacterial transposons is involved and might been coded by the central region of FB4. Against this one has to remember that FB4 is the only FB element known to contain this sequence and its putative gene product might equally well be a transposase for the potential transposable element comprising this region.

The role (if any) of FB elements is unknown. Goldberg *et al.*[10] reported that an FB element lies at one end of one of the very large transposable elements (TE elements) described by Ising[8]. These are several hundred kilobases long and in some cases can be detected cytologically. The DNA involved can include respectable components of the genome, such as the white eye gene (*w*), unlike *copia*-like elements which seem to be genomic parasites. This raises the interesting possibility that any sequence bounded by two FB elements may potentially be transposable.

Inverted repeats can be detected in rapidly re-annealing DNA from many species and one may wonder whether these are similar to FB elements in the same way that endogenous proviruses seem to correspond to *copia*-like elements. In humans, the bulk of inverted repeat structures are comprised of two copies of the 300 base pair 'Alu' sequence in opposite orientation and separated by variable lengths of unrelated DNA[11]. Alu sequences make up a substantial component of human dispersed repetitive DNA and have counterparts in other species[12]. Jagadeeswaren *et al.*[13] have suggested that Alu sequences can themselves transpose but there is no indication that they behave like FB elements. It does not follow that humans and other vertebrates do not contain such elements, however, since even in *D. melanogaster* they make up less than two per cent of inverted repeats. All of this goes to show that there is still much work to be done in the study of repetitive DNA. □

Seamounts and flexure of the lithosphere

from A.B. Watts

MORE than 75 years have passed since the first gravity measurements showed that the Hawaiian islands, in the Pacific Ocean, were associated with large positive gravity anomalies of up to a few hundred mGal. The American geodesists, Hayford and Bowie[1], showed in 1912 that these anomalies could be substantially reduced by taking into account isostasy. The form of isostasy they preferred was the Pratt model, which considered that the islands were locally compensated by lateral variations in crustal density. The model was popular with geodesists since it enabled them to readjust the triangulation system of the US: a task of immense practical importance in mapping and surveying. It was of comparatively little interest, however, to a leading geologist at the time, Barrell, because it did not account for the lateral strength of the crust. Putnam pointed this out to Hayford and Bowie who subsequently amended the Pratt model by extending the compensation from beneath the islands into surrounding regions. They showed that a regional model of isostasy could reduce the gravity anomalies over the Hawaiian islands further than could the Pratt model.

But it was not until 1926, when Vening Meinesz[2] made the first pendulum gravity measurements in a submarine, that it was possible to prove regional, rather than local, isostasy for the Hawaiian islands. The measurements showed that the positive anomalies over the islands were flanked by negative anomalies of up to 100 mGal, which Vening Meinesz first interpreted as a result of downbending or flexure of the crust due to the load of the Hawaiian volcanoes. He used a model of an elastic plate overlying a weak fluid substratum, similar to one developed by Hertz[3] to model the flexure of ice on ponds by skaters. Subsequently, Vening Meinesz demonstrated that a flexure model of isostasy reduced the gravity anomalies over the islands further than could either the Pratt model, favoured by Hayford and Bowie, or the Airy model, preferred by some European geodesists.

Since the development of the concept of plate tectonics the flexure model of isostasy has assumed a special significance. Plate tectonics views the outer layer of the Earth, or lithosphere, as consisting of several large plates which converge, move apart and slide past each other. The plates therefore correspond to the rigid layer argued for earlier, on isostatic grounds, by Barrell and Vening Meinesz. An important assumption of applying plate tectonics to the geological past is that the plates behave rigidly for long periods of time. Thus, one of the objectives of current flexure studies has been to determine the thickness of the rigid layer and whether it varies on long geological time scales.

The numerous oceanic islands and seamounts that occur in the world's oceans have proved particularly satisfactory loads for flexure studies. They are mainly of volcanic origin, form relatively quickly on the plates (as evidenced by the short times between eruptions) and occur in a variety of tectonic settings. Since WW II there have been a number of geological, geophysical and geodetic investigations of seamounts and oceanic islands so there is now a large amount of bathymetry, gravity, geoid and recent crustal movement data for them. By comparing these data with predictions based on elastic plate models it has been possible to estimate the flexural rigidity, and the equivalent elastic thickness of oceanic lithosphere, in different tectonic settings in the oceans[4–7].

Flexure studies at seamounts and

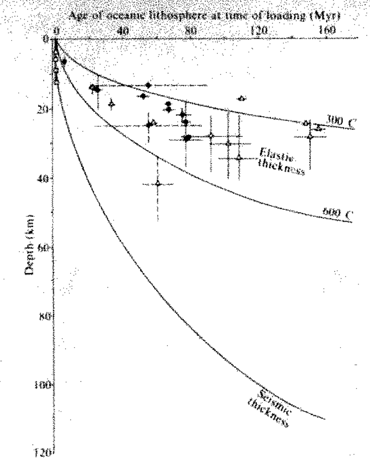
oceanic islands have shown that the elastic thickness of oceanic lithosphere, which is significantly smaller than the seismic thickness, increases with the age of the lithosphere at the time of loading. The large range of ages represented by these features (1–56 Myr) suggest that on loading, the lithosphere rapidly relaxes from its initial short-term (seismic?) thickness to a long-term mechanical thickness. Subsequent relaxation has not been observed, but may occur on very long (> 56 Myr) time scales. The smallest values of elastic thickness (5–8 km) have been determined at features which form on young oceanic lithosphere, such as the western Walvis ridge guyots, while the largest values (17–37 km) have been determined at features which form on old oceanic lithosphere, such as the Hawaiian islands. These variations suggest[8] that as the oceanic lithosphere cools, it becomes progressively more rigid in its response to volcanic loads.

The flexure model, deduced from these studies, is referred to as 'elastic', even though the model parameters actually vary with time. The elastic thickness apparently changes rapidly following loading, approaching an asymptotic value that depends on the plate age. The lithosphere only appears elastic, therefore, after some time has elapsed ($\sim$1 Myr) and, even then, the thickness of the elastic layer is determined by the plate age.

The actual long-term mechanical properties of the lithosphere are, of course, likely to be more complex than would be predicted by an elastic model. A difficulty is that flexure studies only reveal information on the average mechanical properties of the lithosphere. The estimation of elastic thickness from gravity and geoid data, for example, is complicated by uncertainties in the volcanic load and infill densities, the crustal structure before flexure, and the lateral and vertical extents of lithospheric heating at the time of loading. But as Lambeck[9] and others have pointed out, gravity and geoid data are consistent with an elastic model in which the elastic thickness increases with age of the lithosphere at the time of loading. A more difficult problem, though, is that there is no maximum stress a purely elastic plate can store; yet the actual materials of the lithosphere are likely to have some ultimate strength. Goetze and Evans[10] have pointed out, however, that if a more realistic 'yield stress envelope' is used for the lithosphere (based on data from experimental rock mechanics), an elastic core would be expected to develop during flexure that corresponds closely to the elastic thickness determined using the elastic model.

Although an elastic model has been widely used in flexure studies[4–9], it has been criticized by some workers who prefer a viscoelastic (Maxwell) model. A viscoelastic model is characterized by an initial elastic response to a load, followed



Estimates of the elastic thickness (or mechanical thickness) of oceanic lithosphere plotted against age of the lithosphere at the time of loading. The solid symbols are estimates from studies by different workers at seamounts and oceanic islands, open symbols are estimates from studies at mid-ocean ridges (squares), river deltas (diamond) and deep sea trench–outer rises (triangles). As the age of most of the features range from a few Myr to several tens of Myr, flexure studies indicate that on loading the mechanically supportive part of the lithosphere relaxes from its short-term (seismic) thickness to a long-term mechanical thickness. The long-term thickness does not appear to change appreciably with time. Thus, flexure is likely to be an important controlling mechanism in the tectonic evolution of geological features in the oceans and continents.

by a viscous relaxation that rapidly increases with age of the load. Since the model incorporates a form of stress relaxation, the 'equivalent' elastic thickness would be expected to decrease as the load increases in age, the decrease being most apparent for long times (compared with the Maxwell relaxation time) and large loads. But elastic and viscoelastic models produce flexure curves of similar shape. Thus, the best way to distinguish between them is to determine whether the elastic thickness is controlled by the age of the load (viscoelastic model) or by the age of the plate (elastic model).

Walcott[4] first suggested, based on the results of flexure studies of continents and oceans, that the elastic thickness of the lithosphere depends on the age of the load, rather than on the plate age. A difficulty with his study, however, was that he did not satisfactorily account for differences in size or tectonic setting of the various geological features used in these studies. Recently, Lambeck[11] accounted for these differences in a study of the Society and Cook Islands in the South Pacific Ocean and argued for a dependence of the elastic thickness on age of these loads, that indicated a Maxwell time of about 10^7 yr for the oceanic lithosphere. The differences in age between the Society and Cook Islands are too small (1.4–3.1 Myr), however, to resolve satisfactorily whether there has been more relaxation beneath the older load (Cook) than the younger load (Society). The best example of a dependence of the elastic thickness on age of load occurs, in fact, along the Hawaiian–Emperor seamount chain; the younger Hawaiian ridge (4–18 Myr) shows the larger elastic thickness (37 km) and the older Emperor seamounts (44–58.5 Myr) the smaller thickness (22 km). But as Watts[8] pointed out, the small values for the Emperor seamounts can be more simply explained by an elastic, rather than a viscoelastic, model since these seamounts were originally emplaced on young, weak, oceanic lithosphere.

This discussion suggests, therefore, that a consensus is emerging from flexure studies at seamounts and oceanic islands favouring the elastic model as the most useful working hypothesis for the long-term mechanical properties of the lithosphere. The model can also explain (with some modification) the topography of the outer rise seaward of deep-sea trenches, the deep structure of large river deltas, the pattern of late glacial rebound due to the receding Laurentide ice caps and the patterns of gravity anomalies over orogenic belts and Precambrian granite plutons. The model is therefore currently enjoying a wide range of applications in geology that include the determination of the tectonic setting (on-ridge or off-ridge) of intraplate volcanoes, the nature of the control on stratigraphical sequences in sedimentary basins and the gravity and geoid effect of deep processes beneath the lithosphere, such as layered mantle convection.

Clearly, the elastic model remains a working hypothesis that needs to be tested in the future. A critical test would be to determine the actual seismic thickness of the crust and lithosphere in the region of a large volcanic load, such as the Hawaiian islands. Recently, two-ship multichannel seismic experiments, using long arrays and repetitive sound sources, have been carried out in the western and eastern Pacific Ocean[12] that have revealed nearly continuous reflections from the 'Moho' discontinuity at the base of the oceanic crust. Similar experiments in the central Pacific, near the Hawaiian islands, offer the most promise, therefore, to test the flexure model of isostasy during the next decade. □

Gene rearrangement and the generation of diversity

from Miranda Robertson

THE eukaryotic genome has rececently begun to seem less stable, both in evolution[1] and in ontogeny[2], than many biologists had assumed. These trends prompted the Institute of Genetics to invite to its annual Spring meeting speakers on six genetically labile systems: the MHC locus and the immunoglobulin genes of mammals, the genes encoding the surface antigens of trypanosomes, and the genes of plant and animal tumour cells. The MHC locus, which illustrates the evolutionary lability of the vertebrate genome, will be discussed in detail in a later article. What follows here is concerned with the generation of diversity on a much shorter time-scale, in antibodies during the lifetime of vertebrates, and in the surface antigens of parasitic trypanosomes in the course of an infection.*

Both the antibodies of vertebrates and the surface antigens of trypanosomes have evolved the means of extremely rapid diversification through DNA rearrangements leading directly to changes in gene expression. But the selective pressures on antibody-producing vertebrate lymphocytes are different in fundamental ways from those acting on trypanosomes; and those differences may be reflected in the mechanisms by which the genetic changes are achieved. Speakers at Cologne explored both the causes and the consequences of variation in these two systems — and touched on some implications for the normal and abnormal development of multicellular animals.

Deletion and recombination in immunoglobulin

The somatic rearrangement of the DNA of antibody genes takes place in lymphocytes of the lineage whose end-product is the differentiated antibody-secreting B cell, or plasma cell. Its effect is to join the two normally separate gene segments (the V and J segments) to encode the variable region of the light chains of the antibody molecule, and of three separate gene segments (the V,D and J segments) to encode the variable region of the heavy chain (see summary diagram in ref.2). It is no longer disputed that the variability of the variable regions of antibodies arises from the largely random assembly of each of the coding sequences from a large pool of germ-line V segments, a smaller pool of J segments, and (for heavy-chain V regions) a pool of D segments whose extent is still unknown. There is however vigorous debate about the mechanisms by which the recombination takes place.

The only obvious clue yielded by the recombining DNA itself is the presence of conserved 'signal' sequences flanking each of the separate gene segments (see legend to Figure 1). Because these sequences contain inverted DNA repeats, Leder[3] and Tonegawa[4], both in 1979 working on the light-chain genes of mice, proposed that the V-J join results from the formation of a stem structure through intrachromatid base-pairing in which the DNA intervening between the V and the J loops out and is deleted (Fig. 1*a*). In support of this proposal, they reported the absence of the intervening DNA in immunoglobulin-secreting myeloma cells.

The deletion theory however very soon encountered a challenge in the work of Steinmetz *et al.*[5], who found in a mouse myeloma a fragment of the deleted DNA containing a recognizeable pair of back-to-back signal heptanucleotides. It is clear from Fig. 1*a* that such a configuration could be generated by the excision of the Leder/Tonegawa loop-and-stem if it were ligated at its base to form a circle. But the persistence of such circles in antibody-secreting cells is not consistent with the disappearance of the intervening DNA from the cells analyzed by Leder and Tonegawa.

Furthermore, the persistence of back-to-back signal sequences is quite general: they have now been found in many more myelomas and hybridomas, both by Walfield *et al.*[6] and by Van Ness and colleagues (M. Weigert, Institute of Cancer Research, Philadelphia). It has thus become necessary to think again about the mechanism of V-J joining; and one alternative, advocated at Cologne by Weigert and by J. Höchtl (from the laboratory of H. Zachau at the University of Munich where the first back-to-back signal fragment was found) is mitotic recombination resulting in the unequal exchange of DNA between sister chromatids (Fig. 1*b*).

The essential difference between their theory and the Leder/Tonegawa theory is that while the loop-and-stem mechanism

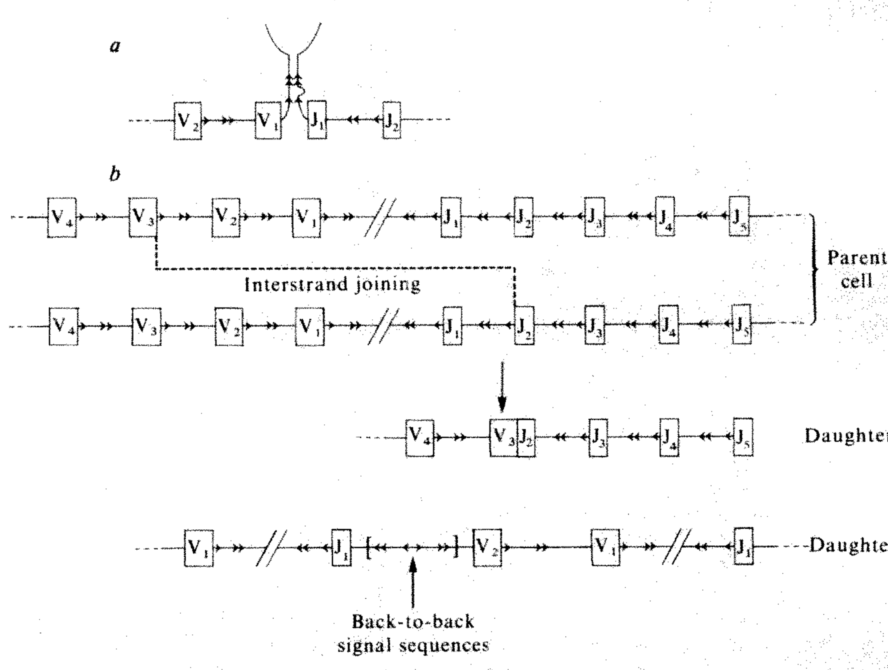

Fig 1. The joining signals for the V and J segments of light-chain genes are a conserved heptanucleotide (>) followed by a conserved nonanucleotide (»), separated by about twelve base-pairs of non-conserved DNA in the case of the V-segment signal, and about 24 base-pairs in the J-segment signal.

For the heavy chain, which is not illustrated here, the conserved sequences are the same but both V and J signals have a 24-base-pair non-conserved spacer. The D segments, which in the assembled coding region come between them, are flanked on both sides by signals with a 12-base-pair spacer. This arrangement has led to the enunciation of the so-called 12-24 rule for segment joining: joining is held to occur only between signals with different spacer lengths.

(*a*) Hypothetical loop-and-stem structure giving rise to a V-J join. If the loop were ligated at the base of the stem, the result would be a back-to-back pair of signal heptanucleotides.

(*b*) The consequences of mitotic recombination with an unequal exchange of material between sister chromatids. One daughter inherits a chromosome with a functional V-J join, the other a back-to-back heptanucleotide pair and the potential for a future V-J join. Only one pair of sister chromatids is shown for the dividing parent, and only one chromosome of each daughter: diploid cells will, of course, have two.

Miranda Robertson is associate editor of Nature.

---

*The Spring Meeting on Molecular Biology, whose theme was the Genetic Basis of Diversity, was held in Cologne on Feburary 24-27, 1982.

0028-0836/82/200184-03$01.00

entails the redistribution of DNA within a chromatid, interstrand joining between sister chromtids entails redistribution between chromatids, with subsequent segregation of the two chromatids to different daughter cells.

Höchtl and Weigert presented circumstantial evidence for such segregation at Cologne. Höchtl *et al.*[7] have now sequenced back-to-back signal fragments from three myelomas, and they find that the flanking regions of the back-to-back signals are not those of the V and J segments actually rearranged int he myeloma cells. This can easily be explained if the myelomas had inherited a chromosome such as that illustrated for daughter 2 in Fig. 1*b*, productive rearrangement of the expressed segments occurring either by a second recombination involving the same chromosome, or by a rearrangement on the other chromosome.

Mitotic recombination can also effortlessly explain the 'deletion' of DNA seen by Leder and Tonegawa, and by Weigert in some cell lines, since after two or more rounds of mitotic recombination a proportion of cells will inherit two shortened chromosomes. Equally, however, it follows that the total DNA content of a population of normal B lymphocytes should be conserved. This prediction has been tested by Van Ness *et al.*[8] who have established that most of the DNA upstream of the J region is retained in a population of normal B lymphocytes from mouse spleen.

Multiple rearrangements

But there is one feature of the data on V-J joining whose explanation is not so obvious. That is the preponderance of rearrangements involving J_1. This is reflected both in the proteins produced by myelomas and in the sequenced back-to-back fragments, all of which so far prove to contain flanking DNA from the J_1 segment. Weigert suggests that this may be a consequence of rearrangements of upstream J segments remaining on the chromosome containing the back-to-back signal fragment: the chromosome of daughter 2 in Fig. 1*b* illustrates such an upstream J. The downstream J segments remaining on daughter 1 would never be rearranged because rearrangement ceases once a V segment has been productively joined to a J. This would lead to an overall bias in favour of J_1.

On the other hand, if multiple rearrangements are frequent then the back-to-back signal fragments would no longer be expected to correspond in a one-to-one fashion with the productively rearranged segments in a given cell, and one of the stronger arguments for exchange between sister chromatids would be weakened. Indeed Baltimore, who has evidence that immunoglobulin genes are capable of multiple rearrangements, places quite a different interpretation on the back-to-back signal sequences that he, too, finds associated with rearranged light-chain genes. His evidence for multiple rearrangements comes, not from light-chain genes but from a recent analysis of heavy-chain V-D-J joining by Alt and Baltimore[9].

By following the fate of the D segments in a pre-B cell line transformed by murine leukaemia virus (MuLV) and still undergoing DNA rearrangement, he and his colleagues have been able to show that multiple rearrangements of D segments are possible; in one case three separate joining events between D and J segments alone must have occurred on a single chromosome. The final result of these rearrangements is a D segment sandwiched between two J segments and therefore incapable of participating in heavy-chain production. But two features of the rearranged chromosome have important general implications for the mechanism of immunoglobulin-gene rearrangement. First, a pair of back-to-back heptamers has been generated upstream from the joined segments; and second, the DNA between the heptamers and the downstream margin of the D segment is inverted (Fig. 2). While the heptamers could in principle be explained by recombination between sister chromatids, the inversion cannot, since it would entail breaking the chromosome. Baltimore believes that the back-to-back heptamers in rearranged light-chain DNA, too, may be generated by the inversion of V segments during V-J joining. (The orientation of the V segments relative to the J segments in germ-line DNA is not in fact known.) At this stage, however, no mechanism for V-J joining can be definitively ruled out.

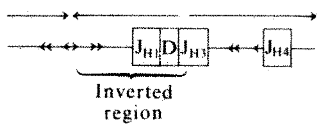

Fig 2. Abortively rearranged heavy-chain DNA of a virus-transformed cell line described by Alt and Baltimore[9]. the arrows indicate the relative orientation of the DNA.

More diversity by mutation and conversion

In any case there is more diversity in the variable-region coding sequences than either mitotic recombination or intrachromosomal deletion can explain on its own. It turns out that somatic mutation occurs perhaps during and certainly after the DNA rearrangements that join the different gene segments[2,10]; this can result in a very large number of substitutions — as many as 44 in a single V region. L. Hood (California Institute of Technology), on the basis of a detailed analysis of expressed and germ-line sequences encoding the V regions of antibodies that bind the hapten phosphorylcholine (PC), has concluded that there must be a special mechanism for generating localized mutations, since almost all of them are confined to the DNA encoding the V region and its immediate vicinity[11]. He calls the phenomenon hypermutation.

It can, however, be difficult to be certain that the substitutions are due to mutation and not recombination between members of the extensive V-gene family. Hood's evidence rests on the identification of a family of germ-line V segments that hybridizes strongly with the expressed anti-PC V sequences and not with other germ-line genes; and furthermore he finds substitutions in the J region, for which all the germ-line sequences are known.

The danger of postulating mutation in the absence of complete information on germ-line sequences was illustrated by collaborators of K. Rajewsky and K. Bayreuther (University of Cologne), who in similar studies have discovered a V-region variant arising *in vitro* in which what was apparently a cluster of mutations in the heavy-chain V region proved to be identical to a part of the germ-line sequence of a different V segment. They have interpreted this striking discovery as a possible instance of gene conversion — a mode of recombination increasingly invoked to account for otherwise inexplicable blocks of homology.

The question of whether conversion makes a significant contribution to antibody diversity *in vivo* however remains open.

Structure and function of antibodies

The random recombination and subsequent mutation, or conversion, of immunoglobulin variable-region gene segments guarantee diversity of structure, but they by no means guarantee diversity of function. The extremely ill understood relationship between the two has been the chief preoccupation of S. Rudikoff (National Institutes of Health) who reported on the basis of an analysis of variants of anti-PC antibodies, that amino-acid substitutions may make remarkably little radical difference to antigen-binding specifity. Hood hazarded that the choice of germ-line segments probably broadly determines the character of the antigen bound, while mutations (or conversions) 'fine-tune' the binding properties of the antibody.

An extraordinarily elegant illustration of this principle was presented by W. Gerhard (Wistar Institute, Philadelphia), in whose laboratory a large panel of hybridomas has been constructed from individual inbred mice immunized with influenza A virus, and the monoclonal antibodies tested for binding to a range of mutant viral haemagglutinins. From among these antibodies, one group could be identified, on the basis of restriction mapping, as a family probably derived from the same re-arrangement of germ-line segments, and thus presumably from the same precursor B cell. The antigen-binding properties of most of them could, however, be clearly distinguished by single-point mutant

haemagglutinins, each of which was recognized by only two or three of the antibodies.

What this means, in practical terms, is that somatic mutation in memory B cells should enable an immunized mammal to keep pace with the continous minor antigenic drift of the influenza haemagglutinin molecule. It may also explain why, by contrast, the more dramatic antigenic shift that occurs every few years can give rise to pandemics[12]: the more profound structural effects of the shift may demand a fresh combination of germ-line segments and leave the animal temporarily unprotected.

Recombination and expression of genes for trypanosomes surface antiges

Like the influenza virus, the African trypanosome has evolved the ability to change its antigenic coat proteins and thus evade the immune armoury of its vertebrate host. Indeed, the surface antigens of trypanosomes change sequentially in the course of a single infection and generally outflank the immune system altogether. But the parallel between trypanosomes and influenza viruses is in many ways less striking than the parallel between trypanosomes and the B lymphocytes of their victims. Trypanosomes, like B lymphocytes, have a family of related genes encoding surface proteins; and, like B lymphocytes, they can vary the expression of the genes by rearrangements of the chromosome containing them[13].

The manner of the rearrangement may however be less like that of antibody genes than that of the mating-type genes in yeast, since the expression of a variable surface glycoprotein (VSG) gene in trypanosomes seems to be preceded, at least in some cases, by duplication and transposition[13], whereas no duplication (so far as is known) accompanies the rearrangement of antibody V segments. P. Borst (University of Amsterdam) has suggested that the duplication-transposition of trypanosome VSG genes could be another instance of gene conversion, in which the gene in the expressed locus — the so-called expression-linked copy — is converted sequentially by the other, co-called basic copy, genes. (The conversion event posulated by the Cologne group in immunoglobulin V segments occurs after gene rearrangement and not as part of its mechanism.) There is moreover no particular reason to expect that the same recombination mechanism will operate in B lymphocytes, which do not need to maintain their genomes intact for transmission to the next generation, and trypanosomes, which do.

Transposition and activation of genes

A significant point of similarity however is that in both cases the rearrangment of DNA results in the activation of the rearranged gene. The question is, how? In the case of antibody genes, it is known that there are promotors upstream of not only the unrearranged constant-region segments at the transcribed locus but each of the germ-line V segments as well. The constant-region sequences are transcribed at low levels from unrearranged chromosomes in both B and T lymphocytes, suggesting that the locus is constitutively active in the lineage. The unrearranged V segments by contrast are silent. Van Ness *et al.* have established that recombination of the V segment (and its promotor) with the J and C segments increases the transcriptional activity of the C region severalfold[13]. They conclude that the total transcriptional activity may depend on the combined effects of both V segment promotors, and the structure of the chromatin at the site of the C segment — the appropriate chromatin structure being the necessary condition for expression. (There is in fact evidence for a region of DNase 1 sensitivity upstream of the C-region genes[15].)

Similar factors may determine VSG gene expression in trypanosomes, though Borst believes the powerful promotor may be at the expression site rather than at the basic copy site. He reported at Cologne that the mRNA transcribed from the expressed gene contains a 5′ sequence that does not correspond to the 5′ flank of the basic-copy gene, and suggested that it is derived from the DNA at the expressed locus, which may contain an upstream promotor[16]. This hypothesis could clearly be tested by cloning the DNA of the expression-linked copy.

But trypanosomes in have in any case more than one way of changing the expression of their VSG genes. Williams *et al.*[17] have found rearrangement of the expressed gene without evidence of duplication; and S. Longacre (Pasteur Institute, Paris) reported that duplicated genes in *T. equiperdum* may persist unexpressed while a second duplicated gene in a different locus is transcribed.

If the rearrangement of trypanosome VSG genes does not bring them under the control of a promotor, perhaps, like antibody genes, they bring their own promotors with them and activation is due to the state of the surrounding chromatin.

This is the mechanism suggested by Nasmyth *et al.*[18] to account for the alternating expression of the a and α mating-type genes of yeast. Each yeast cell carries one silent copy of each of the two related genes, a duplicated a or α gene being expressed in alternate generations at the MAT locus. There is some evidence that the chromatin at the MAT locus is more loosely packed than at the silent loci.

But the importance of chromatin structure may not be confined to its effect on transcriptional activity. Mating-type genes, VSG genes, and immunoglobulin V segments are not transposed to random sites in the genome, and the state of the chromatin may help to determine where they recombine. In every case, new sequences are transposed to an already active site, and Van Ness *et al.* have suggested that, in the case of antibody genes, transcriptional activity may be a prerequisite for recombination. In this context, it may be extremely significant that in mutant yeast strains in which the normally silent mating-type loci are transcribed, these loci, like the normally active site, switch between a and α sequences; in wild-type strains, these silent loci are never expressed and do not switch[19].

Transformation and differentiation

Are these variations in position and expression of related genes a peculiarity of a handful of highly specialized genetic systems, or have they (as Strathern and Herskowitz have suggested for yeast[20]) important implications for the study of differentiation in general? It has already been pointed out[21] that the existence of three families of mobile promotors on the chromosomes containing the three pools of V segments poses a serious oncogenic threat. Since it is now generally held that cancer may be caused by normal cellular genes promoted to abnormally high levels of activity, the arrival of a V segment complete with promotor in the vicinity of such a gene might lead to cancer; and indeed 'here is evidence that some leukaemias may arise in just this way[21].

Speculations on the part played by labile gene families in normal development however are so far largely unconstrained by evidence. Thus unfettered, Hood launched a pan-explanatory schema in which embryogenesis is guided by varying surface markers differentially and sequentially expressed on cells with different developmental destinies, each additional surface marker further narrowing the differentiation pathway open to its bearer — just as differential expression of antibody V-regions narrows the interactions open to a lymphocyte. Such is the present pace of progress that today's imaginative leap may land in tomorrow's text-book. □

REVIEW ARTICLE

Chemistry of hot springs on the East Pacific Rise and their effluent dispersal

J. M. Edmond*, K. L. Von Damm, R. E. McDuff & C. I. Measures

Department of Earth and Planetary Sciences, Massachusetts Institute of Technology, E34-201, Cambridge, Massachusetts 02139, USA

Cold groundwater circulating through submarine ridge crests reacts with hot basalts at temperatures in excess of 300 °C. The resulting solutions ascend and emerge as hot springs on the sea floor. This ridge crest hydrothermal activity is pervasive and chemically uniform. The fluxes of the various elements injected into, or removed from, the ocean are substantial compared with fluvial transport. The dispersal of the effluent is shown to be controlled by global circulation at mid-depth.

LARGE-SCALE, high temperature, hydrothermal activity is a ubiquitous concomitant to the production of oceanic crust at submarine ridge crests. The establishment of this fact has been one of the most important recent developments in oceanography and, indeed, in the earth sciences as a whole. Molten rock is injected at the centres of sea floor spreading at temperatures of around 1,200 °C. The pre-existing crust is highly permeable because of faulting and of fissuring induced by thermal contraction. Cold 'groundwater' derived from the overlying ocean can thus circulate through the crust and penetrates the zone of active intrusion along cracking fronts[1]. Here reactions take place between the seawater and the hot basalt at temperatures in excess of 300 °C. The resulting solutions ascend to the sea floor where they emerge as hot springs.

Geological evidence

The phenomenon was first proposed by Elder[2] from analogy with geothermal systems associated with continental igneous activity. At about the same time Bostrom and Peterson[3] invoked ridge crest hot springs of undefined scale as the source of the elevated concentrations of iron and manganese which they had shown to be a characteristic feature of the sediments on the crestal zone of the East Pacific Rise. Such a local source was required by their observations since abyssal sediments remote from the axes showed no such enrichments. As data were accumulated on the chemistry and mineralogy of basalts dredged from the ridge crests it became clear that, in many cases, they had been pervasively altered by reaction with seawater[4,5]. The partitioning of oxygen isotopes between coexisting secondary minerals, the reaction products of this alteration, demonstrated that the temperatures of the interactions ranged up to several hundred degrees centigrade[6].

Parallel investigations in ophiolites, slabs of oceanic crust tectonically emplaced onto the continents, gave similar results and established that seawater must penetrate over 5 km into the intrusion zone at the ridge crests[7]. Metalliferous sediments were found to be generally associated with the uppermost pillow lavas in the ophiolite sections and to be of hydrothermal origin[8,9]. Ore deposits composed of massive accumulations of pyrite (FeS_2) in the same terrains were shown to require very large volumes of high temperature solutions for their transport and emplacement[10].

Results from the Deep Sea Drilling Project demonstrated that metalliferous sediments are the usual basal deposit in the contemporary oceanic sediment column[11]. The underlying basalts, where sampled, showed evidence of reaction with seawater over a wide range of temperatures[12]. Detection of the primordial, non-radiogenic, isotope of helium, ^3He, at mid-depth in the Pacific water column[13] provided a strong additional indication that hydrothermal activity is occurring along the crest of the East Pacific Rise.

* Present address: Institut de Physique du Globe, Université de Paris VI, France.

Quantitative estimates of the global scale of this seawater convection began to emerge in the mid-1970s from comparison of the measured conductive heat loss from young oceanic crust with that predicted from the thermal models of the plates[14]. A pronounced negative anomaly was observed everywhere[15]. The total deficit for all the active ridges is estimated at between 2 and 8×10^{19} cal yr^{-1} (ref. 16). Assuming that this heat was removed by convective flow at typical temperatures of 300 °C, as suggested by the ^{18}O data[6], then a volume of water equivalent to the whole ocean must circulate through the high temperature intrusion zone in the ridge axes (that is through the 300 °C isotherm) every 8–10 Myr.

The chemical importance of this phenomenon was illustrated in the earliest experimental work on seawater–basalt interactions at elevated temperatures and sea floor pressures[17]. Drastic changes were observed in the compositions of the solutions during the reactions. Magnesium and sulphate were rapidly depleted and potassium, calcium and silica enriched. Simple calculations indicated that ridge crest hydrothermal activity might be a major, hitherto unconsidered, component of the chemical mass balance of the oceans over geological time[15].

Chemistry of ridge crest hot springs

Finding and sampling actual examples of ridge crest hot springs proved to be complex. Although numerous indications of hydrothermal activity had been detected in the water column over the axial zone[18,19], it was not until 1977 that a comprehensive exploration programme at the Galapagos Spreading Centre in 86° W in the eastern equatorial Pacific succeeded in locating and collecting water from discrete vents[20]. This required use of high resolution bathymetric charts, an accurately navigated, large-field, survey camera and the research submersible *Alvin*.

The hot springs at the Galapagos Spreading Centre were found to occur in extensive fields[21] associated with diverse and exotic fauna[22]. The exit temperatures were low, in the range 6–20 °C above that of the ambient water column at the axial depth (2.05 °C, 2,500 m). However, systematic investigation of the chemistry of the solutions demonstrated that these low and variable temperatures were actually an artefact of large-scale, sub-surface mixing between a very high temperature component and 'groundwater' indistinguishable in properties from the ambient seawater[23,24]. Individual chemical elements in solution respond differently to this process. The hydrothermal solutions were cool, contained variable amounts of H_2S (10–160 μmol kg^{-1}) and were mildly acidic[25]. Elements which do not form insoluble phases in such conditions are unaffected by the mixing process.

The experimental data[17] indicated the complete removal of dissolved magnesium during high temperature seawater–basalt reactions. Assuming that the fluids sampled at Galapagos represented a simple mixture between cold 'groundwater' and a single hydrothermal endmember then the temperature of the latter could be estimated by extrapolating the observed negative

0028-0836/82/200187–05$01.00

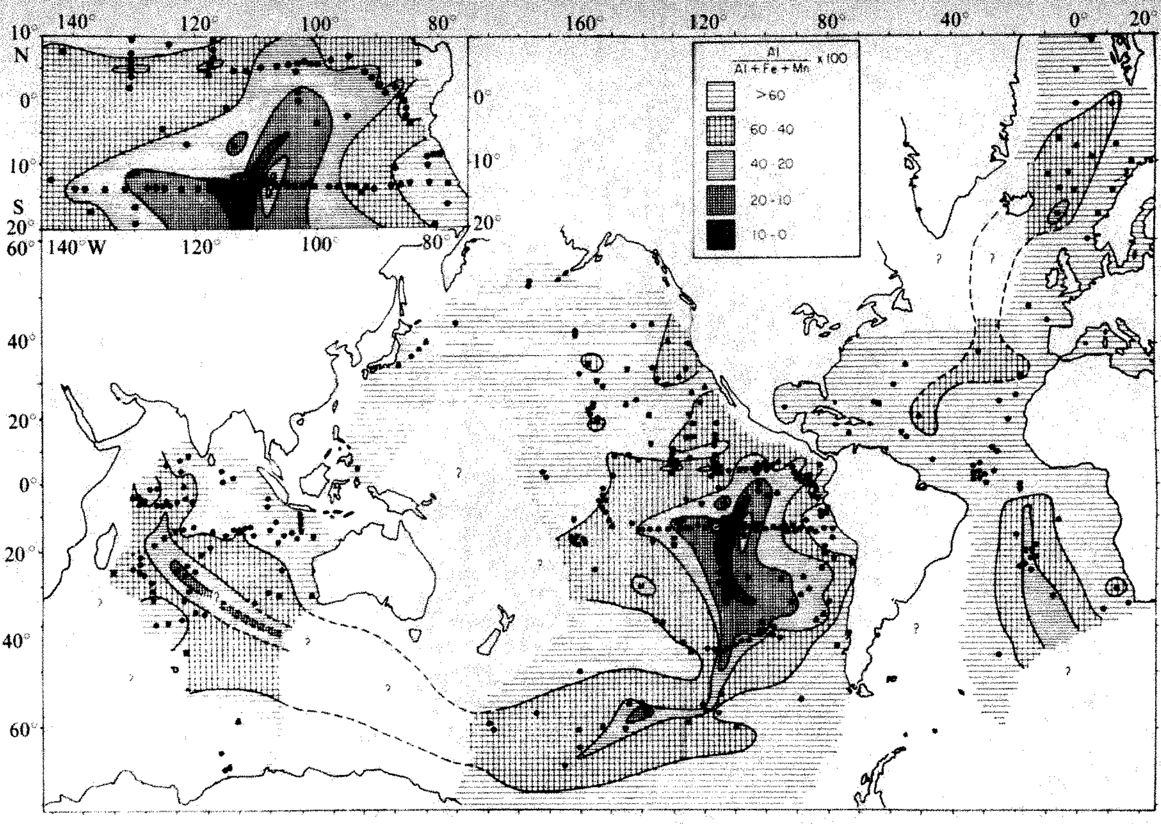

Fig. 1 Distribution of metalliferous surface sediments in the ocean as indicated by the ratio Al/(Al+Fe+Mn). As these deposits are poor in aluminium relative to continental detritus their abundance is inversely proportional to the value of the ratio. Figure reproduced from ref. 38.

magnesium–temperature relationship in the samples to zero concentration. An intercept was obtained at ~350 °C (ref. 23). This was confirmed by application of the quartz solubility criterion—quartz geothermometry[26]—to the parallel data for dissolved silica. Extrapolation of the concentration–temperature trends for the other conservative species then allowed estimates to be made of the composition of this putative 350 °C endmember (Table 1). Elements which form insoluble precipitates—sulphides and oxides—in the conditions observed in the Galapagos solutions showed sharp depletions with increasing temperature, their concentration levels extrapolating to zero between 30 and 40 °C (ref. 24). Not only were these elements—Cu, Ni, Cd, Se, U, Cr—being removed from the high temperature component of the fluids but also from the admixed groundwaters. It was not possible, therefore, to obtain any information on the concentrations of these potentially ore-forming elements in the high temperature solution.

Despite such complexities some remarkable results were obtained from the Galapagos data: these supported far-reaching conclusions as to the global significance of ridge crest hydrothermal activity. Most important are the fluxes involved. For ^{3}He the ratio to transported heat is 2.2×10^{-17} mol cal^{-1} (ref. 27). Integration of the water column ^{3}He anomaly, coupled with ^{14}C-calibrated models for the oceanic overturn rate, results in a flux of ^{3}He into the ocean, necessary to maintain the anomaly, of 1,100 mol yr^{-1} (ref. 28). This is in good agreement with the terrestrial budget which is dominated by a loss term due to gravitational escape to space. If it is assumed that all the ^{3}He delivered to the oceans is from hot springs in the ratio to heat observed at Galapagos then the associated heat flux can be calculated. This independent estimate agrees exactly with the geophysical results[27].

The apparent success of this approach coupled with appreciation of the close constancy in composition of the hydrothermal reactants, tholeiite basalts and seawater, justified similar calculations for the other dissolved species. The resulting values for elemental fluxes into and out of the axial zone are in many cases comparable with or greater than those estimated for fluvial transport of the products of continental weathering[23]. Thus the ridge is the major sink for magnesium and sulphate, the major source for lithium, rubidium and manganese and a substantial contributor of calcium, barium and silica. Several long-standing problems in the construction of oceanic chemical balances are resolved by inclusion of the hydrothermal term. The situation for the non-conservative elements cannot be evaluated[22] as the global distribution of exit temperatures—the average extent of sub-surface mixing—is, of course, unknown.

The validity of the deductions based on the Galapagos data was confirmed by the discovery, 2 years later, of hydrothermal fields on the crest of the East Pacific Rise in 21° N, south of the mouth of the Gulf of California[29,30]. Here, in depths of 2,500 m, solutions at temperatures of 350 °C were observed issuing from the sea floor. They had associated with them constructional features, chimneys up to 10 m high, composed

Table 1 Comparison of the estimated composition of a 350 °C hydrothermal endmember based on extrapolation of the Galapagos data with that observed at 21° N

	Galapagos	21° N	Seawater
Li (μmol kg^{-1})	1,142–689	820	28
K (mmol kg^{-1})	18.8	25.0	10.1
Rb (μmol kg^{-1})	20.3–13.4	26.0	1.32
Mg (mmol kg^{-1})	0	0	52.7
Ca (mmol kg^{-1})	40.2–24.6	21.5	10.3
Sr (μmol kg^{-1})	87	90	87
Ba (μmol kg^{-1})	42.6–17.2	95–35	0.145
Mn (μmol kg^{-1})	1,140–360	610	0.002
Fe (μmol kg^{-1})	+	1,800	—
Si (mmol kg^{-1})	21.9	21.5	0.160
SO_4 (mmol kg^{-1})	0	0	28.6
H_2S (mmol kg^{-1})	+	6.5	0

The ranges in the Galapagos results derive from the different trends for composition versus heat observed between individual vent fields[23]. +, Non-conservative to sub-surface mixing; —, seawater concentration not accurately known.

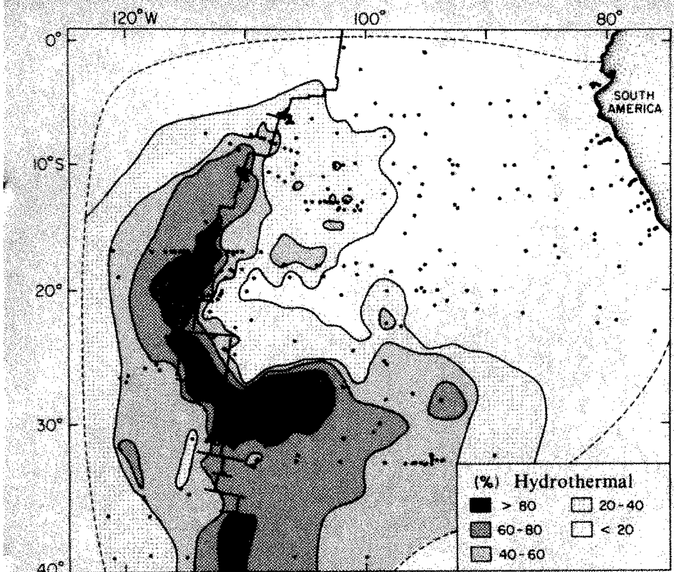

Fig. 2 The weight percentage of the hydrothermal component on a carbonate and salt-free basis in surface sediments of the Nazca Plate[33]. The abundance of this component is calculated from chemical data for the bulk sediment using a normative composition model.

predominantly of iron, zinc and copper sulphides. These grow from the hydrothermal solutions as they mix with the ambient seawater. However, most of the precipitation occurs as very fine-grained particles entrained in a turbulent plume rising tens of metres above the orifices of the springs[30].

Sampling of these hot springs established that they are indeed the compositional endmember postulated on the basis of the Galapagos data[31]. The waters exit as clear, homogeneous solutions within a few degrees of 350 °C. They are completely depleted in magnesium and sulphate and appear to be saturated with quartz. The concentrations of the conservative species are close to the Galapagos extrapolations (Table 1). The ^{3}He/heat ratio is identical to that from Galapagos[32]. The validity of the flux calculations is substantially confirmed.

These undiluted solutions also preserve the signatures of elements precipitated during Galapagos-type sub-surface mixing. The iron concentration is 1.8 mmol kg^{-1}, the sulphide 6.5 mmol kg^{-1}. The Fe/Mn ratio is close to 3, coincidentally identical to the average in ridge crest metalliferous sediments[33]. This low value, as compared with that in basalt (50–60), indicates the importance of iron oxidation in the reduction of seawater sulphate in the reaction zone. There is also a possible solubility control by pyrrhotite (FeS) although existing thermodynamic data are inadequate to be certain of this[34].

The isotopic data as well as confirming the ^{3}He/heat ratio[30], show that the substantial enrichment of CO_2 in the solutions is of mantle origin ($\delta^{13}C = -6‰$). The ^{18}O in the existing fluids[32], +1.6‰ reflects basalt equilibrium, confirming the previous results for dredged rocks and ophiolites. The isotopic composition of the dissolved strontium (ref. 35 and R.E.McD. and J.M.E., unpublished data) is essentially the same as in the basalts, 0.703. It has been realized for some time[36,37] that a large flux of non-radiogenic strontium is required to balance the river input (>0.712) and maintain the oceanic value at 0.709. The ridge component is sufficient to close this balance, resolving the problem and supporting the generality of the flux calculations.

Dispersal of hydrothermal effluent

The hot springs at 21° N are ore-transporting solutions such as are responsible for the massive sulphide deposits found in ophiolites and greenstone belts[10]. However, the abundance of springs at 21° N is apparently insufficient to produce more than small accumulations[30,31]. In addition their position in the local topography and hence in the ambient current field prevents significant local deposition of sedimentary sulphides from the plumes. The particulate sulphides and the large amounts of dissolved, divalent manganese are therefore dissipated by the general mid-depth circulation, and on oxidation in the water column precipitate out regionally contributing to the metalliferous sediments characteristic of the East Pacific Rise. During their chemical evolution in the plumes, the water column and sediments these Fe–Mn oxides must interact extensively with other elements in solution producing the diverse compositional and isotopic signatures observed[11].

While the chemistry involved in this evolution is not understood beyond the descriptive level, a significant body of information does exist on the distribution of these hydrothermal sediments in the Pacific. The original maps of Bostrom *et al.*[38] showed a pronounced asymmetry in the index Al/(Al+Fe+Mn) about the axis of the East Pacific Rise (Fig. 1). The magnitude of this ratio is inversely proportional to the abundance of the hydrothermal component which is, like the hot spring solutions and the water column, depleted in aluminium. More detailed work by Dymond[33] on the surface sediments of the south-east Pacific (Nazca Plate) confirms the southeastern lobe in Bostrom's distribution, centred on 30° S (Fig. 2). Recent work in the Tiki Basin[39], between the East Pacific Rise and the Marquesas, establishes the extent and nature of the western limb along 15° S. In both instances hydrothermal precipitates are being transported for thousands of kilometres before eventual deposition. Moreover the direction of transport is strongly dependent on latitude. The western lobe is exactly coincident with the ^{3}He plume recently identified by Lupton and Craig[40] (Fig. 3). This remarkable feature appears to originate as an intense ^{3}He maximum over the ridge axis at 15° S and propagates westwards at mid-depth with no discernable 'leakage' to the east.

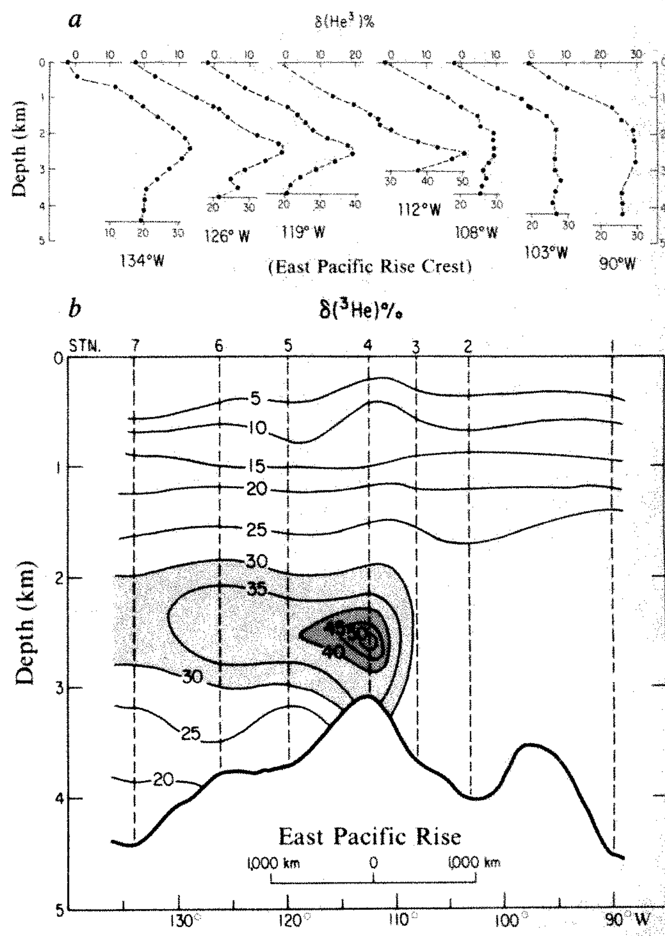

Fig. 3 δ^3He section along ~15° S in the south-east Pacific[40]. *a*, The individual profiles; *b*, the contoured values.

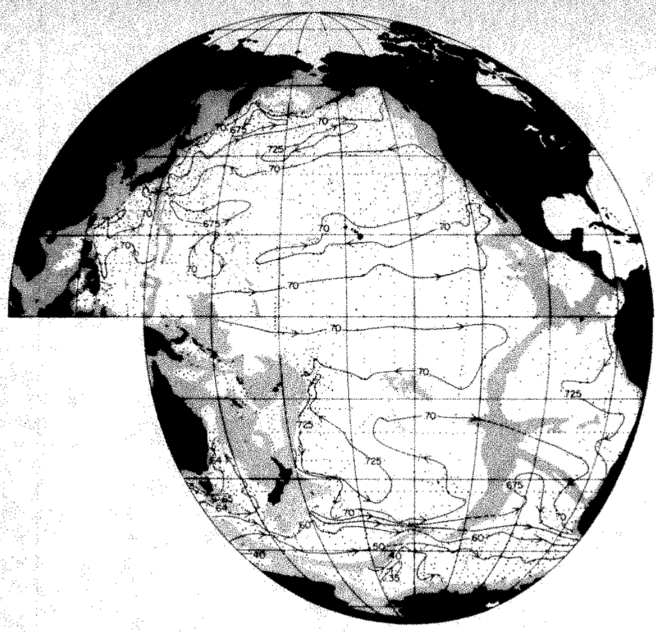

Fig. 4 Steric height at 2,000–3,500 db in dynamic metres ($10\ m^2\ s^{-2}$ or $10\ J\ kg^{-1}$) for the Pacific[42]. Shaded area is <3,500 m water depth.

These strongly developed asymmetries require a pronounced latitudinal zonality in the mid-depth circulation in the South Pacific, contrary to the predictions of the classical geostrophic models[41]. That this indeed exists has been dramatically demonstrated recently by Reid[42] who mapped the distributions of salinity, oxygen and the major nutrients on an isopycnal surface which is coincident with the ridge crest at mid-latitudes in the Pacific. He has also mapped the steric height at 2,000 db relative to 3,500 db (Fig. 4). Interpreting this measure of the relative geostrophic shear in terms of the mean flow directions (away from the western boundary) results in a circulation scheme consistent with the associated distributions of salinity and the non-conservative species[42]. Moreover comparison of the figures presented here shows the coincidence of the flow field with the distribution of metalliferous sediments and of ^3He to be exact.

The shear field in the South Pacific contains an anti-cyclonic gyre near 35–40° S. An eastwards flow leaves this gyre along 25° S in the east. There is a pronounced westwards flow along 15° S and an eastwards flow in the equatorial region. Flow over the basins east of the East Pacific Rise is generally southwards. This pattern is mirrored in the North Pacific (Fig. 4).

Of particular importance here is the circulation pattern in the region of the axis of the East Pacific Rise. Between about 5° and 15° S the flow is towards the south-southwest parallel to the rise crest. At 15–20° S the flow lines turn abruptly westwards and continue in that direction across the ocean. By 25° S the flow directions are reversed, passing east-southeast directly normal to the axis. In the extreme south-east Pacific, south of about 35° S the flow is to the north-east along the crest.

The exact concordance of the independently derived distributions of hydrothermal sediment and ^3He with the inferred flow is a remarkable demonstration of the importance of the mid-depth circulation in the dispersal of the hot spring effluents injected all along the East Pacific Rise. There are several consequences to this. First, and most obvious, the ^3He 'plume' along 15° S is but one section through a complex three-dimensional feature. The major axial anomaly results from the accumulation of ^3He injected along a flow-line almost 1,000 km in extent—the polewards flowing water above the ridge axis between 5° and 15° S. The plume is the expression of the dissipation of this anomaly along the westwards flow trajectory. The absence of any eastwards 'leakage' of ^3He is as expected. Since the extent of hydrothermal activity under the crestal station on the section (112° W) is not yet known it is not possible to separate the flow-integrating component in the ^3He maximum from any local injection. The very sharp spike of 50% δ^3He (Fig. 3) may reflect the immediate presence of a 21° N-type plume. Recent sampling on the East Pacific Rise has produced isolated ^3He anomalies of even greater magnitudes where the samplers were navigated to be immediately above known hydrothermal vents[43]. However, the broad maximum in δ^3He (35–45%) must be a regional rather than a local feature. Thus the spectacular section along 15° S does not require, of necessity, particularly vigorous hot spring activity on the axial zone beneath it. It does require that there be substantial injection of ^3He along the 5–15° S segment of the East Pacific Rise.

It should be possible to separate local from regional influences on the axial ^3He anomaly using parallel measurements of manganese[43]. As this element is rapidly removed by oxidation and sedimentation the regional $Mn/^3He$ anomaly ratio should be lower than any local one. The resolution of this approach requires much more data for its estimation as the rates of manganese removal are only crudely known[19].

Given the axial alignment of the flow between 5° and 15° S one might expect to see, in this segment, a progressive southwards increase in the abundance of metalliferous sediments accumulating as drift deposits. The data of Dymond[33] indicate this effect. While the spreading rate, a measure of the primary hydrothermal source function, increases from ~15 to 17.5 $cm\ yr^{-1}$ (ref. 44) between 5° and 15° S the percentage of hydrothermal sediments goes up by over 30% (Fig. 2) and the measured accumulation rates from 100 to >300 $mg\ cm^{-2}\ kyr^{-1}$ (ref. 31). While the latter data are sparse and the former biased by independent, systematic, latitudinal changes in the abundance of the other sedimentary components the trend is sufficiently suggestive and consistent to warrant more detailed study.

The systematics observed in the South Pacific have great potential importance in the validation of the estimates of the fluxes of hydrothermal effluents. The problem has two aspects; the generality of the computations for conservative species based on Galapagos and 21° N; the estimation of the general importance of sub-surface mixing—the average exit temperature—for the non-conservative elements. Components from either category which are unreactive in the water column at mid-depth will display an anomaly ratio to ^3He characteristic of the exit values at the hot springs. Sampling, if suitably located in the circulation field (Fig. 4), would provide values for these ratios integrated over particular segments of the ridge axis.

In the water column the concentration of a conservative species, C_A, is the sum of the background concentration, C_B, and an injected concentration, C_I:

$$C_A = C_B + C_I \tag{1}$$

The injected concentration is proportional to the injected ^3He:

$$C_I = R \times {}^3He_I \tag{2}$$

where $R = dC/d^3He$ for the discharging fluids. In terms of the 350 °C endmember:

$$R = \frac{C_{350} - C_A}{{}^3He_{350} - {}^3He_A} \tag{3}$$

Combining equations:

$$\frac{C_A - C_B}{C_A} = \left(\frac{C_{350}}{C_A} - 1\right)\frac{{}^3He_A - {}^3He_B}{{}^3He_{350} - {}^3He_A} \tag{4}$$

Recognizing that ${}^3He_{350} \gg {}^3He_A$ and that $\Delta^3He = ({}^3He_A/{}^3He_B) - 1$:

$$\frac{C_A - C_B}{C_A} = \frac{C_I}{C_A} = \left(\frac{C_{350}}{C_A} - 1\right)\frac{\Delta^3He}{{}^3He_{350}/{}^3He_B} \tag{5}$$

When C_{350} is known then the conservative value for C_I/C_A can be specified as a function of the ^3He anomaly: conversely when C_A and C_B are known at a given Δ^3He then C_{350} can be calculated.

The value for C_B is important both in determining the magnitude of the water column signature and in allowing accurate computation of the anomaly ratio. For ^{3}He, C_B is maintained at a low value because of its low solubility and relatively rapid escape from the atmosphere to space. For manganese efficient removal of the oxidized element from the water column produces the same effect. In the simplest case an average C_R can be established from work in the water column. Elements which are non-conservative in the sub-surface mixing regime will have exit concentrations which may be non-linear functions of temperature, depending on the details of the thermodynamic and kinetic responses of the precipitating phases to changing temperature, pH and so on[34]. This can be established empirically by sampling hot springs over the range of exit temperatures. It will be possible to do this at 21° N where individual hot spring occurrences have been observed spanning the range 20–350 °C. Non-conservative processes in the water column can be examined by sampling along flow lines, for example along 15° S. In principle therefore, the average fluxes from the ridge crest can be determined from work in the water column. However, a considerable amount of analytical development will be required for realizing this objective.

Conclusions

It seems that ridge crest hydrothermal activity is a pervasive and chemically relatively uniform phenomenon. The fluxes of the various elements injected into (or removed from) the ocean are substantial when compared with fluvial transport. The dispersal of this effluent is controlled by the global oceanic circulation at mid-depth. This effect allows integrated measures of effluent composition to be established from comparison of the water column anomaly ratios to ^{3}He at locations remote from the ridge axis. The sedimentary record of accumulation of precipitates of hydrothermal origin will therefore provide a history of variations in the circulation itself. This may be of some importance in palaeoclimatic studies. The internal consistency of the water column and sedimentary distributions of ridge crest effluents and the flow field validates the latter in a striking way. Maps of dynamic height for suitable depth ranges are therefore a valuable predictive tool in the planning of disposal of toxic or radioactive waste in the deep sea and in the exploration for and exploitation of mineral deposits of hydrothermal origin. For hot-spring organisms that have motile, benthic larvae it is likely that their dispersal is also controlled by the circulation field. The intriguing possibility therefore exists of a regional biogeography reflecting the latitudinal variations in the flow directions.

We thank Drs Lupton, Dymond and Reid for providing preprints and for stimulating discussions. J.M.E. thanks Dr C. Allègre for providing a place for work. This research is supported at MIT by grants from the NSF and International Decade of Ocean Exploration and from the US Office of Naval Research.

Motion of the Local Group of galaxies and isotropy of the Universe

L. Hart* & R. D. Davies

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

H I observations of 84 nearby Sbc spiral galaxies lying in the redshift range 1,000–5,500 km s^{-1} have been used to determine the motion of the Sun and the Local Group of galaxies relative to the backdrop of galaxies extending out to 70 Mpc. This study yields a Local Group velocity of 436±55 km s^{-1} towards $l = 264° \pm 18°$, $b = 45° \pm 12°$, in close agreement with the value inferred from the dipole anisotropy of the 3 K cosmic microwave background. The agreement shows that most of the dipole anisotropy is locally (extrinsically) induced and is not an intrinsic property of the Universe as has been implied. The component of the Local Group motion in the direction of the Virgo cluster is 410±55 km s^{-1}, a value similar to that derived recently by independent methods. This implies that the local value of the density of the Universe is 0.15–0.50 of that required to close the Universe.

* Present address: Instituto Argentino de Radioastronomia 1894 Villa Elisa (Prov. de Bs. As), Argentina.

0028-0836/82/200191—06$01.00

THE dipole anisotropy of amplitude ~3.5 mK in the 3 K cosmic microwave background has conventionally been interpreted as the result of the motion of the Sun at a velocity of ~400 km s^{-1} towards RA ~11.4 h, dec. ~5° (refs 1–3). When correction is made for the motion of the Sun relative to the centre of mass of the Local Group of galaxies, the resulting velocity of the Local Group becomes 550 km s^{-1} towards galactic coordinates $l=265°$, $b=35°$ (supergalactic coordinates $L=128°$, $B=-36°$). However, with the available observational data it is by no means certain that the dipole asymmetry in the cosmic microwave background is locally (that is, extrinsically) induced by the motion of the Sun and the Local Group. Dipole and higher order intrinsic asymmetries on the cosmic background have been proposed to explain the microwave observations. For example, Silk and Wilson[4] predict asymmetries arising from large-scale fluctuations in matter and radiation in the early Universe while Peebles[5] estimates that gravitational potential fluctuations induced by large-scale clustering could produce the observed large-scale asymmetries.

The suggestion that the microwave dipole asymmetry is largely intrinsic arises from the lack of agreement between the Local Group velocity inferred from the microwave measurements and that obtained from measurements of the motion of the Local Group relative to the backdrop of nearby galaxies. The most widely quoted and systematic search for this motion has been made by Rubin *et al.*[6,7] who found a motion for the Local Group of 450 km s^{-1} towards $l=163°$, $b=-11°$, a direction almost orthogonal to that given by the cosmic microwave asymmetry.

A genuine difference between the apparent motion of the Local Group relative to the microwave background and that relative to the backdrop of nearby galaxies has fundamental implications for cosmology. One possible consequence already alluded to is that the microwave background dipole asymmetry may be due to an intrinsic anisotropy[4,5,8]. Alternatively, if the microwave background is intrinsically isotropic and the dipole asymmetry is the result of the Local Group motion, then the implication is that the whole body of galaxies out to a radius of 90 Mpc is in systematic motion relative to the microwave background with a velocity of 750 km s^{-1}. Such large departures from a uniform Hubble flow are not, however, generally accepted[9]. The situation regarding a possible genuine difference between the Local Group motion determined by these two methods has not yet been resolved[10,11], particularly as different optical solutions for the Local Group motion have been published elsewhere[12–14].

We present here a new approach to deriving the Local Group motion relative to the backdrop of galaxies based on 21-cm wavelength H I observations alone, which obviates many of the difficulties in the optical determinations. Two independent H I data sets each give a Local Group motion in close agreement with that inferred from the dipole anisotropy in the 3K cosmic microwave background. The implications of these results for cosmology are discussed.

Rationale and observational material

The rationale behind our approach to measuring the Local Group motion was to use for distance measurement an H I standard candle independent of the optical methods which gave results disagreeing among themselves. The H I mass (proportional to the integrated H I flux density F_H) provides a standard candle and the half power velocity width $\Delta V_{1/2}$ of the integrated H I spectrum provides a third variable which indicates whether the galaxy is a giant or a dwarf. The H I integral is easily measured and calibrated in an all-sky survey and does not require the substantial corrections for galactic absorption, internal absorption, luminosity class, zenith angle, diameter and so on, which are applied to optical data. A detailed discussion of the observations and the selection criteria will be given elsewhere. However, we mention here that the dispersion in the H I mass of the sample of galaxies used in the present work is similar to the dispersion in the optical luminosity, when these properties are plotted against radius, luminosity class and so on. Ultimately we hope to use, H I, optical and IR data to obtain a composite distance indicator.

The objective of this programme of observations was to obtain a first-order solution for the local group motion using an optimal selection of galaxies whose motions were not seriously influenced by the gravitational potential of the Virgo cluster. Accordingly galaxies were chosen with velocities in the range 1,000–5,500 km s^{-1}; the small fraction of these galaxies likely to be most affected by the Virgo cluster were then eliminated from the list. A good sky coverage was achieved for galaxies in each velocity interval.

The galaxies used in this investigation were chosen from the list of 100 spiral galaxies of type Sbc (de Vaucouleurs type $T=4$) being studied in the λ21-cm line of neutral hydrogen at Jodrell Bank in a programme including optical, radio continuum and X-ray observations. These are essentially all the Sbc galaxies in the Second Reference Catalogue of galaxies[15] (RC2) for which luminosity classes have been assigned and for which the velocity, V_c, corrected for a solar motion of 300 km s^{-1} towards $l=90°$, $b=0°$ is $>1,000$ km s^{-1}. Most were of luminosity classes 1 to 4. H I observations have been made by Davies and Johnson (manuscript in preparation) of the integrated H I flux F_H, the full velocity width at half-power $\Delta V_{1/2}$ of the integrated profile and the systemic velocity V_c of each galaxy. To obtain a full coverage of the sky, the list was augmented by 12 galaxies at declinations south of dec. = −33° taken from a survey of bright southern galaxies by H. van Woerden *et al.* made at the Australian National Radio Astronomy Observatory (ANRAO), Parkes, New South Wales. The neutral hydrogen flux density scale of the latter survey was tied into the Jodrell Bank scale by comparing 18 galaxies

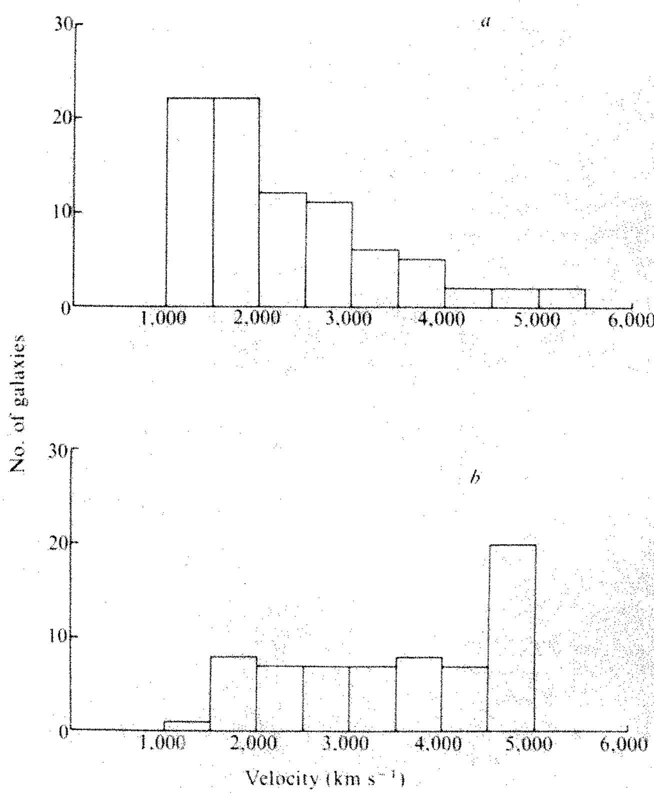

Fig. 1 The velocity distribution of galaxies used in the analysis of the Local Group motion. Velocities have been corrected by the standard solar motion towards the Local Group of 300 km s^{-1} towards $l=90°$, $b=0°$. Velocities $<1,000$ km s^{-1} have not been used. *a*, Sbc ($T=4$) galaxies from the Jodrell Bank sample supplemented by southern galaxies observed at ANRAO. *b*, Sc ($T=5$) galaxies from the Rubin *et al.* sample supplemented by southern galaxies; only galaxies with velocities $<5,000$ km s^{-1} are used.

Table 1 Observations of the motion of the Sun and the Local Group of galaxies

Method	Velocity of the Sun					Velocity of the Local Group*					
	$V_\odot$ (km s^{-1})	RA (h)	dec. (°)	l (°)	b (°)	V_{LG} (km s^{-1})	l (°)	b (°)	L (°)	B (°)	No. of galaxies
(1) H I fluxes: Sbc galaxies ($1{,}000 < V_c < 5{,}500$ km s^{-1}, $i > 30°$)	314 ±50	12.9 ±0.7	10 ±12	309 ±35	73 ±12	383 ±50	256 ±18	52 ±16	110 ±16	−27 ±14	84
(2) H I fluxes: Sbc galaxies (as for 1, but excluding high Virgo-centric velocities)	310 ±55	12.3 ±0.7	30 ±12	192 ±60	83 ±12	436 ±55	264 ±18	45 ±12	119 ±14	−29 ±12	78
(3) H I fluxes: Sc galaxies ($1{,}000 < V_c < 5{,}000$ km s^{-1})	419 ±62	10.2 ±0.6	19 ± 9	218 ±15	53 ± 9	580 ±62	245 ±18	35 ± 9	111 ±13	−45 ± 9	53
(4) Optical luminosity: Sbc galaxies	350 ±40	7.8 ±1.8	56 ±16	162 ±20	31 ±16	397 ±90	216 ±20	27 ±15	72 ±28	−55 ±16	79

(7) Average of 2+3+5+6‡ (best estimates of motion)	368 ±50	11.5 ±0.5	15 ±12	243 ±30	68 ±12	546 ±70	261 ± 9	39 ± 7	122 ± 9	−35 ± 7	

* The solar motion relative to the Local Group of galaxies is taken to be 300 km s^{-1} towards $l = 90°$, $b = 0°$.
† The microwave background temperature is assumed to be 2.7 K: velocities are reduced by ~40 km s^{-1} for 3.0 K.
‡ Methods 2 and 3 are combined with weights 2 : 1.

common to the two lists. F_H and $\Delta V_{1/2}$ are accurate to better than 10% and V_c was accurate to 20 km s^{-1} or better for all the galaxies. The edge-on velocity width of each velocity profile, $\Delta V_{1/2}$ cosec $i = \Delta V_0$, was estimated using the inclination, i, of each galaxy derived from the axial ratio given in RC2 and an assumed intrinsic thickness-to-diameter ratio of 0.2.

Derivation of motion of the Local Group

This analysis is based on the use of the neutral hydrogen mass of a galaxy as a standard candle and using ΔV_0 as a third variable. The use of ΔV_0 in this analysis is similar to using the Fisher–Tully relation for optical distance determination.

In the analysis we take the observed velocity of a galaxy, V_c, corrected to the centre of the Local Group, to be composed of the following components

$$V_c = V_H + \Delta V_G + V_{pec}$$

where V_H is the velocity it would have in participating in the universal Hubble flow, ΔV_G is the component in the direction of the galaxy of the velocity of the Local Group relative to the backdrop of galaxies, and V_{pec} is the random velocity of the galaxy. V_H determines the true distance of the galaxy. We are interested to determine, from a series of expressions of this form, the vector V_G giving the velocity of the Local Group relative to the backdrop of Sbc galaxies. An estimate of the true distance of each galaxy, and hence V_H, is provided by its measured (apparent) H I flux density F_H where $F_H = M_H/D^2$, M_H is the H I mass and D is the distance.

Our first analysis follows the approach of Rubin *et al.*, where we express the difference in redshift distance and luminosity distance in terms of an H I Hubble modulus, HM, analogous to their optical HM in which

$$HM = 2 \log V_c - a \log \Delta V_0 + \log F_H \tag{1}$$

where a is the index of the calibration relation $M_H \propto \Delta V_0^a$. Then for each galaxy

$$\begin{aligned} -\mathbf{\Delta V}_G &= V_c - V_H - V_{pec} \\ &= V_c - 10^{1/2(\langle HM\rangle + a \log \Delta V_0 - \log F_H)} - V_{pec} \end{aligned} \tag{2}$$

We can use $\langle HM \rangle$, the average value of HM, and assume that V_{pec} is randomly distributed so that its expected value is zero to obtain a set of linear equations of the form

$$\begin{aligned} \mathbf{\Delta V}_{Gi} &= l_i X + m_i Y + n_i Z \\ &= V_c - 10^{1/2(\langle HM\rangle + a \log \Delta V_{0i} - \log F_{Hi})} \end{aligned} \tag{3}$$

which relates $\mathbf{\Delta V}_{Gi}$ to observed quantities where X, Y and Z are the components of the Local Group motion and l_i, m_i and n_i are the direction cosines of the ith galaxy. A least-squares solution of this over-determined set of equations gives an estimate of the vector $\mathbf{V}_G$.

A second and more rigorous statistical approach is to treat this as a well-defined non-linear minimization problem. We take the relation between M_H and ΔV_0 to be of the form

$$M_H = b\, \Delta V_0^a \tag{4}$$

M_H is related to the observed integrated flux density by $M_H = \text{const}\, F_H \cdot V_H^2$ where V_H is the Hubble velocity representing the true distance as defined above. Accordingly an estimate of V_H is

$$V_H = C\, \Delta V_0^{a/2} F_H^{1/2} \tag{5}$$

In the analysis V_{pec} is assumed to be normally distributed with a mean value of zero. The quantity to be minimized in determining the Local Group motion (X, Y, Z) is

$$\begin{aligned} \sum V_{pec\,i}^2 &= \sum [V_{ci} - (V_{Hi} + l_i X + m_i Y + n_i Z)]^2 \\ &= \sum [V_{ci} - c\, \Delta V_{0i}^{a/2} F_{Hi}^{-1/2} - (l_i X + m_i Y + n_i Z)]^2 \end{aligned} \tag{6}$$

The minimization is performed with respect to a, C, X, Y and Z. The solutions obtained by this more rigorous method agree well with those using the first method thereby indicating that the details of the analysis procedures are not too important for this set of data.

The main analysis described here is based on 84 Sbc galaxies with an inclination $i > 30°$ ($i = 0°$ for face-on galaxies) and $V_c > 1{,}000$ km s^{-1}. Figure 1*a* gives the velocity spread of the galaxies used in this analysis; the median velocity is 1,800 km s^{-1}. For galaxies more face-on than $i = 30°$ the inclination, and hence $\Delta V_{1/2}$ cosec i, becomes more uncertain. By making solutions for the Local Group motion with different cutoff values of i, we find that they are not strongly dependent on the cutoff value.

The motion found for the Local Group is 383 ± 50 km s^{-1} towards $l = 256° \pm 18°$, $b = +52° \pm 16°$ (supergalactic coordinates $L = 110° \pm 16°$, $B = -27° \pm 14°$). This solution corresponds

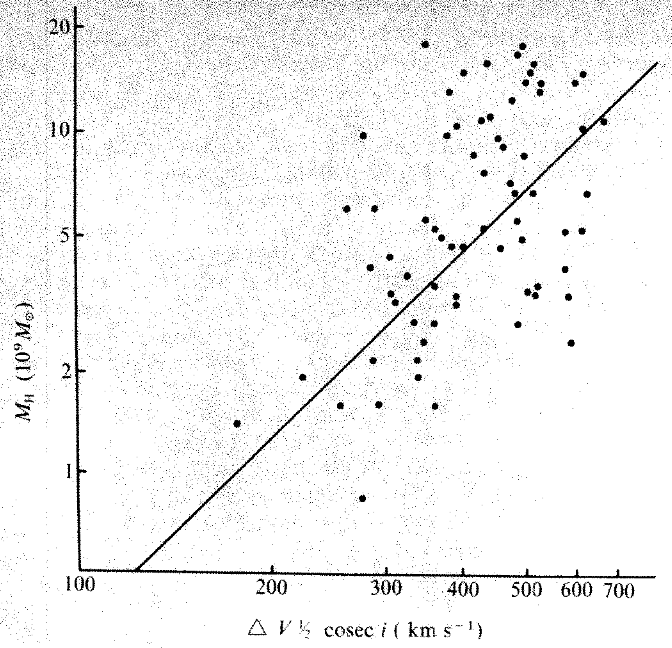

Fig. 2 The correlation between the neutral hydrogen mass M_H of Sbc ($T=4$) galaxies and their profile widths $\Delta V_{1/2}$ cosec i. $\Delta V_{1/2}$ is the width at half-power and i is the inclination of the galaxy. M_H is the neutral hydrogen luminosity indicator used in the solution for the Local Group motion. $M_H = F_H D^2$ where F_H is the integrated flux density and D is the distance in Mpc.

to a solar velocity of 314 ± 50 km s^{-1} towards RA = 12.9 h ± 0.7 h, dec. = 10° ± 12° (galactic coordinates l = 309° ± 35°, b = 73° ± 12°). The standard motion of the Sun relative to the Local Group of galaxies of 300 km s^{-1} towards l = 90°, b = 0° is used throughout.

Figure 2 shows the correlation between the neutral hydrogen luminosity of each galaxy, expressed as the total mass of neutral hydrogen, $M_H = F_H \cdot D^2$, plotted as a function of the observed profile width, ΔV_0, corrected for inclination. This correlation was obtained from the fitting procedures described above and yields a value of $a = 1.85 \pm 0.25$. Essentially each galaxy in Fig. 2 is placed at its 'true' redshift distance D based on the observed redshift and the derived value of the solar motion.

An indication of the validity of the analytical solution for the Local Group motion obtained here can be obtained by simply plotting as a function of supergalactic longitude L the difference between the observed redshift and the luminosity distance expressed as a redshift. Because the Local Group motion is in a direction close to the supergalactic plane this plot should show a sinusoidal variation of velocity difference with longitude. The amplitude plotted in Fig. 3 is 436 km s^{-1} directed towards L = 119°. The plot includes only the galaxies with $1{,}000 < V_c < 3{,}200$ km s^{-1} and supergalactic latitude $|B| < 50°$. The full solution in Table 1, of course, includes all the galaxies in the sample with $V_c > 1{,}000$ km s^{-1} and covers the whole sky.

It is relevant at this stage to comment on the possible effects on the solutions for the Local Group motion of Malmquist bias[6,16] in which the more distant galaxies in a magnitude limited sample tend to have higher intrinsic luminosity (or H I mass in our case). A plot of M_H against redshift shows only a weak Malmquist bias, largely because the galaxies in both the Sbc and Sc samples have a restricted luminosity class, corresponding to a restricted range of luminosity or H I mass. This latter property is illustrated by the small (~a factor of 2) range of ΔV_0 seen in Fig. 2. More important, the effects of any residual bias in the data are removed if there is a uniform distribution of galaxies in redshift around the sky; our galaxies satisfy this criterion. Further, the effects of Malmquist bias are also largely eliminated by the use of a third variable, ΔV_0, in our case. We are confident that the effects of Malmquist bias do not seriously affect our solution for the Local Group motion. This is confirmed by the fact that we obtain similar solutions for the Sbc and Sc galaxies and by using galaxies at different redshifts. These important matters will be discussed in more detail elsewhere.

The Virgo cluster of galaxies probably had a significant influence on the motion of the galaxies lying in the neighbourhood of the cluster; indeed we shall argue below that the Virgo cluster is responsible for the major part of the Local Group motion. Two solutions have been made using different criteria for excluding galaxies influenced by the Virgo cluster. In the first, members of the Virgo cluster are excluded; the Local Group is found to move at 434 km s^{-1} towards l = 262°, b = 52°. In the second, those galaxies with a line of sight component of Virgo-centric infall velocity greater than our own are eliminated; the Local Group is then found to move at 436 km s^{-1} towards l = 264°, b = 45°. We consider this to be our best estimate of the Local Group motion based on the H I observations of Sbc galaxies.

A value for the Local Group motion has also been derived from the optical data for the Sbc galaxies using an approach of minimum sophistication. The blue luminosities in RC2 were used as standard candles using the velocity width ΔV_0 as a third variable as for the H I analysis. This solution has lower precision than that obtained from the H I data; the solution is 397 ± 90 km s^{-1} towards l = 216° ± 20°, b = 27° ± 15°, a value similar to the H I result.

A completely independent data set is available for an analysis identical to that performed on our Sbc H I data. Rubin *et al.*[6] give H I parameters and plot H I spectra for a substantial fraction of their list of Sc galaxies. We have used all their galaxies with $1{,}000 < V_c < 5{,}000$ km s^{-1} and supplemented them with southern Sc galaxies from van Woerden *et al.* (in preparation) to provide a full sky coverage. Figure 1*b* shows the velocity distribution of this set of galaxies. The 53 Sc galaxies in this combined data set give a solution for the Local Group motion of 580 km s^{-1} towards l = 245°, b = 35°. This motion is consistent with the result obtained for the Sbc galaxies.

The results obtained from the present study are compared in Table 1 and Fig. 4 with the motion of the Sun and the Local Group relative to the microwave background derived on the assumption that the dipole anisotropy is entirely the result of solar motion. For a microwave background temperature of 2.7 K (ref. 17), the mean of the recent dipole determinations by Boughn *et al.*[2] and by Gorenstein and Smoot[1] implies a solar motion of 410 ± 45 km s^{-1} towards RA = 11.4 h ± 0.3 h and dec. = 3° ± 15° (l = 259°, b = 58°). The corresponding motion of the Local Group is 620 ± 50 km s^{-1} towards l = 265° ± 9°, b = 35° ± 7° (L = 128°, B = −36°). If the microwave background temperature is 3.0 K (ref. 18) instead of 2.7 K the solar velocity is reduced to 370 km s^{-1} towards l = 259°, b = 58° and the Local

Table 2 Component of the motion of the Local Group towards the Virgo cluster*

Method	Velocity (km s^{-1})	Ref.

(2) 2.7 K cosmic microwave background, dipole anisotropy	450±50†	1, 2
(3) Four nearby clusters in IR with Fisher–Tully correction	480±75	23
(4) E galaxies in and around the Virgo cluster	470±75	24
(5) Mean value of methods 1, 2, 3, 4	447±40	

* The Virgo cluster is assumed to be centred at l = 280.4°, b = 74.6° (L = 102.2°, B = −3.0°). See ref. 26.

† Value for a background temperature of 2.7 K; the value is 430 km s^{-1} for a background temperature of 3.0 K.

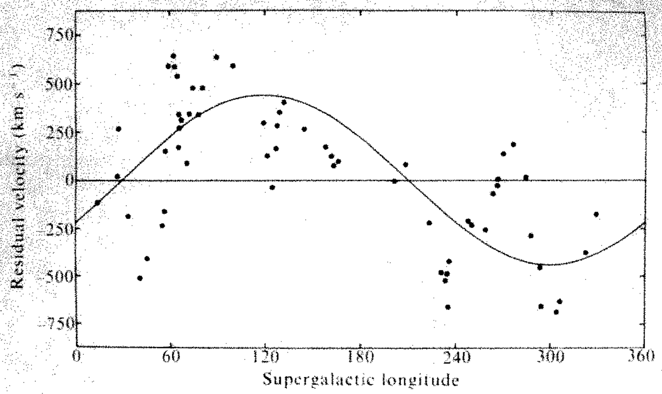

Fig. 3 The velocity residual between the luminosity distance of Sbc ($T=4$) galaxies estimated as a redshift and the observed redshift plotted as a function of supergalactic longitude, L. Only galaxies with $1{,}000 < V_c < 3{,}500$ km s^{-1} and within 50° of the supergalactic plane are included. The velocity residual shows a sinusoidal variation with L which is a consequence of the Local Group motion towards $L \sim 120°$. The sinewave plotted is that expected for a velocity of 436 km s^{-1} towards $L = 119°$, the solution found from a full analysis of all the Sbc galaxies; it is not a fit to plotted points alone—see text.

Group velocity reduces to 580 km s^{-1} towards $l = 266°$, $b = 32°$. The magnitude and direction of the solar motion determined from the H I observations of Sbc and Sc galaxies agree with the microwave dipole values to within two standard deviations (s.d.) of the combined errors.

The present results emphasize the disagreement between the Rubin *et al.* optical result[6,7] and that obtained from the microwave background measurements. The agreement found here between the determination based on H I data for the Rubin *et al.* galaxies and the other results in Table 1 confirms that the optical data base or the reduction procedures of Rubin *et al.* are in error[11,19]. Note that de Vaucouleurs and colleagues[12-14] find a solution for the solar motion calculated relative to the backdrop of spiral galaxies which is similar to our optical result. However, their solution is displaced by 4 s.d. from the statistically more accurate H I solutions which we believe are representative of the backdrop of galaxies since the H I sample is relatively free of contamination by galaxies whose velocities may be strongly affected by the Virgo cluster. The de Vaucouleurs galaxy samples on the other hand include ~30% with heliocentric velocities <1,000 km s^{-1} and a substantial number (~10%) of Virgo cluster members.

Consequences of Local Group motion

The close agreement between the velocity of the Local Group calculated relative to the backdrop of nearby galaxies and that derived from the 3 K cosmic microwave background dipole anisotropy argues strongly that the anisotropy is produced by the Local Group motion. This agreement is all the more significant as the velocity is directed to within 35° of the Virgo cluster ($l = 280°$, $b = 75°$, $L = 102°$, $B = -3°$) which is likely to have a major influence on the motion of the Local Group. The mean value of the motion derived from the two recent and independent microwave background results and from the two H I results is 546 ± 70 km s^{-1} towards $l = 261° \pm 9°$, $b = 39° \pm 7°$ ($L = 122° \pm 9°$, $B = -35° \pm 7°$). We consider that this is the best estimate of the Local Group motion available.

It is still possible that a fraction of the 3 K dipole anisotropy is intrinsic. An estimate of this intrinsic anisotropy can be derived from the velocity difference between the Local Group motion calculated relative to the backdrop of galaxies and that relative to the 3 K microwave background. The velocity difference is 130 ± 70 km s^{-1} for an assumed microwave background temperature of 2.7 K or 90 ± 65 km s^{-1} for 3.0 K. The corresponding difference amplitudes of the dipole component are 1.3 ± 0.7 and 0.9 ± 0.7 mK or 26–37% of the observed dipole anisotropy of ~3.5 mK.

Our present results therefore rule out the possibility that most of the cosmic background dipole anisotropy is intrinsic[4,5,20] and is due to an anisotropic cosmology or a large scale anisotropic matter distribution in the Universe. The relatively small velocity difference between the microwave background and the backdrop of galaxies implies much lower amplitude long-range galaxy correlations than suggested by Clutton-Brock and Peebles[8]. Further, our results raise some doubt about whether the tentative detections of some quadrupole components in the microwave background can be interpreted in terms of the anisotropic models of Silk and Wilson[4] or of Peebles[5]. Silk and Wilson predict quadrupole components which are 3×10^{-1} to 10^{-3} of the dipole component depending on the index of the power-law fluctuation spectrum; Peebles predicts a ratio of 3×10^{-1}. Our limit on the intrinsic dipole anisotropy apparently indicates that some reported quadrupole components are comparable with or greater than the intrinsic dipole component in disagreement with the above predictions.

Component of velocity towards the Virgo cluster

An evaluation of the component of the Local Group motion towards the Virgo cluster provides a means[21,22] of estimating the density of the Universe. Several estimates of this Virgocentric motion are already available; these will be compared and combined with the present determination of the Virgocentric motion.

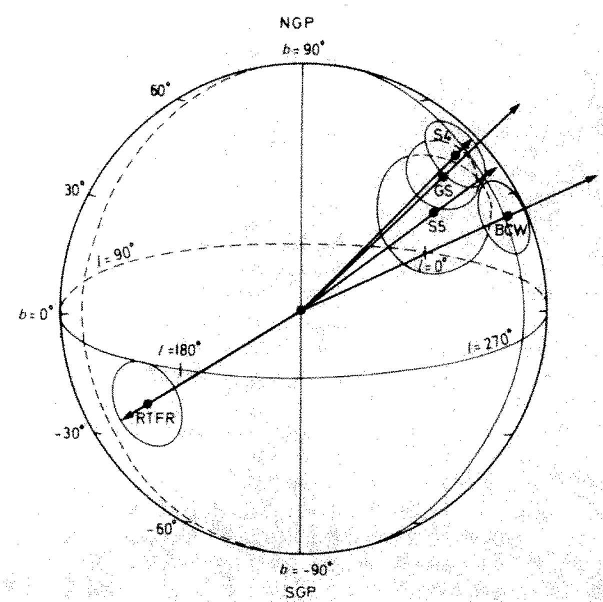

Fig. 4 Various solutions for the motion of the Local Group of galaxies plotted as vectors in galactic coordinates. Each solution is shown as a velocity with the appropriate length and with an error in angle described by a small circle on the surface of the celestial sphere. The vectors are coded as follows; S4, the Sbc ($T=4$) H I data of the present study; S5, the Sc ($T=5$) H I of the present study; GS, the microwave background dipole anisotropy from Gorenstein and Smoot; BCW, the microwave anisotropy from Boughn, Cheng and Wilkinson; RTFR, the Sbc galaxy optical data of Rubin *et al.* The agreement between the microwave background results and the H I results are evident. The Rubin *et al.* results are clearly discordant. The centre of the Virgo cluster lies at $l = 280°$, $b = 75°$ (from ref. 26).

The H I solution for the Sbc and Sc galaxies and for the microwave background give a Virgo-centric component of Local Group motion of ~ 450 km s^{-1} (Table 2). Another estimate of high precision (>5 s.d.) comes from work of Aaronson *et al.*[23] who used IR fluxes of individual galaxies corrected by the Fisher–Tully relation in four nearby clusters at redshifts in the range 4,000–6,000 km s^{-1}. Tonry and Davis[24] determined the Virgo-centric velocity from a study of E galaxies in and around the Virgo cluster. There is remarkably good agreement between these four high accuracy results.

Other estimates of the Virgo-centric motion[9,19,25] are available with lower quoted accuracy. Some of these refer to nearby galaxy samples which may themselves be influenced by the gravitational potential of the Virgo cluster. We consider that these results are not in serious agreement with the adopted Virgo-centric infall velocity of 447 ± 50 km s^{-1}.

Finally, we comment on the component of Local Group motion which is orthogonal to the direction of the Virgo cluster. The best estimate of the motion of the Local Group of 546 km s^{-1} towards $l = 261° \pm 9°$, $b = 39° \pm 7°$ (Table 1) is in a direction lying outside the errors of measurement of direction given by Sandage and Tammann[26] for the centre of luminosity of the Virgo cluster at $l = 280°$, $b = 75°$. Assuming that this is also the mass centre of the Virgo cluster, the difference in direction may be interpreted as the result of a component of motion in a direction orthogonal to the line of sight to the Virgo cluster. This motion is 320 ± 70 km s^{-1} towards $l \sim 254°$, $b \sim -14°$. Taken at its face value this motion is a 4.5 s.d. result for a Hubble flow departure in a velocity of 2,500 km s^{-1}, the mean of the Sbc and Sc galaxies. Such a motion provides a deviation $\Delta H_0/H_0$ in the Hubble flow of $320/2{,}500 = 0.13$ and is not at variance with the known departures[27] from the mean Hubble flow. However, the major component (300 km s^{-1}) of this orthogonal motion is directed towards the supergalactic plane and may be the result of collapse onto the flattened Virgo supercluster mass distribution[28]. The resultant motion in the Supergalactic plane perpendicular to the Virgo direction would be 100 km s^{-1} leading to $\Delta H_0/H_0 = 0.04$ for the random motion of the Local Group.

Virgo-centric motion and estimates of Ω and q_0

The evidence from the dipole anisotropy in the microwave background and the motion of the Sun relative to the backdrop of nearby galaxies strongly suggests that the Local Group is falling towards the centre of the Virgo cluster at a velocity of 447 ± 40 km s^{-1}. Such a departure from the Hubble flow of the Universe can be used to derive a local value for the deceleration parameter q_0 and for the ratio, Ω ($= 2q_0$ for Friedmann cosmologies), of the local density to the closure density of the Universe[19–22,24,29,30]. The calculation of q_0 and Ω requires an estimate of the density enhancement δ in the Virgo cluster relative to that in the smoothed-out Universe. Yahil *et al.*[29,30] find $\delta = 3.5 \pm 0.4$ while Davis *et al.*[31] find a value of 2.0 ± 0.3 from a different sample of galaxies. A detailed treatment[22,31] of the peculiar velocity v_p produced by a spherically symmetric density distribution gives, from a linear perturbation analysis,

$$\Omega = \left(\frac{3v_p}{\delta(v_p + v_{VC})}\right)^{1.67} \qquad (7)$$

where v_{VC} is the Virgo cluster velocity relative to the Local Group and is taken as 1,060 km s^{-1}. This yields a value of $\Omega = 0.10$–0.26 for $v_p = 447$ km s^{-1} and δ in the range 2–3.5. Using the results of a more exact non-linear calculation[31] we find $\Omega = 0.18 \pm 0.04$ to 0.39 ± 0.11 for this range of δ. Clearly the high value of the peculiar Virgo-centric velocity found in the present results and in the microwave background results implies a value of local density approaching the closure density, with $\Omega = 2q_0 = 0.15$–0.50 where the higher values correspond to the lower value of density enhancement ($\delta = 2$) in the Virgo cluster. Although this high value of Ω has been found for the local region of the Universe, essentially the local supercluster, there is no reason to believe that it is in any way different from the Universe at large. The infall velocity from which it is derived is the result of an acceleration acting over the age of the Universe.

Conclusion

The present observations demonstrate the use of a method of obtaining the statistical distances of spiral galaxies using H I data alone, namely H I fluxes and profile velocity widths. This method seems to be comparable in accuracy with related optical methods and has the advantage of requiring fewer correction factors. When applied to the determination of the motion of the Local Group of galaxies relative to the backdrop of nearby Sbc galaxies the method gives a velocity of 436 ± 55 km s^{-1} towards $l = 264° \pm 18°$, $b = 45° \pm 12°$, in agreement with the velocity implied by the dipole anisotropy in the 3 K cosmic microwave background.

The agreement between the motion of the Local Group determined relative to the nearby galaxies and that inferred from the microwave background is of fundamental significance. It implies that the major part at least of the dipole anisotropy is extrinsic, due to the Local Group motion, and is not intrinsic as implied in some cosmologies. The maximum intrinsic dipole anisotropy allowed by the combined data is ~ 1 mK, indicating that $\Delta T/T \leq 3 \times 10^{-4}$ for any intrinsic dipole anisotropy in the temperature distribution of the early ($z \sim 1{,}500$) Universe. The claimed quadrupole anisotropy[2] cannot then be the result of the processes envisaged by Silk and Wilson[4] and by Peebles[5].

The Virgo-centric velocity of the Local Group of galaxies is now well-determined from several independent methods. The inferred local values of q_0 and Ω depend on the assumed model of the mass density distribution in the Virgo cluster. In any case, high values of Ω (0.15–0.50) are implied by the observed Virgo-centric velocity. Such values, if applicable to the Universe as a whole, will produce a significant deceleration of the expansion of the Universe.

We thank Mr S. C. Johnson for discussions regarding the H I data base and Dr A. N. Lasenby regarding statistical techniques, also Professor H. van Woerden for supplying in advance of publication the southern H I data.

Testing the theory of evolution by comparing phylogenetic trees constructed from five different protein sequences

David Penny*, L. R. Foulds† & M. D. Hendy‡

* Department of Botany and Zoology, and ‡ Department of Mathematics and Statistics, Massey University, Palmerston North, New Zealand
† Operations Research, University of Canterbury, Christchurch, New Zealand

The theory of evolution predicts that similar phylogenetic trees should be obtained from different sets of character data. We have tested this prediction using sequence data for 5 proteins from 11 species. Our results are consistent with the theory of evolution.

THE theory of evolution continues to be a focus for nearly all biological thought. Nevertheless, there have been doubts about the philosophical status of the theory, particularly on the extent to which it can be tested or falsified. The best known of these doubts have been expressed by the leading philosopher on scientific method, Karl Popper[1], who concluded that "darwinism is not a testable scientific theory, but a 'metaphysical research program'—a possible framework for testable scientific theories". Popper did not in any way reject evolution. He pointed out (ref. 1, p. 169) that "no serious competitor has come forward" and commented on "the strange similarity between my theory of the growth of knowledge and darwinism". In particular, he suggests that only one prediction is possible from darwinism: "Gradualism is thus, from a logical point of view, the central prediction of the theory. (It seems to me that it is the only prediction.)" (ref. 1, p. 172).

Popper has recently modified these criticisms[2], pointing out that criticisms by some authors were inconsistent, such as that natural selection is a tautology, and that it explains too much. A tautology explains nothing, so cannot simultaneously explain "too much". In addition, the suggestion was made that the existence of an evolutionary tree was falsifiable, but no reasoning was given for this new opinion.

These criticisms have aroused considerable interest[3-5]. Most of the discussion has, however, been qualitative, so it would be useful to be able to make quantitative tests. This is the purpose of the present article.

Popper makes the important distinction between the existence of an evolutionary tree (an evolutionary history) and the mechanism of evolution put forward to explain the processes that produced that history. Here we present a programme, applying graph theory[6,7], by which it is theoretically possible to refute the existence of an evolutionary tree.

Another prediction from evolution

It has been long been considered that protein sequence data contain evolutionary information[8]. In particular, the tree of minimal length (minimum number of mutations, maximum parsimony) makes no assumptions about the mechanism of evolution, and has been widely used as a model for evolutionary relationships[9-11]. Given any comparative data, irrespective of origin, one can construct trees of an evolutionary form, and hence a minimal tree must exist. So in general, finding a minimal tree for protein sequence data is not in itself independent evidence for the existence of an evolutionary tree.

However, another prediction can be made if there has been an evolutionary tree and if the maximum parsimony model is a good predictor of that tree. The prediction is that minimal trees with the same taxa should be similar, or 'congruent'[12], when constructed from different protein sequences. We need a measure of tree similarity having biological significance so that the values can be compared with the hypothesis that the trees are randomly selected. Such a measure is described below.

Our strategy is to take different protein sequences for a common set of taxa, find all the minimal (and near minimal) evolutionary trees and then compare them. Should the probability be high that these trees are unrelated, this would indicate that the protein sequences do not contain similar evolutionary information, and hence would contradict the existence of an evolutionary tree for those taxa.

We conclude that the existence of an evolutionary tree for these taxa is a falsifiable hypothesis, and therefore meets Popper's criteria for scientific theories. In addition, our methods allow us to identify a consensus tree which incorporates the most common features of all the near minimal trees.

Finding minimal evolutionary trees

It is easily shown that any minimal evolutionary tree can be represented by a binary tree. Using the double factorial notation (!!) there are $(2n-5)!! = 1\times3\times5\ldots\times(2n-5)$ unrooted binary trees spanning n sequences[13,14]. To determine the trees of maximum parsimony (minimal length), one must potentially consider a vast number of different tree topologies. But for all but a small number of sequences ($n \leq 8$), present day computers cannot consider them all[10].

Table 1 The frequency $p(m, n)$ of occurrence of $d(Ti, Tj) = m$ for binary trees spanning n taxa $4 \leq n \leq 11$

	$m=0$	2	4	6	8	10	12	14	16	$E(n)$
$n=4$	3.3×10^{-1}	6.7×10^{-1}								1.34
5	6.7×10^{-2}	2.7×10^{-1}	6.7×10^{-1}							3.20
6	9.5×10^{-3}	5.7×10^{-2}	2.4×10^{-1}	7.0×10^{-1}						5.24
7	1.1×10^{-3}	8.5×10^{-3}	4.6×10^{-2}	2.2×10^{-1}	7.3×10^{-1}					7.32
8	9.6×10^{-5}	9.6×10^{-4}	6.5×10^{-3}	3.8×10^{-2}	2.0×10^{-1}	7.5×10^{-1}				9.40
9	7.4×10^{-6}	8.9×10^{-5}	7.0×10^{-4}	4.8×10^{-3}	3.1×10^{-2}	1.9×10^{-1}	7.7×10^{-1}			11.46
10	4.9×10^{-7}	6.9×10^{-6}	6.2×10^{-5}	4.8×10^{-4}	3.6×10^{-3}	2.7×10^{-2}	1.8×10^{-1}	7.9×10^{-1}		13.52
11	2.9×10^{-8}	4.6×10^{-7}	4.7×10^{-6}	4.0×10^{-5}	3.3×10^{-4}	2.8×10^{-3}	2.3×10^{-2}	1.7×10^{-1}	8.1×10^{-1}	15.55

$E(n) = \Sigma\, mp(m, n)$ is the weighted mean or 'expected value' of $d(Ti, Tj)$ for randomly selected binary trees Ti, Tj spanning n taxa.

0028-0836/82/200197—06$01.00

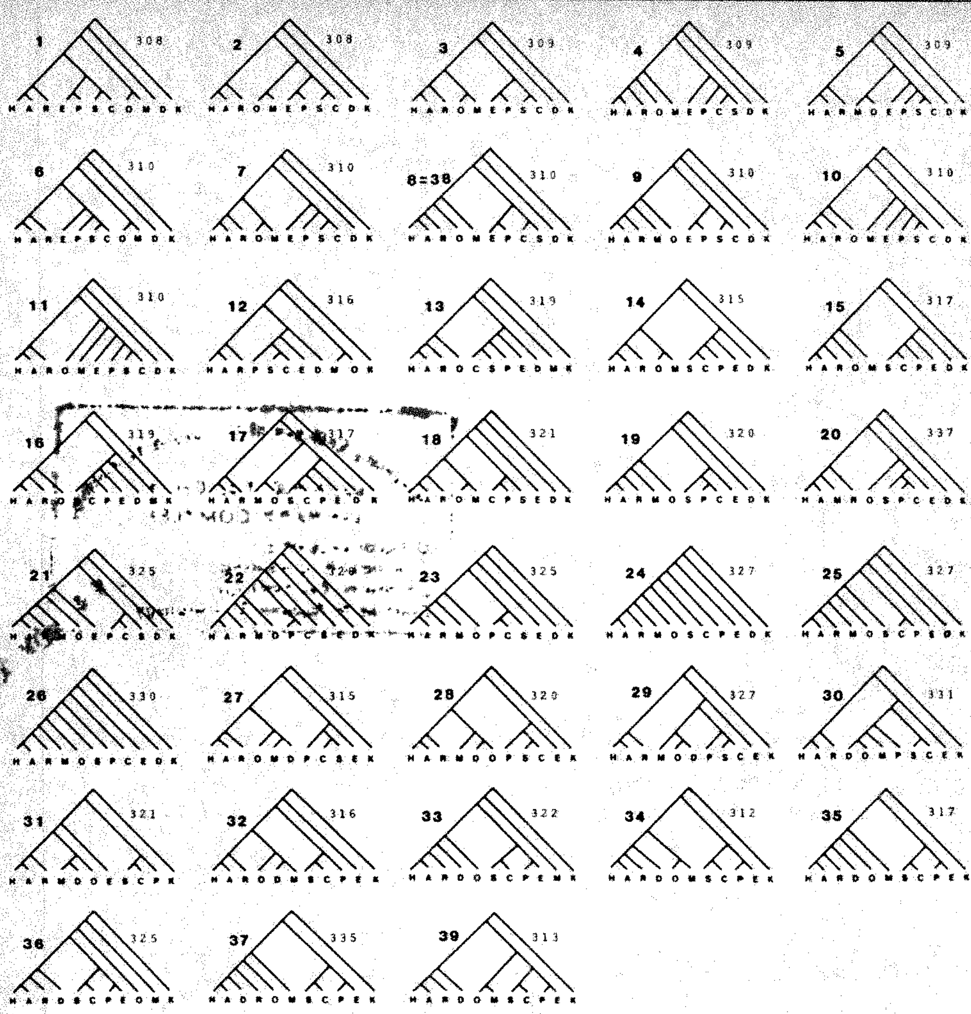

Fig. 1 The 39 minimal and near minimal trees spanning the 11 taxa given in Table 2. $T1$–$T11$ are generated from the complete sequences, $T12$–$T17$ from cytochrome *c*, $T18$ from fibrinopeptide A, $T19$–$T26$ from fibrinopeptide B, $T27$–$T32$ from haemoglobin *A*, and $T33$–$T39$ from haemoglobin *B*. The trees are arranged with their sequences in increasing lengths (see Table 3). The total number of mutations of each tree for the combined sequences is shown. The lengths of individual links are not shown, only the branching sequence is indicated. See Table 2 legend for definition of letter abbreviations.

We have shown that the problem of finding minimal length trees is an example of the Steiner problem in graphs[15,16] which makes no assumptions about the existence of an evolutionary history. Two recent techniques developed by the authors (refs 15–17 and D.P., in preparation) have enabled us to solve this for some larger sets of sequences (in one case a tree with 25 species has been proved minimal). These techniques rely on the inherent structural content of the data and are found not to work well on random data. This is an indication that there may be considerable tree-like structure within the sequence data. However, these observations are not easily quantifiable and the inability to use such methods on some data sets of this size ($8<n<25$) could not be taken as evidence for or against the existence of an evolutionary tree.

Here we have used a recently developed (ref. 17 and D.P., in preparation) 'branch and bound' method[7] which, for the data in Table 2, has found all minimal and near minimal trees.

Comparison of trees

Several methods have been proposed[18] that measure some features of the difference between a pair of trees, but it is important that any method chosen has biological relevance. Apart from satisfying a historical curiosity, a major application of an evolutionary tree is to assist in the classification of the taxa into groups at different levels. The set of taxa that are descendants of a given common ancestor will form a group of related taxa. In a strictly bifurcating (binary) tree spanning n taxa, there will be $n-2$ such non-trivial classes of the taxa. As in Robinson and Foulds[19], we measure the difference $d(T1, T2)$ of two trees $T1$ and $T2$, as the number of classes which are derived from $T1$ or $T2$, but not both. It is easily shown that this measure forms a metric on the space of all trees spanning these n taxa.

Given a non-directed tree T (one in which the root has not been specified), the removal of any internal link will partition the taxa into two subsets, one of which (depending on orientation) will be a group of related taxa. Waterman and Smith[20] have shown that the set of all such partitions uniquely defines T. Thus, $d(T1, T2)$ also represents the number of partitions of the taxa formed by deleting internal links, which differ in the two trees. This analysis is independent of whether or not the tree is a rooted tree.

Probabilities and tree comparisons

We can, for any specific tree T, determine the value of $d(T, T')$ for each of the $(2n-5)!!$ trees T'. Then the proportion of trees with $d(T, T')=m$ will represent the probability that a randomly selected tree T' is distance m from T.

For binary trees the number of internal links is $n-3$, so each tree defines $n-3$ partitions. If Ti, Tj have m partitions in common, $d(Ti, Tj)=2(n-3-m)$ which is even, and can range from 0 to $2n-6$. The value $d(Ti, Tj)=0$ can occur only for $i=j$, so the frequency of $d(Ti, Tj)=0$ is $1/N$, where $N=(2n-5)!!$. If $d(Ti, Tj)=2$ then there is only one link at which the two trees disagree. If we delete one internal link of Ti, there are two alternative ways of rejoining it to give values $d(Ti, Tj)=2$. This could occur at any of the $n-3$ internal links, so we find $d(Ti, Tj)=2$ with frequency $(2n-6)/N$.

The values of $d(Ti, Tj)$ over all pairs of binary trees spanning n species for $4\leq n\leq 11$ have been determined using recursive generating functions (D.P. and M.D.H., in preparation). These results are summarized in Table 1.

We can, for a given value of m, use these frequencies to estimate the probability of randomly selecting two trees Ti, Tj with $d(Ti, Tj)=m$. Referring to the case $n=11$, we would, for example, expect $d(Ti, Tj)=4$ to occur with probability

4.7×10^{-6}. The weighted values, $E(n)$, given in Table 1 are the estimate of the expected value $(2n-6)$. Small values of $d(Ti, Tj)$ are very rare.

We have at this point established: (1) a method that can guarantee to find all minimal and near minimal trees, (2) a quantitative method of comparing trees and (3) a method of associating frequencies with the comparison of trees. The next stage is to apply these methods to comparative biological data.

Application to sequence data

When this study began there were polypeptide sequences available that were common to 11 taxa. The proteins are cytochrome *c*, haemoglobin A, haemoglobin B, fibrinopeptide A and the last 13 amino acids of fibrinopeptide B. The original data are from the *Atlas of Protein Sequence and Structure*[21], together with its supplements. There are cases, such as kangaroo, where two species of the same genus have been used (*Macropus conguru* and *Macropus giganteus*), but this does not affect the result. Table 2 lists the species. Our methods will work with more species and/or more sequences (for example, myoglobin, α-crystallin A, RNase), but we frequently find just one sequence is not available. There is an urgent need for more coordination in selecting sequences for analysis.

The protein sequences were converted to nucleotide sequences[22] (with haemoglobin B, some nucleotide sequences were available[23]). The sequence data were edited to remove invariant sites and other sites with no comparative information, as these have no effect on the structure of the phylogenetic trees (refs 10, 16 and D.P., in preparation). This left only a small number of sites, particularly for cytochrome *c*, as it shows little variation among these taxa. The final data are listed in Table 2, with 40 sites from haemoglobin A, 43 from haemoglobin B, 13 from fibrinopeptide A, 14 from fibrinopeptide B and 13 sites from cytochrome *c*.

Evolutionary tree construction

For 11 taxa there are 17!! = 34459425 unrooted binary trees to be considered. The branch and bound algorithm was applied to each of the five protein sequences individually, as well as to the combined sequences. Table 3 lists the numbers of trees close to minimal length for each of the five data sets and for the combined data. The 39 trees whose lengths are within 1.25% of the minimal lengths were selected for detailed comparisons and are illustrated in Fig. 1. In order that they should be presented as rooted evolutionary trees, the marsupial (kangaroo) was selected as determining the root or ancestor of the tree.

Tree comparisons

It can be seen from Fig. 1 that there are only two identical trees among these 39, $T8 = T38$. Using the comparison algorithm outlined above, we obtain the ${}_{39}C_2 = 741$ values of $d(Ti, Tj)$ ranging from 0 (1 value) to 14 (8 values) out of the maximum of 16, with a mean value of 7.57. Interpolating from the frequencies in Table 1, we would expect such a value to occur between a pair of random trees with probability 1.9×10^{-4}. There are, of course, 741 comparisons but they cannot be considered to be independent values. The average similarity for comparisons of trees from the same sequences is 4.1 and for comparisons of trees from different sequences is 8.33. The expected and observed values of m are as follows:

m =	0	2	4	6	8	10	12	14	16
Exp.	0	0	0	0	0	2	17	125	597
Obs.	1	53	87	163	200	145	84	8	0

Table 3 The minimal length and number of trees close to minimal length for each of the five sequences individually and combined

Sequence	Minimal length	min	(min + 1)	(min + 2)	(min + 3)	(min + 4)
Cytochrome *c*	17	6*	55	195	321	368
Fibrinopeptide A	29	1*	37	403	2,724	12,449
Fibrinopeptide B	36	8*	126	475	1,313	4,660
Haemoglobin A	89	1*	5*	26	143	400
Haemoglobin B	124	3*	4*	25	41	105
Combined sequences	308	2*	3*	6*	0*	8

* Those 39 trees with length ≤1.25% of the minimal. These 39 trees were used in the comparative analysis and are shown in Fig. 1.

Table 4 The average distance between trees derived from two sequences

	CS	Cc	FA	FB	HA	HB
CS	2.0/3.9	7.0	8.0	9.8	8.0	5.3
Cc	5.8	3.1	8.3	10.2	6.0	5.7
FA	6.9	8.3	—	4.8	10.0	11.3
FB	8.2	10.2	4.8	4.5	8.8	11.8
HA	8.4	7.6	10.3	11.2	—/4.7	6.7
HB	6.5	7.6	11.1	11.5	9.0	2.7/4.4

The values in the upper triangle are from comparisons among the 21 minimal trees, the values in the lower triangle are from comparisons among the 39 trees studied. CS = combined sequences, Cc = cytochrome *c*; FA, FB = fibrinopeptides A and B; HA, HB = haemoglobins A and B.

There is thus a strong divergence away from random towards the trees being very similar. Note that it is logically possible for the trees to have been more dissimilar than expected.

Table 4 gives the mean values of $d(Ti, Tj)$ between trees of different sequences, the upper values being obtained only from the minimal trees, and the lower values obtained from all 39 trees. The largest mean that occurs is 11.75 between the minimal length trees of fibrinopeptide B and haemoglobin B. This value would occur between a pair of random trees with probability 1.8×10^{-2}. All other values have probabilities less than this, ranging down to 1.1×10^{-5} for fibrinopeptides A and B.

Clearly, we can reject any idea that the trees from the different sequences are independent. The different protein sequences give trees that are markedly similar, showing a relationship between them that is consistent with the theory of evolution. This supports the theory but of course does not prove it; scientific theories are falsifiable but not provable[1,24].

Consensus tree

Of the 34459425 unrooted binary trees for 11 taxa, we have selected the 39 near minimal trees for further study. The minimal trees with the combined sequences are one estimate for the most likely tree from these data, but it is also possible to derive a 'consensus tree' which incorporates the most common features of the 39 trees.

We can, by using the partitions, find a particular tree T such that the sum $d(T, T1)+d(T, T2)+\cdots+d(T, T39)$ is minimal. In calculating the tree distances, we computed the number of times each particular partition occurred in a given tree. The nine most frequent partitions and the number of trees in which they occur are {H, A} (39); {H, A, R} (37); {S, C} (30); {S, C, P, E} (28); {S, C, P} (22); {K, D} (21); {H, A, R, O, M} (16); {E, P} (12); {O, M} (12) (see Table 2 legend for definition of abbreviations). For example, the first partition is {H, A} which is human and ape, and this occurs in all 39 trees. Each partition is defined by listing the smaller of the two subsets, and so in this case ({H, A}) the remaining nine taxa are in the other subset. The tenth most frequent partition occurs in only seven trees.

The partition {E, P} with frequency 12 is inconsistent with partition {S, C, P} with frequency 22. If we delete {E, P}, the remaining 8 partitions uniquely define the 8 links of a binary tree T spanning the 11 taxa. This tree is, in fact, the tree $T7$ in Fig. 1 of length 310 on the complete data and with an average distance of 5.5 to the other trees. We call this tree the consensus tree of the set of trees and it could be regarded as being representative of the set. It is the tree which will give the minimal sum of m values when comparisons are made with all 39 trees. It is a markedly better tree on this test than any other. Other consensus tree methods are available[25] but were less appropriate for this application.

The consensus tree does have the advantage over the two combined sequence minimal trees ($T1$, $T2$) in that in the ungulates, the horse (perissodactyl) is separated from the three artiodactyls (cow, sheep and pig). References to results of mammalian phylogeny from palaeontological evidence can be found elsewhere[26,27]. In McKenna's published scheme[26], lagomorphs (rabbit) would be the first branch after the marsupials. This does not occur in any of our 39 trees.

Conclusion

The general conclusions from the present work are that (1) it is possible to make falsifiable predictions from the hypothesis that species have been linked in the past by an evolutionary tree and (2) there is strong support from these five sequences for the theory of evolution. There may be exceptions where different sequences will lead to different trees as, for example, in the serial symbiosis theory[28]. Also, in pre-cellular evolution a network with circuits may be a better model than a tree[29]. Note also that this work has so far been confined to the question of the existence of an evolutionary tree and has not discussed the mechanism of evolution. The work can be extended by using criteria of optimality that assume particular mechanisms of evolution.

An interesting philosophical question would arise if the results of this work had falsified the prediction that the trees would be similar. Would this disprove the theory of evolution, or could it just mean that the sequences had changed so rapidly that they had lost all information about their early history, thus contradicting the hypothesis of Zuckerkandl and Pauling[8]? It could be argued that because proteins from different species can be aligned so readily, this in itself is independent evidence that the proteins retain evolutionary information. However, it is probably true that specific predictions from hypotheses, rather than the hypotheses themselves, are falsifiable. This idea is inherent in Popper's writing, but is more clearly expressed by Lakatos[30]. To this extent, we suggest that Popper's criticisms of evolutionary theory have shown incompleteness in the application of evolutionary theory, but at the same time evolutionary theory has helped clarify some inadequacies in Popper's model of the growth of knowledge.

DNA sequence of a foldback transposable element in *Drosophila*

S. Steven Potter

Department of Biology, Wesleyan University, Middletown, Connecticut 06457, USA

The bizarre structures of the Drosophila *foldback (FB) transposable elements are discussed here, and arguments favouring a transposase-mediated mobility are presented. The complete 4,089-base pair nucleotide sequence of transposable element FB4 reveals the full pattern of periodicity within the inverted repeats and the nature of the loop-inverted repeat junctions, as well as the coding potential of the loop sequence.*

TRANSPOSABLE elements are discrete units of DNA that are capable of occupying new genomic locations; they can covalently insert into different positions in the genome. Since their discovery[1], advances in technology have allowed the molecular isolation and characterization of a wide variety of transposable elements from bacteria and eukaryotes[2-9] (for reviews see refs 10, 11).

Here we present the complete nucleotide sequence (4,089 base pairs, bp) of the FB4 transposable element from *Drosophila melanogaster*. We have previously shown that the FB family of mobile sequences is distinct from the retrovirus-like transposable elements, such as *copia*[12,13]. The FB elements represent the only eukaryotic transposable elements discovered which have large inverted terminal repeats. Moreover, these FB terminal repeats vary in size from one element to the next, and many FB elements consist entirely of contiguous inverted terminal repeats, with no detectable separating DNA.

The FB4 nucleotide sequence is of interest for the following reasons. First, the data reveal the structural details of the periodicities found within the inverted repeats. Second, comparison of the two inverted repeats of FB4 shows differences that reflect the nature of some of the genetic events associated with these elements. Third, the loop sequence of FB4, separating the inverted repeats, is quite different from that found on any of the other cloned FB elements. Sequence analysis yields the structure of the loop–inverted repeat junctions and reveals the coding potential of the loop sequence.

The restriction map of FB4 and the sequencing strategy used are shown in Fig. 1. The complete base sequence of FB4 is presented in Fig. 2.

Inverted repeat structure

Each inverted repeat of FB4 is constructed primarily of small direct repeats. Near the distal termini of the inverted repeats there are multiple imperfect copies of the 10-bp sequence CGTTTGCCCA. These short repeats are, however, generally separated by large regions of more diverse DNA. At nucleotide 222 this 10-bp repeat is expanded to give 20 base pairs, CGTTTGCCCACCCTTTAAAA. This 20-bp repeat is also present in multiple imperfect copies, separated by variable regions of A+T-rich DNA. Starting at 499 bp from the end we find 31-bp contiguous tandem repeats which contain within them the 20-bp repeat. These 31-bp repeats continue for the ~500 bp remaining in the inverted repeats.

Figure 3 illustrates schematically this unusual sequence construction. The thick arrow represents one of the inverted repeats of FB4, and the shorter arrows the 10-bp repeats found near the distal termini. Figure 3 is only schematic, thus there are more copies of the various repeats than those shown.

Figure 4 illustrates the periodicity found within the tandem repeats of the 31-bp sequence. Not all copies of this repeat are identical. Five types of 31-bp repeat together make up a 155-bp (5×31) repeat that is itself tandemly repeated. In Fig. 4 the sequence from the proximal portions of the inverted repeats is shown with the 31-bp repeats in register and labelled according to type. The periodicity, with every fifth repeat being of the same type, is apparent.

This unusual sequence organization, with 10-bp repeats within 20-bp repeats within 31-bp repeats within 155-bp repeats within inverted repeats, leads us to speculate on the possible function. We propose the following scheme. Transposase levels in the eukaryotic cell, even in optimum conditions, may be extremely low, and the termini of an individual transposable element represent a minute fraction of the large genome. Therefore the rate-limiting step in the transposition process may be the recognition and binding of transposase to the ends of the transposable element, where the enzyme has its effect. The tandem repeats may serve to increase the size of the target

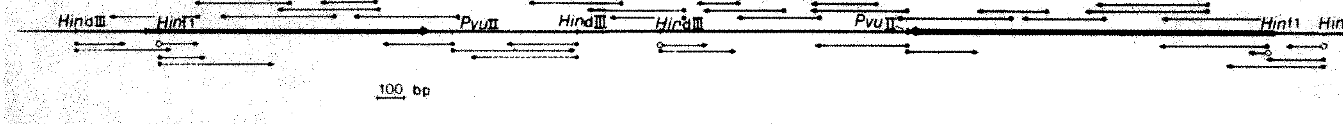

Fig. 1 Sequencing strategy. The arrows underneath represent sequencing experiments using the existing restriction recognition sites shown. Because of the repetitious nature of the inverted repeats there are relatively large regions of FB4 having few restriction sites. We therefore introduced new restriction sites by mutagenesis *in vitro*. The purified plasmid pDmFB4 (for a complete restriction map see Potter *et al.*[12]) was cleaved with *Xba*I and then treated for varying periods of time with the exonuclease *Bal*31. The reaction was monitored by gel electrophoresis. Synthetic polynucleotide linkers carrying *Xba*I recognition sites were blunt-end-ligated to the plasmid with T4 ligase. The DNA was then digested with *Xba*I, circularized by a second round of ligation, and used to transform *Escherichia coli* K-12 HB101. Ampicillin-resistant colonies were selected and screened by restriction analyses. The arrows above the map of FB4 represent sequencing experiments using the restriction sites introduced by *in vitro* mutagenesis. Enzymes and polynucleotide linkers were from New England Biolabs; isotope was from NEN. Sequencing was by the procedure of Maxam and Gilbert[28]. The five reactions—G, GA, CT, T and A—were used. End-labelling was performed as described previously[13,22,28].

Fig. 2 Nucleotide sequence of the FB4 transposable element. The complete base sequence of FB4 is shown, starting with the first nucleotide of the left inverted repeat. The various imperfect copies of the 10- and 20-bp repeats within the left inverted repeat are underlined, as are the punctuation signals surrounding the open reading frame of the loop and the 33-bp inverted terminal repeat of the loop. CAT, the CAT box; G–H, the Goldberg–Hogness box; poly(A), the polyadenylation signal.

recognized by the transposase. In a two-stage binding process, the transposase would first attach loosely but specifically at the tandem repeats and then move randomly (although a more directed movement is possible) until encountering the FB termini, where tighter binding and catalytic activity would occur.

This 'bind and slide' model, although conjectural, does provide testable predictions. For example, other factors being equal, an FB element having larger inverted repeats (and hence a larger transposase target size) will undergo more frequent transposition. In addition, the model suggests an affinity column transposase purification procedure, using the tandem repeats for selective binding.

There is a precedent for the proposed two-stage recognition. For example, the *lac* repressor apparently binds loosely to any DNA sequence, moves randomly along the DNA until it locates the specific recognition site, and then binds tightly[14].

Comparison of inverted repeats

Although the two inverted repeats of FB4 are very similar, there are, nevertheless, many single base differences and more dramatic differences involving entire copies of the 31-bp sequence. There are two 31-bp repeats missing in the left inverted repeat (Fig. 4) which are present at corresponding positions in the right inverted repeat. Differences of this sort could be generated by unequal cross-over events. Given the structure of the FB elements, both interchromosomal and intrachromosomal unequal cross-overs are possible. An intrachromosomal event, involving the two inverted repeats of a single FB4, would delete sequence from one inverted repeat and transfer it to the other. Because there are no extra copies of the 31-bp sequence at the corresponding positions on the right inverted repeat, we conclude that interchromosomal events generated these particular deletions.

Intrachromosomal recombinations between the inverted repeats of a single FB element would also result in an inversion of the loop sequence and part of the inverted repeats. Such inversions in analogous structures in *Salmonella*[15] and Mu phage[16] have been related to the regulation of gene expression. It is tempting to consider that such gene control mechanisms may also exist in eukaryotes.

Because the FB elements afford multiple possibilities for out-of-register pairing, they may represent 'hotspots' for normal homology-dependent recombination events. In this way they would contribute to genetic diversity by simply accelerating the regular recombination process at selected points along the chromosomes.

Further comparison of the two inverted repeats of FB4 reveals a missing 31-bp sequence in the right inverted repeat (Fig. 4). Note also that the right inverted repeat structure is significantly larger, with approximately two extra copies of the 155-bp repeat. Our restriction mapping data for several FB members suggest that such a difference in size of the 'inverted repeats' of a single FB element is common. Indeed the 'loop' sequences, as observed by electron microscopy, are apparently often the result of this size difference. That is, the 'extra' tandem repeats from one of the inverted repeats can form the loop.

The FB4 element, however, represents a striking exception in that the bulk of the relatively large loop appears by restriction mapping to be unrelated in sequence to the inverted repeats.

The FB4 loop

The 31-bp repeats terminate abruptly at the proximal junctions with the loop. This is in marked contrast to their gradual development from the distal ends, where 10-bp repeats become 20-bp repeats, which in turn become 31-bp repeats.

Directly abutting the proximal end of the right inverted terminal repeat is a 33-bp sequence (unrelated to the 31-bp repeat) that is also found in a nearly perfect (32/33 bp) inverted repeat near the other inverted repeat–loop junction. That is, a 33-bp sequence at the right inverted repeat–loop junction is also found, in an inverted orientation, 95 bp from the left inverted repeat–loop junction. The significance of this observation, if any, is unknown. The presence of such terminal repeats suggests that the loop itself may be a transposable element, and that FB4 is a composite structure, consisting of a mobile element (loop) within a mobile element (FB).

One of the signal characteristics of a transposable element is the presence of short direct flanking sequences that result from the duplication of target site DNA during the insertion process. The *Pvu*II recognition sites near the loop-inverted repeat boundaries are within 8-bp palindromes (ACAGCTGT) which can be regarded as either part of the full 33-bp inverted repeats of the loop, or as direct repeats flanking a shorter version of these inverted repeats (now only 20 bp long). Further support for the loop being a distinct transposable element is provided by preliminary results which indicate that these loop sequences are present at numerous genomic positions, where they are not always associated with FB elements (S.S.P., unpublished observations).

Alternatively, the loop may represent an integral and natural component of the FB4 element. This explanation avoids some of the difficult questions posed by the 'transposable element within a transposable element' model. For example, why is there a 95-bp space between the left inverted repeat–loop junction and the 33-bp 'terminal' repeat of the loop? And why did the loop transposable element insert into the centre of the FB element? (If it inserted within one of the inverted repeats, then a polarity switch would be seen in the tandem repeats of

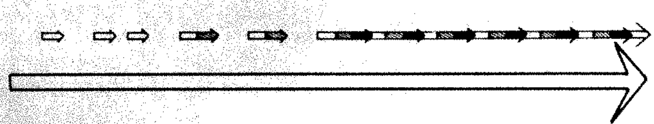

Fig. 3 Construction of the inverted repeats. The short arrows represent the 10-bp repeats, which expand to form 20-bp repeats which expand again to form 31-bp tandem repeats within the inverted repeat. There are many more copies of these various repeats than shown in this diagram.

Fig. 4 Periodicity of the 31-bp repeats. The sequences of the proximal portions of the inverted repeats are shown. Each type of 31-bp repeat is labelled by a number. The periodicity of types is apparent, although in three cases an expected copy of the 31-bp repeat is absent. To facilitate comparison, the reverse complement of the right inverted repeat is shown: the left inverted repeat sequence illustrated starts with nucleotide 499 and ends at position 1,018, while the right inverted repeat sequence shown starts with base 3,595 and ends at 2,761. Underlined bases deviate from the standard sequence of that repeat type. Underlined blank spaces represent a missing nucleotide that is normally present.

the other side of the FB element.) The integral component model is also attractive because it allows the FB4 element greater sequence complexity. The inverted repeats of the FB elements, although sometimes over 1 kb long, consist of repetitious sequences with frequent translational stop signals in all three possible reading frames, and it is therefore unlikely that they encode proteins. Where, then, is the transposase responsible for movement of these FB elements encoded? Loop sequences are obvious candidates, especially as bacterial transposons can carry transposase genes within their loops[17].

The loop sequence of FB4 contains a single large open reading frame, with the methionine codon beginning at nucleotide 1,494 and the next stop codon, TGA, beginning at nucleotide 1,938, allowing a maximum of 148 amino acids to be encoded. The consensus sequence GG$\frac{C}{T}$CAATCT, termed the CAT box, is often found upstream from eukaryotic genes. At the appropriate distance upstream from the coding region there is the sequence GATCAATAT which agrees with the CAT box for seven out of nine bases. There is also a good Goldberg–Hogness box and after the open reading frame, a perfect copy of the sequence AATAAA which is generally found 14–30 nucleotides upstream from the poly(A) tract of most mRNAs. It seems reasonable, therefore, to conclude that this open

reading frame sequence is a real gene, although the function of the gene product remains unknown.

It is also possible that other regions of FB4 encode small polypeptides, or that RNA splicing allows them to encode more substantial proteins.

Mechanism of transposition

Two distinct modes of duplication–transposition are now clear in outline, if not in detail. The bacterial transposons apparently move strictly via DNA intermediates, as proposed, for example, by the Shapiro model[18]. The finding of 'cointegrate' transposition intermediates[10], in which the two transposons are still linked, before the resolution event, strongly supports this general type of model.

The integrated proviral DNA copies of retrovirus RNA genomes undergo a more complicated duplication–transposition process. The proviral genome is transcribed into RNA which is packaged into a viral particle and eventually enters another cell, where it is reverse-transcribed[19], and a circular DNA intermediate having one or two copies of the long terminal repeats, is formed. This DNA circle can then integrate into the new host genome[20]. To generate retroviral intragenomic duplication–transposition events one need only eliminate the virion stage. The proviral transcript would be immediately reverse-transcribed, circularized and reintegrated at another chromosomal location.

The *copia*-like transposable elements in *Drosophila* are indistinguishable from integrated proviral retrovirus genomes. Structurally they both carry long direct terminal repeats[4,21,22] and the transcription patterns are very similar[23]. In addition, Flavell and Ish-Horowicz have shown[24] that *copia* elements give rise to circular DNA intermediates having one or two copies of the long direct terminal repeat, just as the retroviruses do. It therefore seems probable that the retroviruses and retrovirus-like transposable elements such as *copia* share a common duplication–transposition mechanism involving reverse transcription.

It has also been proposed that the human snRNA pseudogenes, with their dispersed and truncated organization, might result from a reverse transcription duplication–transposition process[25]. However, for these sequences, unlike the retroviruses which are designed to be reverse-transcribed, the process generally produces fragmentary versions of the original gene.

Jagadeeswaran *et al.*[26] have suggested that the human *alu* sequences could also duplicate and transpose by reverse transcription. Because these genes can be transcribed by RNA polymerase III, which recognizes internal promoters, the process is potentially 'explosive'. (The new *alu* genes can also be transcribed, giving rise to still more *alu* genes.) Furthermore, the *alu* transcripts would be capable of self priming for reverse transcriptase, giving rise to more faithful copies of the *alu* sequence.

Structurally the FB sequences are unique. They carry very large inverted terminal repeats, unlike anything found in a retrovirus, and do not seem to be designed for reverse transcription. Moreover, they have highly conserved termini, which argues against transposition by a less precise reverse transcription process, such as suggested for the *alu* and snRNA genes. Structurally the FB elements most closely resemble those bacterial transposons which have large inverted terminal repeats. As the bacterial elements move via transposase one can argue, by analogy, that the FB elements do also. Furthermore, as discussed previously, such a transposition mechanism can be invoked to help explain the unusual structure of the FB inverted repeats. The tandem repeats might serve to facilitate the binding of the low levels of transposase within the nucleoplasm. The retroviruses and retrovirus-like transposable elements, in contrast, rely on the much more abundant enzyme RNA polymerase to accomplish the onset of transposition. They therefore do not need to duplicate binding sequences.

Conclusion

The complete base sequence of FB4 reveals the full pattern of periodicity found within the inverted repeats. Near the distal termini there are occasional copies of a 10-bp sequence. Further along, this 10-bp sequence expands to 20 bp and this 20-bp repeat in turn expands to a 31-bp sequence which is tandemly repeated. There are five types of 31-bp repeat that together comprise a 155-bp repeat. This hierarchal repetition then terminates abruptly at the loop–inverted repeat junctions. Many differences exist between the left and right inverted repeats. The data suggest that these sequences are hotspots for unequal crossing-over.

The precise nature of the FB4 loop sequence remains uncertain. It is clear, however, that in this case most of the loop shows no significant homology with the inverted repeats. The presence of a gene within the loop is suggested by an open reading frame flanked by the correct punctuation signals.

It is intriguing that most FB elements cannot encode transposase. Such a dependence on transposase encoded elsewhere would seem hazardous to the transposable elements. Inactivation of the transposase gene(s) by deletion or mutation would render all the FB sequences immobile, at which point they might simply rest, accumulate mutations, and perhaps eventually be deleted themselves.

Finally, note that transposable elements interacting with transposase can generate a variety of chromosomal rearrangements, including inversions and deletions in contiguous sequences[18]. We have previously shown, by Southern blot experiments, the existence of several different DNA configurations within the vicinity of FB4 (ref. 12). The intriguing results of Goldberg *et al.*[27] also strongly suggest that two FB elements can cooperate to mobilize a large block of separating DNA. This further accentuates the many similarities found between the FB sequences and the bacterial transposable elements.

Avian sarcoma virus Y73 genome sequence and structural similarity of its transforming gene product to that of Rous sarcoma virus

N. Kitamura*, A. Kitamura, K. Toyoshima‡, Y. Hirayama & M. Yoshida†

Cancer Institute, Toshima-ku, Tokyo 170, Japan and ‡ Institute for Medical Sciences, University of Tokyo, Tokyo 108, Japan

From the complete nucleotide sequence of the genome of the avian sarcoma virus Y73, we have predicted amino acid sequence of p90$^{gag\text{-}yes}$, the product of the transforming gene. Contrary to previous evidence from molecular hybridization studies, p90$^{gag\text{-}yes}$ was found to have much homology with the transforming gene product p60^{src} of Rous sarcoma virus, suggesting that the cellular counterparts of the two (c-yes and c-src) originated from a common prototype sequence.

A GROUP of retroviruses, the acute leukaemia/sarcoma viruses, contains the transforming gene (v-*onc*), which is responsible for initiation and maintenance of cellular transformation[1]. More than 13 genes have been identified as v-*onc* and shown to be acquired from a normal cellular sequence as an integral part of their genome. Three distinct classes of transforming gene capable of inducing fibrosarcomas in chicken were defined among avian sarcoma viruses (ASV), that is, *src* in Rous sarcoma virus (RSV), *yes*[2,3] in Y73 and Esh sarcoma virus, and *fps*[4-6] in Fujinami and PRCII strains of ASV. These three transforming genes have no homology in nucleic acid hybridization[2-5], and are derived from the respective sequences in normal cells by recombination with viral sequences[2,7,8]. Furthermore, the cellular counterparts homologous with these transforming genes have been conserved during evolution[9] (M.Y., unpublished data) and expressed in normal cells[10], suggesting some that these genes perform some crucial role in normal cells.

In the light of these observations it is surprising that the transforming gene products of all these classes have protein kinase activity phosphorylating tyrosine on target proteins[11-14], and that this enzyme activity seems to be essential for cellular transformation[15,16]. Therefore, we have investigated the structure of these genes and the gene products in an attempt to understand not only the structural basis of the functions, but also the mechanism of biogenesis of the transforming genes.

The nucleotide sequence of *src* in Schmidt–Ruppin strain RSV (SR-RSV) has been established, and the function of the gene product (p60^{src}) and biogenesis of the *src* have been discussed on the basis of the nucleotide and amino acid sequences[17]. We have studied a recent isolate of ASV, Y73[18], which is defective in its replication and associated with leukosis virus (YAV) of subgroup A. The genome of Y73 is 26S RNA and contains *yes* as a transforming gene in its middle portion[19], which encodes polyprotein with a molecular weight of 90,000 (p90$^{gag\text{-}yes}$) consisting of a *gag*-gene derived part and Y73-specific portion. *In vitro* translation of 26S RNA[4] showed directly that p90$^{gag\text{-}yes}$ is coded by the Y73-specific RNA sequence. The association of protein kinase activity with p90$^{gag\text{-}yes}$ suggests that p90$^{gag\text{-}yes}$ is a transforming gene product.

To investigate the structure of p90$^{gag\text{-}yes}$, we determined the nucleotide sequence of the whole genome DNA. The sequence contains an uninterrupted reading frame that can code for p90$^{gag\text{-}yes}$ and the predicted amino acid sequence of p90$^{gag\text{-}yes}$ is strikingly similar to that of p60^{src}.

Sequencing strategy

For determination of the nucleotide sequence, we used the molecular cloning technique to amplify Y73 genome DNA. Closed circular DNA specific to Y73 was isolated from Y73-infected chick embryo cells by extraction of DNA by Hirt's procedure[20] followed by acid phenol extraction[21] and agarose gel electrophoresis. The purified DNA was linearized with restriction endonuclease *Sst*I and inserted into λ phage Charon 16A[22] at site of *Sst*I. Several clones containing the Y73-specific sequence were isolated and one of them, λY73-11A, was selected for sequencing, because it was shown by transfection assay to contain the complete sequence of Y73 RNA. Cotransfection of this cloned DNA together with cloned helper proviral DNA induced cellular transformation of chick cells and viral replication, the progeny virus was indistinguishable from the original Y73 virus. Details of the cloning the transfection will be reported elsewhere (manuscript in preparation).

Figure 1 shows a restriction map of clone λY73-11A insert containing two long terminal repeats (LTRs). The DNA fragments generated by digestion with *Hpa*II, *Hin*fI, and *Sau*3A were used for sequencing. The fragments were phosphorylated at the 5′ end with polynucleotide kinase and [γ-^{32}P]ATP, separated by either strand separation or further digestion with various restriction enzymes and sequenced by the method of Maxam and Gilbert[23]. Most of the sequences were confirmed by sequencing the complementary strand, or the fragments generated by digestions with different enzymes.

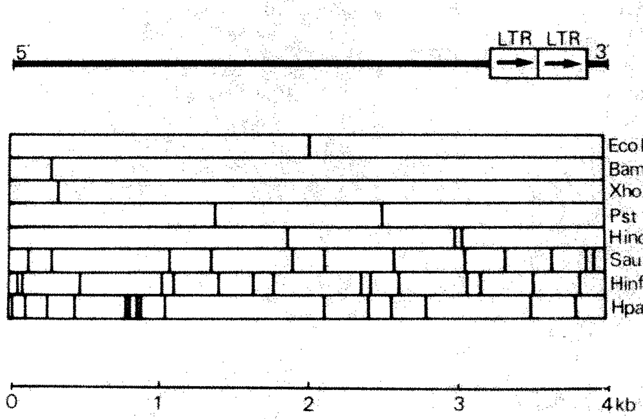

Fig. 1 Restriction map of Y73 genome cloned in λY73-11A. The circular DNA was linearized and inserted into λ Charon 16A vector at *Sst*I site and the cloned DNA contained two direct repeats of LTR.

0028-0836/82/200205—04$01.00

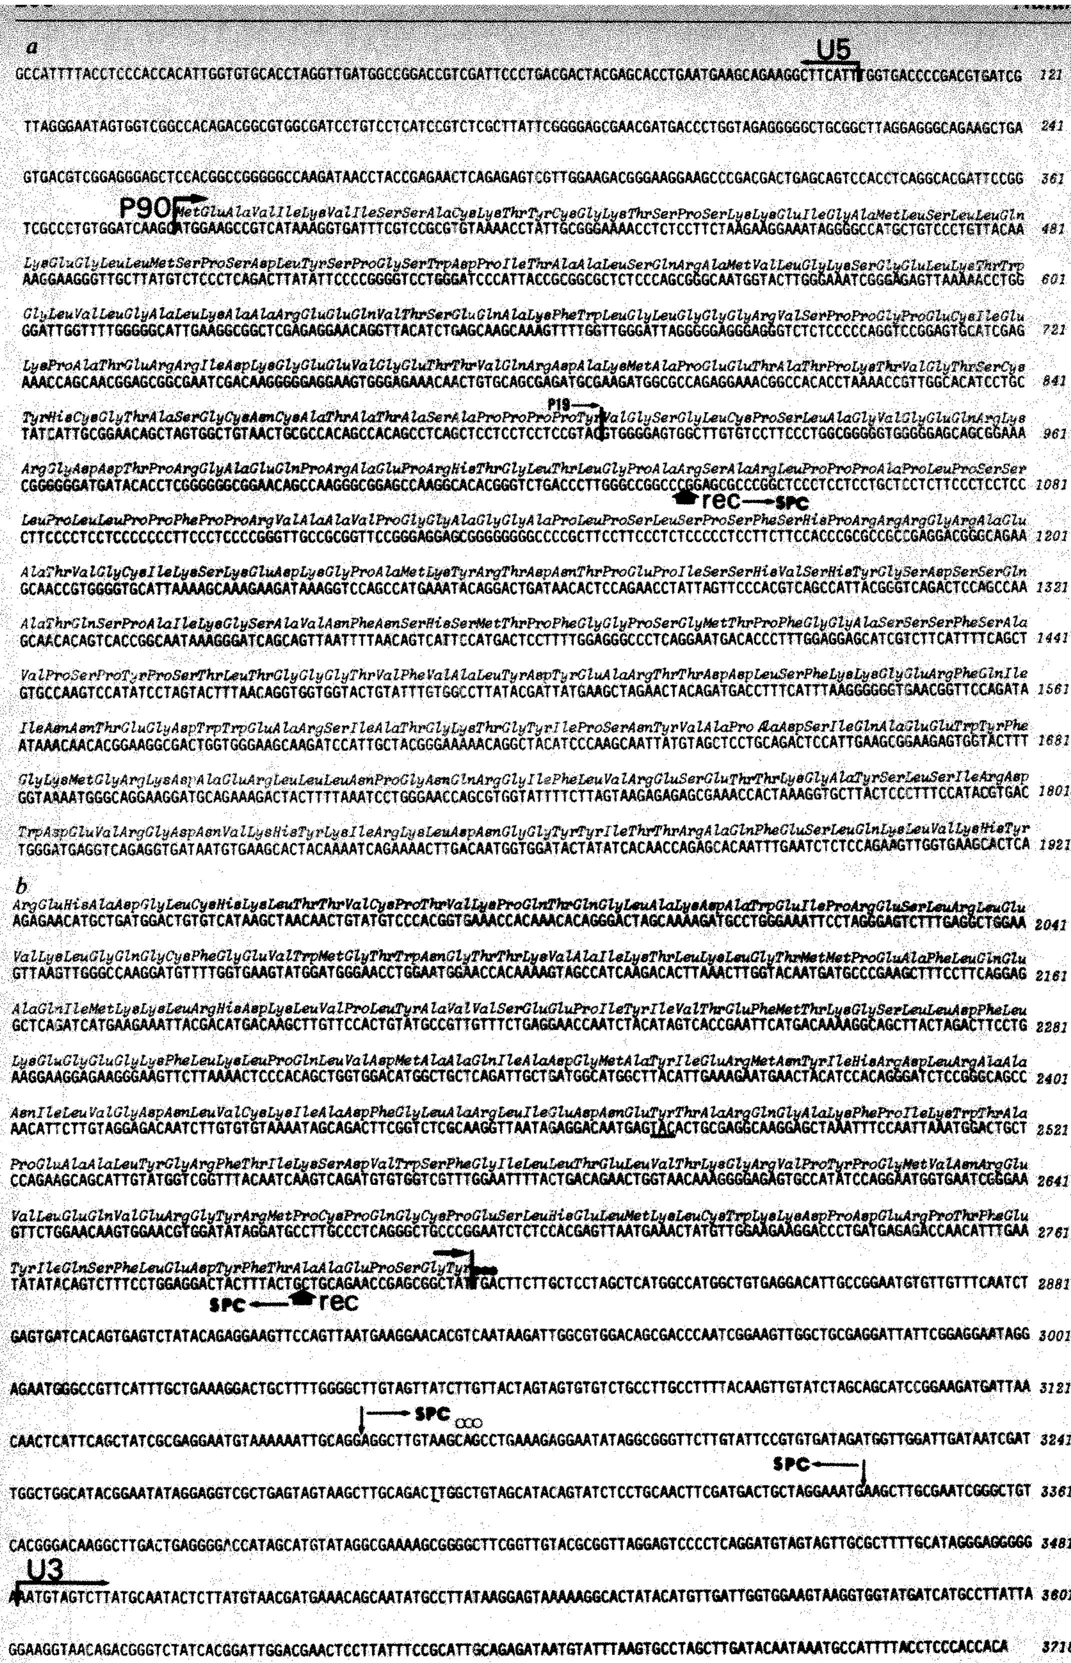

Fig. 2 Total nucleotide sequence of Y73 viral genome and the predicted amino acid sequence of p90$^{gag\text{-}yes}$. The complete sequence of the cloned DNA in λY73-11A was shown in the arrange of RNA genome from 5′ to 3′ direction. U5 and U3 indicate the unique sequence to 5′ and 3′ terminal regions. Thick solid arrows with 'rec' shows the predicted recombination sites between c-*yes* and YAV sequences, and 'spc' represents sequence which is not contained in RSV. The horizontal thick arrows indicate the initiation and termination sites for p90$^{gag\text{-}yes}$. The small arrow with p19 indicates a sequence homologous to the carboxy-terminus of p19 of Pr-RSV. The closed bar between nucleotides 2,477 and 2,479 shows the putative phosphoacceptor tyrosine contained in the same nonapeptide described by Neil *et al.*[26] and the small open circles between 3,174 and 3,176 show the position expected as termination codon for gp37, if present.

Nucleotide sequence

Previously, fingerprint analysis of Y73 26S RNA and YAV RNA[19] demonstrated that 26S RNA contained a specific sequence that represents the transforming gene of Y73. This specific sequence was mapped in the middle of the genome with sequences common to YAV RNA at both ends. The transforming gene product p90$^{gag\text{-}yes}$ encoded by the Y73-specific sequence was coprecipitated with antibody against p19, a *gag*-gene product, suggesting that p90$^{gag\text{-}yes}$ contained at least p19 in the amino-terminal portion[12].

The entire nucleotide sequence of the Y73 genome, shown in Fig. 2, consists of 3,718 nucleotides, confirming the previous data described above. The genome was significantly shorter than 4.8 kilobases, the value estimated previously by agarose gel electrophoresis of the genomic RNA.

The noncoding sequence at the 5′-terminus, including U5 and a primer tRNA binding site, was found to be homologous with that of the SR-RSV genome[31,32] (93% homology). The open reading frame, starting at position 380, contained the entire sequence coding for p19, which is located at the amino-

terminus of the *gag*-precursor, Pr76, indicating that AUG at position 380 is the initiation codon for p90$^{gag\text{-}yes}$. The proposed amino acid sequence of p19 was identical with that of p19 of Prague strain of RSV (D. Schwartz *et al.*, personal communication), except for the 2 amino acid insertions (positions 169 and 170) and 2 amino acid substitutions (positions 64 and 161). After the coding sequence for p19, 130 nucleotides were homologous with those of RSV and then there was a specific sequence. The sequence coding for p27, which follows after p19 in Pr76, was not present. Therefore, recombination between the viral sequence and the *yes*-related cellular sequence (c-*yes*) seems to have taken place in the sequence between those coding for p19 and p27. A pyrimidine-rich sequence was present after the putative recombination site, but, the significance of this sequence is not known. From the putative recombination site, the Y73-specific sequence extended to position 2,795. These specific 1,755 nucleotides are the only candidates for a coding sequence of the specific portion of p90$^{gag\text{-}yes}$. After this specific region, there was a sequence homologous to that coding for gp37 of SR-RSV[17], which is one of the *env*-gene products. Thus the recombination site at the 3′-side seemed to be within the sequence coding for gp37. Part of the sequence homologous to that coding for gp37 in SR-RSV was utilized for the carboxy-terminal peptide of p90$^{gag\text{-}yes}$ using a different frame from that for gp37. The UGA codon in the gp37 sequence was the predicted termination codon for p90$^{gag\text{-}yes}$.

Another 161 base sequence around the termination codon for gp37 is not homologous to that in PR-RSV (Schwartz *et al.*, personal communication), however, it seems too small to code any protein required for transformation. The origin of this specific sequence is not clear, but possibly the unique sequence was contained in, and originated from, the helper virus (YAV) genome. The common sequence at the 3′-end was homologous with that of SR-RSV[17,31] (87% homology) except for a 14 nucleotide deletion within the U3 region near the 5′ end. This deletion did not affect expression of the Y73 genome because the cloned DNA had transforming activity in transfection.

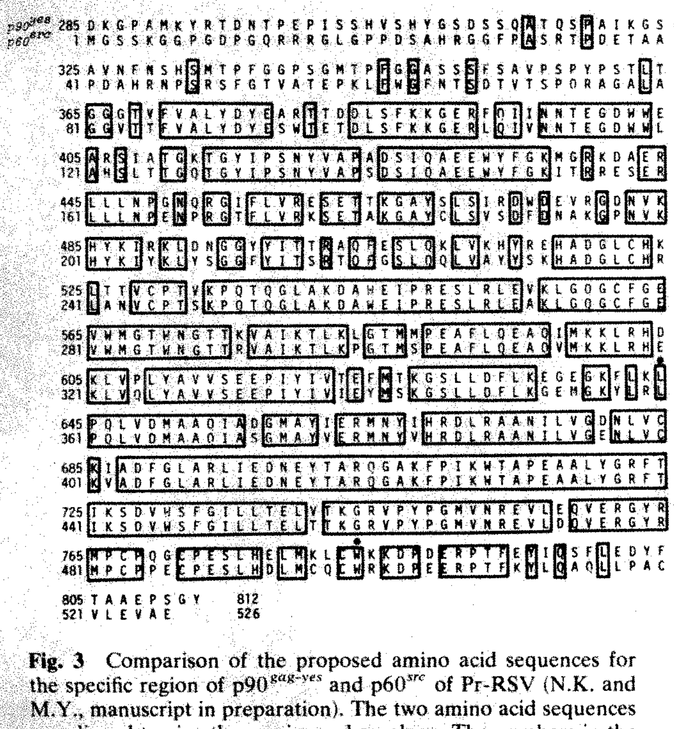

Fig. 3 Comparison of the proposed amino acid sequences for the specific region of p90$^{gag\text{-}yes}$ and p60^{src} of Pr-RSV (N.K. and M.Y., manuscript in preparation). The two amino acid sequences are aligned to give the maximum homology. The numbers in the left are the amino acid residues from the initiation methionine and area of identity are depicted by boxes. The nucleotide sequences between two marks (*) are compared in Fig. 4. A, Ala; C, Cys; D, Asp; E, Glu; F, Phe; G, Gly; H, His; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; W, Trp; Y, Tyr.

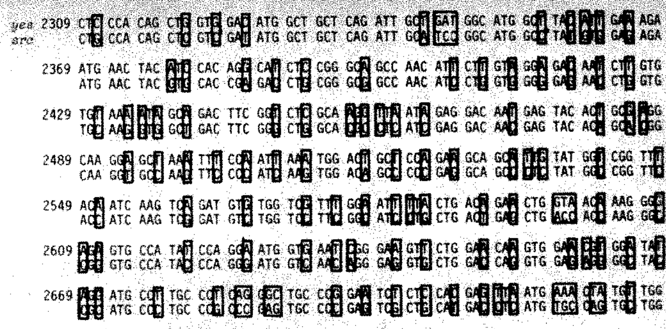

Fig. 4 Comparison between nucleotide sequences for the regions of *yes* and *src* of Pr-RSV coding for the highly homologous amino acid sequences. The nucleotide sequences corresponding to the amino acid sequences marked (*) in Fig. 3 are compared between *yes* and *src*, in which 93% homology was observed in amino acid sequences. Non-identical nucleotides are depicted by boxes.

Amino acid sequence of p90$^{gag\text{-}yes}$

Figure 2 also shows the predicted amino acid sequence of the gene product p90$^{gag\text{-}yes}$ of Y73. P90$^{gag\text{-}yes}$ consists of 812 amino acids and has a molecular weight of 88,697, which is in good agreement with the value of 90,000 estimated by SDS polyacrylamide gel electrophoresis[12]. As mentioned above, p19 was located at the amino acid terminus of the protein followed by a sequence unrelated to the RSV gene product.

Comparison of the amino acid sequence of part of p90$^{gag\text{-}yes}$ and p60^{src} is shown in Fig. 3. The amino acid sequence of p60^{src} was predicted by the nucleotide sequence of *src* in Pr-RSV, which was determined in our laboratory analysing molecularly cloned *Eco*RI fragment of the integrated proviral DNA (N.K. and M.Y., in preparation). Our sequence of *src* in Pr-RSV only differed in 12 nucleotides from that determined by Schwartz *et al.* (personal communication) but differed considerably from that of Czernilofsky *et al.* for SR-RSV, affecting a part of the reading frame for p60^{src}. Seventy-three out of 80 amino acids of the amino-terminus and 10 of the carboxy-terminus of p60^{src} were totally different from the corresponding regions of p90$^{gag\text{-}yes}$ when arranged to get maximum homology, but the other 436 amino acids of p60^{src} were largely homologous (82%) with those of p90$^{gag\text{-}yes}$. In particular 133 amino acids between positions 644 and 766 of p90$^{gag\text{-}yes}$ showed 93% homology with the corresponding region of p60^{src}.

Discussion

In earlier experiments[2,12], the Y73 specific cDNA sequence did not hybridize with *src* RNA. From this finding it was concluded that the transforming gene *yes* is distinct from *src* of RSV. However, our results show a large extent of homology in the amino acid sequences of the transforming gene products, p90$^{gag\text{-}yes}$ and p60^{src}. This discrepancy is due to the diversity of the genetic codes for each amino acid. Of 356 identical amino acids between positions 365 and 800, 221 utilized different codons from those for p60^{src} mainly owing to differences in the third base of the codons (Fig. 4). At the level of nucleotides, 31% of the 1,308 bases of the region are different in *src* and *yes*, and the longest homologous stretch is only 17 nucleotides long. These mismatches can explain the previous finding that cDNA of *yes* did not hybridize with *src* RNA under stringent conditions.

The highly homologous sequences of amino acids in p90$^{gag\text{-}yes}$ and p60^{src} are consistent with the fact that both gene products have protein kinase activity phosphorylating tyrosine[12,24,25]. Furthermore, these homologies strongly suggest that the two transforming genes were derived from a common prototype sequence. This was previously proposed by Neil *et al.*[26] from the finding of similar tryptic peptides containing phosphoaccep-

tor tyrosine in p60[src] and p90[gag-yes]. Our nucleotide sequence data clearly show homology over a wider range covering most of p60[src], thus supporting the proposal of Neil *et al.*[26]. Some similarity between p60[src] and the *mos* gene product of Mo-MSV was reported[27] and similarity was also found between two transforming gene products coded by Ha- and Ki-MSV[28].

Protein kinase activity phosphorylating tyrosine residues is a common feature of the transforming gene products of all avian sarcoma viruses so far tested. Therefore, it would be very interesting to know the amino acid sequences of the gene products of other avian sarcoma viruses such as Fujinami virus and PRCII.

As previously reported[2,8], there are DNA sequences homologous to those of *yes* and *src*, respectively in normal chick cells (c-*yes* and c-*src*), and these cellular sequences have been well conserved during evolution, being found in fish and in humans, suggesting some important function for these genes[9]. Therefore, the similarity of p90[gag-yes] and p60[src] at a protein level implies similarity of the gene products coded by c-*yes* and c-*src*, and suggests that c-*yes* and c-*src* diverged from a common prototype sequence at a very early stage of vertebrate evolution.

C-*src* was shown to be expressed in protein p60[c-src] in normal cells[10,11] and c-*yes* was shown to be transcribed into mRNA (M.Y., unpublished data). We have no data that could explain why different genes coding for proteins with similar structure and function are conserved and expressed in normal cells, although some speculations are possible. For example, expression of these cellular genes might depend on different types of differentiation or differences in the cellular distributions, and thus functions, of the proteins.

The structural similarity between p90[gag-yes] and p60[src] does not necessarily imply that the mechanisms of cellular transformation by these viruses are the same. Similarity in the carboxy-terminal domain could explain the similar protein kinase activity[29], but, differences in the amino-terminal domain suggest a different distribution of the proteins within cells, and thus that they phosphorylate different target proteins, since the amino-terminal domain of p60[src] is reported to be involved in anchorage of the protein to the plasma membrane[30].

We thank Dr Haruo Sugano for his useful discussions. This work was partly supported by Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture of Japan.

Magnetic fields, convection and solar luminosity variability

W. C. Livingston

Kitt Peak National Observatory, Tucson, Arizona 85726, USA

Model calculations universally indicate that heat transport from the solar interior is almost entirely by convection in the outer envelope. Spiegel and Weiss[1] have recently discussed how magnetic fields can intrude into this envelope to affect convection and thus introduce transients into the Sun's luminosity. I demonstrate here from Fourier transform spectrometer observations of Fraunhofer line asymmetry that granular convection is retarded in the presence of surface magnetism. I then present full disk observations which suggest a lessening of convection over the past 5 yr. As this time interval coincides with the rise from a minimum to a maximum of solar activity, with the presumed injection of new magnetic flux from the interior, the resolved disk and full disk observations are consistent. Finally I note the continued temporal decrease in the spectroscopic temperature of the low photosphere and consider how a change of convection and the lowering temperature may be related.

The convective process is plainly manifest at the Sun's surface by the granulation pattern. Rising bright granules, transporting excess energy which is then radiated into space, are surrounded by the cooler intergranule gas which is falling. This causes a velocity–brightness correlation which in turn gives rise to an asymmetry in Fraunhofer lines observed near disk centre[2,3].

Spectral line asymmetries are traditionally represented by plotting the shifts of the bisectors of the line profile (as in Fig. 1). These bisectors have a characteristic 'C' shape, the middle of which is blueshifted in wavelength relative to the laboratory value. The upper end of the C is less blueshifted, as increased density low in the photosphere, coupled with the condition of flow continuity, results in lower convective velocities. The lower end is also less blueshifted, because of the cessation of upward velocity at the top of the granulation layer as represented by the line core. Detailed calculations by Nordlund[4] provide a quantitative basis for the above hypothesis.

A Fourier transform spectrometer (FTS) is preferred for bisector observations; it has a symmetric response profile, is capable of giving absolute wavelengths, records many lines simultaneously and is easily fed with unfocused (integrated) sunlight[5]. In a day-long sequence of full disk 1-m FTS measurements, mid C values typically display a wavelength variance of ~0.1 mÅ, corresponding to a velocity noise of 5 m s^{-1}. For historical reasons, some of the data presented here were obtained with a 13.5-m grating spectrometer. The greatest problem in this spectrograph is thermal drift which introduces a time-dependent asymmetric instrumental profile. Velocity noise is also about 10 times worse than with the FTS, but by averaging many records the noise in the data becomes tolerable.

Figure 1 shows line bisectors for a region of high magnetic flux compared with a non-magnetic area nearby. The spatial resolution is purposely low, about 1 × 2 arc min, to average over local conditions. This record is typical of some 50 regions

studied. In all cases near the disk centre the magnetic region line bisector has a smaller curvature and is less displaced to the blue than are bisectors for quiet regions. Although Fe 5,250.6 Å is a magnetically sensitive line (Landé $g = 1.5$), the $g = 0$ line Fe 5,576.1 Å gives the same result, demonstrating that we are not troubled by an instrumental artefact arising from telescope polarization, for instance, or other conceivable effects of Zeeman splitting. Dravins *et al.*[3] also find that line asymmetry is independent of *g*.

Figure 2*a* compares the full disk Fe 5,250.6 mean bisector for 1976–77 with the bisector for 1980–81. These are observations made with the 13.5-m spectrometer, the records having the worst thermal drift being eliminated, and 21 days of data (a total of 14 h) averaged together for each epoch. The error bars in wavelength are derived from the dispersion of the day averages. Errors in intensity are negligible. The maximum distance between the bisectors relative to the wavelength error occurs around an intensity level 20% down from the continuum. Here the formal error is 0.25 mÅ (12 m s^{-1}) while the separation is 1.5 mÅ (75 m s^{-1}).

Since May 1980 we have obtained full disk FTS bisector observations at 4–5-month intervals. As mentioned above, we have greater confidence in the FTS data than in those obtained with the spectrograph. For the FTS the error in wavelength is formally ~0.04 mÅ (2 m s^{-1}) based on six observations. The trend towards diminishing convection continues and is evident in the FTS bisector (Fig. 2*b*) even though solar maximum seems to have occurred in November 1979. Perhaps much of the flux which emerged at that time, largely concentrated in sunspots, is now slowly being distributed polewards to affect a growing fraction of the solar disk[6].

These bisector studies are an outgrowth of our line-strength monitoring programme which began in 1975 and which has been pursued vigorously. The cooling trend indicated early on

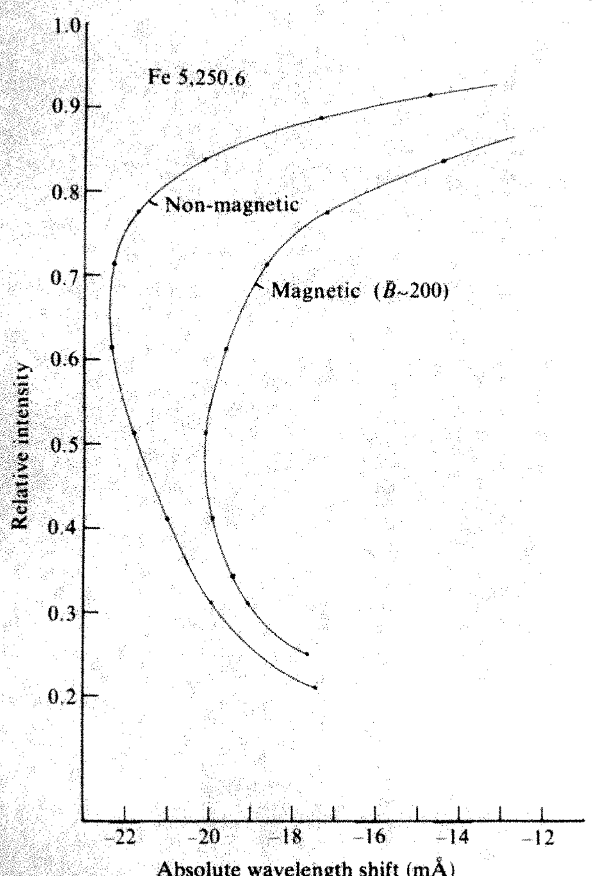

Fig. 1 Typical FTS line bisectors for adjacent magnetic and non-magnetic regions, observed at a spatial resolution of 1 × 2 arc min. The large, net blueshift arises from solar rotation. Note the non-magnetic C has larger amplitude and is more blueshifted than the magnetic C.

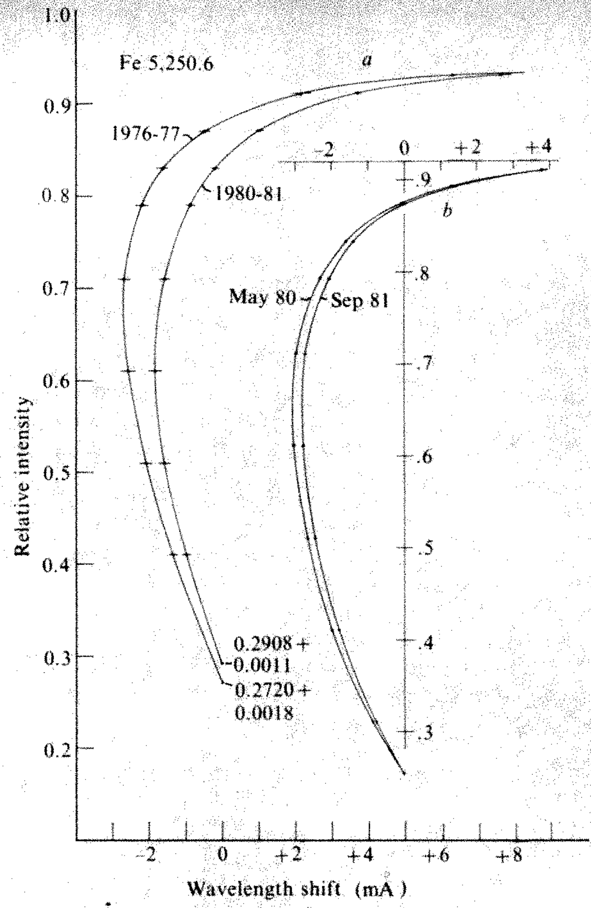

Fig. 2 *a*, Full disk spectrograph bisectors for solar minimum and maximum compared. The implication is decreased convection. *b*, As *a* except for a recent 16-month interval and using single day FTS data. In this case the formal errors are comparable with the size of the plotted points.

by a weakening of C 5,380 Å continues unabated. It was prematurely reported[7] that Fe 5,379 Å, which has the opposite temperature response to C 5,380 Å, was synchronously strengthening, as would have been expected. Instead, 4 yr of additional data show it unequivocally to be weakening also. This apparent inconsistency was resolved by Holweger[8] who used the fact that the two lines do not originate in the same atmospheric levels. He proposes that the low photosphere is temporally cooling, the upper photosphere is heating, and the result is a flattening of the temperature gradient. The quantitative implications of this change of temperature gradient on solar irradiance have not yet been determined.

I conclude that Fraunhofer lines in the Sun's integrated light spectrum display asymmetries which arise from convection. Observations resolving magnetic regions indicate that the amplitudes of the line asymmetries are smaller than in quiet regions. I have now observed a secular diminishing of the line asymmetry in full disk data from 1976 to 1981, corresponding to a period of increasing magnetic activity. Thus increasing surface magnetic flux (perhaps related to the phase of the activity cycle) is slightly retarding granular convection. Finally, this retarded convection may be the root cause of our observed line weakening and deduced solar cooling.

I thank Dr C. A. Lindsey for helpful suggestions.

Constraints on the Moon's origin from the partitioning behaviour of tungsten

Horton E. Newsom* & Michael J. Drake†

Lunar and Planetary Laboratory, and Departments of *Geosciences and †Planetary Sciences, The University of Arizona, Tucson, Arizona 85721, USA

The Moon, Earth and eucritic meteorites display W/La ratios which correspond to depletions of W relative to chondrites by factors of ~19 (ref. 1). This depletion can be attributed to metal/silicate fractionation. Ordinary chondrites and Cl chondrites with widely varying metal contents and oxidation states have similar W/La ratios, suggesting that nebular fractionations were unimportant. Therefore, assuming that both W and La are refractory and incompatible, the depletions of W relative to La in the Earth, Moon and eucrites are presumably due to separation of metal from silicate during planetary-scale igneous events. For the Moon, Rammensee and Wänke[2] concluded that any geophysically reasonable metallic lunar core would be too small to explain the large lunar depletion of W. It was therefore suggested[2] that the Moon acquired its depletion of W in a non-lunar igneous event, supporting the hypothesis that the Moon formed by fission from the proto-Earth, the upper portion of which was depleted in W due to terrestrial core formation[3-5]. We show here that this conclusion is implicity based on a special case, namely equilibrium between metal and silicate phases with total melting of silicates. In the geologically more general case where metal fractionates from silicate at relatively low degrees of partial melting, the incompatible nature of W may negate this conclusion. A geophysically plausible metallic core can account for the depletion of W in lunar surface and, presumably, lunar mantle rocks. The low W/La ratio in the Moon cannot be used as unconditional evidence for a terrestrial origin of the Moon.

We first consider the initial concentrations of W and La in the Moon or in precursor lunar material. The presence of correlated pairs of refractory lithophile elements (for example, Ba/La) with Cl ratios in the Earth, Moon and eucrites argues strongly for a chondritic W/La ratio in the Moon or precursor lunar material[6]. The abundances of W and La in lunar rocks and chondritic meteorites are plotted in Fig. 1. The magnitude of the lunar W depletion relative to Cl and ordinary chondrites was calculated from the data in Fig. 1 and is listed in Table 1. The range of depletion factors for the Moon relative to the chondrites is 19 to 29, but there are large uncertainties in these values due to the uncertainties in both the lunar and chondrite W/La ratios.

We next consider the amount of metal that may be present in the Moon. Geophysical evidence for the metal content of the Moon is inconclusive. The tightest constraint on the size of a lunar core, by Hood *et al.*[7], is a maximum radius ≤ 360 km, corresponding to 2% metal. Other investigations[8,9] find indirect

Table 1 W/La ratios in chondrites, and corresponding depletion factors for the Moon

Chondrite type	W/La ratios	Depletion factor (a) Moon/chondrite
Cl	0.36 ± 0.04	19 ± 7
H	0.55 ± 0.06	29 ± 11
L	0.45 ± 0.11	24 ± 10
LL	0.40 ± 0.09	21 ± 9

Lunar W/La ratio $= 0.019 \pm 0.007$, data from Fig. 1.

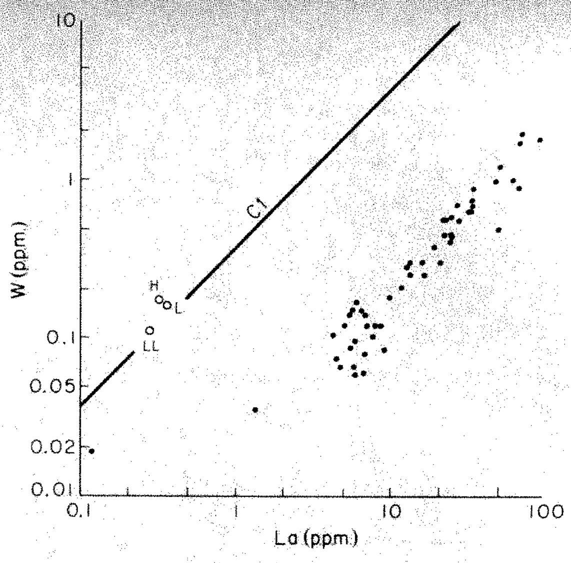

Fig. 1 Concentrations of W and La in lunar rocks, average values for three classes of chondrites, and the Cl chondrite W/La ratio[17-20].

indications of a metal core with a radius of 200 to 500 km. A 500-km radius core corresponds to ~5.5% metal.

With information on the possible magnitudes of the lunar W depletion and the possible lunar metal content, we now evaluate the parameters which control the partitioning of W between metal and silicate in the Moon. The most important parameters are the degree of partial melting, because of the incompatible nature of W, and the metal/(silicate liquid) partition coefficient for W. The partition coefficient depends on the oxidation state, which depends on the FeO content, the Ni content of the metal and the temperature of the Moon. The bulk composition and, hence, oxidation state of the Moon is uncertain. The effects of these parameters on the W/La ratio are illustrated in Figs 2 and 3 and discussed below.

The behaviour of W at low degrees of partial melting is particularly important. Tungsten is an incompatible element, with siderophile affinities in lunar conditions of low oxygen fugacity. Therefore, W prefers metal to silicate melt and prefers silicate melt to silicate solid. At low degrees of partial melting the concentration of W in the silicate melt and in the metal is very high because W is substantially excluded from solid silicates. Partitioning of W between solid metal and liquid metal is unimportant because the partition coefficient is close to unity[10]. Figure 2 shows that, at low degrees of partial melting, significant depletion of W relative to La can occur even if the metal/(silicate liquid) partition coefficient D(W) is relatively small. This is because the bulk metal/(silicate liquid + silicate solid) partition coefficient (bulk $D^{M/\Sigma S}$) is much larger than the D(W) at low degrees of partial melting.

The effective degree of partial melting in the Moon during metal/silicate fractionation is important to determine because of its large effect on the bulk $D^{M/\Sigma S}$. In their calculations Rammensee and Wänke[2] implicitly assumed that total melting of the silicates occurred, and that D(W) equals the bulk $D^{M/\Sigma S}$. In these conditions a very large D(W) is required if a geophysically plausible metallic core is responsible for the depletion of W in the Moon. It seems geologically more reasonable, however, that equilibrium between silicate and metal be confined to small degrees of partial melting, because metal will rapidly sink and the melt will rapidly rise before a large degree of partial melting can occur. As the metal starts sinking and aggregating, the decreasing time scale and increasing length scale for diffusion will rapidly terminate equilibration of the silicates with the metal[11]. A possible limit on the effective degree of partial melting is $F = 0.22$, where crystalline grains will no longer remain in contact with each other at the intergranular faces[12]. The investigation by Walker *et al.*[13] of the stability of

0028-0836/82/200210—03\$01.00

the terrestrial low-velocity zone may also be relevant. They found that for $F = 0.1$ the terrestrial low velocity zone could be largely drained of melt on a time scale of centuries, although this result is dependent on the scale of the melting system. Because of the large density difference between metal and silicate a value of $F < 0.1$ may be reasonable for the degree of partial melting during metal–silicate equilibration in the Moon, although the Moon may have continued to melt after effective isolation of the metal phase.

The other critical factor is D(W), the metal/(silicate liquid) partition coefficient for the Moon. D(W) depends strongly on the oxidation state of the Moon, which is related to the FeO content of the silicates and the Ni content of the metal in the Moon. The two scales plotted on the right ordinate of Fig. 2 show the relationship between D(W) and the FeO content of the silicates for both 6% Ni and 52% Ni in the metal: 6% Ni corresponds to the assumption that the Ni/Fe ratio in the metal is approximately the cosmic ratio; 52% Ni assumes a chondritic model for the relationship between Ni content of the metal phase and total metal content[14]. The actual Ni content of metal in the lunar interior probably falls within these limits. Model lunar compositions cover a wide range in FeO content[15] (2.3–13.9%), corresponding to a large range in D(W). Most of the recent model compositions tend towards higher values of FeO corresponding to lower values of D(W).

Figures 2 and 3 may be used to examine the conditions in which the depletion of W in the Moon could be explained by partitioning of W into metal within the Moon. The conditions discussed by Rammensee and Wänke[2] are a relatively high FeO content (13%), which corresponds to a low D(W) of 53, and total melting of the silicates ($F = 0.98$ in Fig. 3). For these

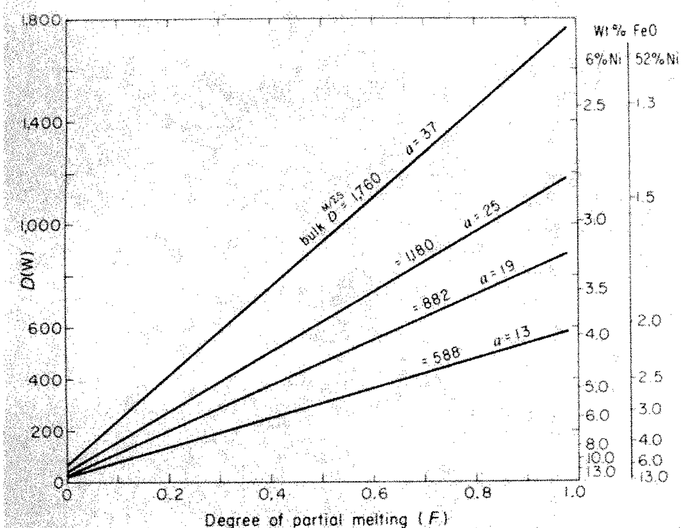

Fig. 2 The main constraints on the partitioning of W in the Moon constructed by calculating the bulk metal/(liquid silicate + solid silicate) partition coefficient (bulk $D^{M/\Sigma S}$), using an equilibrium partial melting model[21], for different degrees of partial melting (F) and different metal/silicate liquid partition coefficients, D(W). The solid silicate/liquid silicate partition coefficients used for both La and W are: olivine, 0.01; low-calcium pyroxene, 0.006; high-calcium pyroxene, 0.07; plagioclase, 0.14. Tungsten may be more incompatible than La, but no experimental mineral-melt data are known[22]. The model lunar silicate composition used was Hodges and Kushiro[15]. The diagonal lines represent the constant bulk $D^{M/\Sigma S}$ necessary to achieve a given depletion factor (a), assuming a metal content (x) of 2%. The relationship between bulk $D^{M/\Sigma S}$ and the depletion factor was calculated from the equation[2] $x = (a-1)/(\text{bulk } D^{M/\Sigma S} + a - 1)$. Breaks in slope occur when phases are exhausted, but the changes are small and are not shown. The two FeO scales plotted at the side were calculated by determining f_{O_2} (fugacity) for a given FeO content assuming 1,300 °C and ideal solution behaviour and 6% Ni or 52% Ni in the metal[23]. The corresponding D(W) was then calculated from the relation $\log D(\text{W}) = -\log f_{O_2} - 10.83$ determined experimentally by Rammensee and Wänke[2].

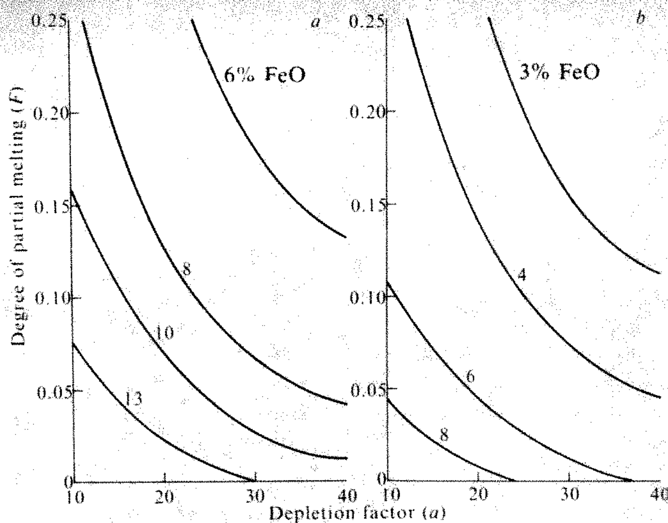

Fig. 3 a, b, The combination of per cent partial melting and FeO content required to achieve a reasonable depletion factor for the Moon (see Table 1): a, 2% metal containing 6% Ni; b, 2% metal containing 52% Ni. The plots were derived graphically from Fig. 2.

conditions Fig. 2 shows that a small metal content consistent with geophysical constraints could not be responsible for the observed depletion of W. We have argued, however, that equilibrium of silicate phases with metal at high degrees of partial melting is geologically unlikely. The situation at low degrees of partial melting is illustrated in a different way in Fig. 3a and b, which are derived directly from Fig. 2 for 6% Ni and for 52% Ni in the metal respectively. Figure 3a shows for the assumption of 6% Ni in the metal that reasonable lunar depletion factors (Table 1) can be achieved for lunar FeO contents as great as 13%. Figure 3b shows for the assumption of 52% Ni in the metal that reasonable depletion factors can be achieved only if the lunar FeO content is <6–8%. The actual ranges of values of D(W) and F which are consistent with the lunar depletion of W are uncertain due to the wide range in possible lunar depletion values (Table 1) and the uncertainty in the FeO content of mafic silicates and Ni content of metal in the Moon. The only situation where the low W/La ratio in the Moon could not be explained by a 2% metal core is the combination of a high lunar FeO content with a very high Ni content in the metal. Even this constraint would be greatly relaxed if a core larger than 2% metal exists[8,9].

Of less importance, but of significance, is the variation in the modal composition of the Moon for different lunar bulk compositions. Compositions with low FeO contents tend to have high normative plagioclase contents. A large amount of plagioclase reduces the bulk $D^{M/\Sigma S}$ at low degrees of partial melting, because plagioclase may have a higher solid silicate/liquid silicate partition coefficient for W than does olivine or pyroxene.

A major question regarding depletion of W during partial melting is explaining the very homogeneous W/La ratios in lunar samples. Figure 3 shows the large sensitivity of the depletion factors to small changes in the degree of partial melting. Several factors may help explain this problem. A closer look at the actual mechanism of metal segregation is needed. Assuming that the metal grains are not all the same size, the partitioning of W and the settling of metal grains probably occur over a significant range in the degree of partial melting. This suggests that an important control on the depletion of W is the size–frequency distribution of metal. A relatively constant size–frequency distribution and metal content of accreting material may lead to a relatively constant W/La ratio. Other mechanisms following core formation could also lead to homogenization. These include convection and the possible formation of a lunar magma ocean.

We conclude from the above analysis that a metal content consistent with present geophysical constraints on the size of a

metallic lunar core could account for the depletion of W observed in lunar rocks. The low W/La ratio of the Moon cannot be used as evidence for the formation of the Moon from the Earth's mantle by fission following terrestrial core formation. The approximate coincidence of W/La ratios in the Earth, Moon and eucrite parent body may only reflect the operation of the same depletion mechanism in similar conditions on several parent bodies[16].

We thank W. Rammensee for a helpful review. This work was supported by NASA grant NSG 7576.

High-resolution coherent Raman spectroscopy of matrix-isolated carbon monoxide

I. R. Beattie, T. R. Gilson, S. N. Jenny & S. J. Williams

Department of Chemistry, The University, Southampton SO9 5NH, UK

IR spectroscopy of species isolated at low concentrations in inert matrices at cryogenic temperatures is an important physical technique in many branches of science. Raman spectra of such systems are much more difficult to obtain even at a resolution of only 1 cm^{-1}. Coherent Raman spectroscopy with an attainable resolution of at least 0.001 cm^{-1} is capable of rivalling diode laser or Fourier transform IR spectrometers. We report here the first coherent Raman spectrum of a matrix-isolated species. The system chosen is carbon monoxide in nitrogen (15K) at 0.13% concentration with a resolution of 0.13 cm^{-1}.

Although coherent Raman spectroscopy is experimentally demanding compared with spontaneous Raman spectroscopy it can enable experiments to be carried out that would otherwise be impossible. Perhaps the most spectacular results are those of Owyoung and co-workers[1] who used Raman loss spectroscopy (inverse Raman) to obtain spectra of $^{13}CH_4$ at 1.3 torr pressure. The resolution was Dopper limited at 0.009 cm^{-1} resolution. A more familiar coherent Raman experiment is coherent anti-Stokes Raman spectroscopy (CARS) which is experimentally easier to set up (and less expensive) than a sophisticated Raman gain/loss experiment.

The selection rules for both Raman gain/loss spectroscopy and CARS are the same as for those of the spontaneous Raman effect[2]. However there are important differences between the two coherent phenomena. Raman gain/loss spectroscopy is a two-photon process whereas CARS is a four-photon parametric process. The CARS intensity in phase-matched conditions is given by[2]:

$$I_3 = \left(\frac{8\pi^2 c^2 \omega_s}{h\omega_2^4}\right)^2 I_1^2 I_2 L^2 \sum_0^J \Delta N_J^2 \left(\frac{d\sigma}{d\Omega}\right)^2 \left[\frac{1}{2\Delta\omega_J - i\Gamma_J}\right]^2$$

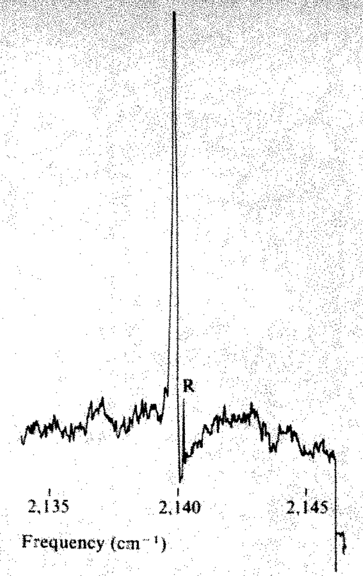

Fig. 1 The CARS spectrum of carbon monoxide in a nitrogen matrix at a concentration of 0.13%. (R = etalon reset.)

where ω_1, ω_2 and ω_3 and I_1, I_2 and I_3 are the pump (laser), Stokes (laser) and anti-Stokes (signal) frequencies and intensities respectively; ΔN is the population difference between ground and excited states; L is the interaction length; $d\sigma/d\Omega$ is the Raman scattering cross-section; $\Delta\omega_J$ is the Raman shift for the Jth resonance; and Γ a convolution of natural and laser line widths. Note the squared dependence on ΔN, concentration, interaction length and $1/\Gamma_J$.

Consideration of the above factors led us to attempt to obtain CARS spectra of matrix-isolated species at cryogenic temperatures. Matrix isolation spectroscopy involves the trapping of a molecule (atom or fragment) in an inert substrate at low concentration so that the molecule is well isolated from other molecules. Conventional matrices are the inert gases and nitrogen. As guest molecules do not normally rotate in the host matrix, the lines will be sharp (frequently <1 cm^{-1}). Furthermore, at the isolation temperatures (of the order of 10K), the molecules will be in their ground vibrational states. Thus ΔN and $1/\Gamma_J$ are both maximized. For these experiments we chose nitrogen as the matrix gas because: (1) it gave us a strong signal from the substrate for initial lining up; (2) it has the advantage that the $^{14}N^{15}N$ (0.7 mol% concentration) peak may be used as a test for alignment and sensitivity. Carbon monoxide was chosen as the species to be isolated because not only has it been extensively studied, but also it has a vibrational frequency close to that of nitrogen.

Figure 1 shows the first coherent Raman spectrum of a matrix-isolated species. The concentration of the carbon monoxide is 0.13% and the resolution of the experiment is of the order of 0.13 cm^{-1}, which is an order of magnitude better than that obtained in a conventional matrix isolation Raman experiment. A further order of magnitude improvement in resolution could be obtained without significantly altering the nature of this experiment.

The spectrum was recorded using a carbon monoxide–nitrogen premix pulsed on to a calcium fluoride plate held in a Displex closed-cycle cooler operating in the region of 15K. The CARS system used a J K Lasers Q-switched Nd/YAG laser as pump, operating at 16.7 Hz repetition rate, with a 10 ns pulse length. The probe laser was a Chromatix CMX4 flash lamp pumped scanning dye laser amplified to ~100 kW peak power. For colourless matrices we find a laser damage threshold at a few hundred kilowatts peak power for a focused beam diameter of ~10^{-2} cm. The spectra were recorded by scanning the CMX4 synchronously with (but in the opposite sense to) a Cary 81 double monochromator used as a high quality filter. The signal was detected by conventional means using a photo-

0028-0836/82/200212—02$01.00

multiplier and boxcar detection. The frequency of the carbon monoxide transition was calibrated by running IR spectra on the same matrices, as the CARS spectra in these experiments were only recorded to an accuracy of $\pm 1\ cm^{-1}$.

Attempts to carry out studies in argon led to poor-quality spectra, which were only obtained at concentrations of the order of 1%. This is clearly due to line broadening coupled with interference between the resonant signal and the non-resonant background, leading to the observation of derivative type spectra. (There are several techniques available for minimizing this effect but they all lead to a reduction in signal.) In nitrogen the rotation of the carbon monoxide (which is thought to account for the line broadening in argon[3]) is presumably suppressed, leading to a narrow line.

Note that with Raman gain/loss spectroscopy a conventional Raman spectrum is obtained without the complications outlined above for CARS. There is also the possibility of a further order of magnitude improvement in resolution (leading to $0.001\ cm^{-1}$ as a reasonable limit).

Rapid localized glacio-isostatic uplift at Glen Roy, Scotland

J. B. Sissons & R. Cornish

Department of Geography, High School Yards, Edinburgh EH1 1NR, UK

Many studies involving measurement of the altitudes of fossil marine and lacustrine shorelines have demonstrated glacio-isostatic tilting, particularly in North America, Fennoscandia and the British Isles. Such studies are normally illustrated by height–distance diagrams in which fossil shorelines are portrayed as straight lines. In some studies the shoreline-relation diagram is used to analyse and illustrate the altitudinal data[1–3]: before constructing such a diagram it is assumed that a simple pattern of glacio-isostatic uplift has prevailed. Warping of shorelines, as opposed to uniform tilting, has been inferred in North America[4–6]. On the other hand, Härme[7] envisaged block movements in Fennoscandia. Sauramo[8] also proposed dislocations, but his interpretation was rejected by Hyyppä[9]. More recently the concept of the Scandinavian shield as a stable area has been dismissed[10,11]. Here we provide evidence from Scotland for shoreline dislocation by differential movement of blocks of the Earth's crust.

The study of former crustal movements from fossil shorelines requires accurate, very closely spaced measurement, which has rarely been attempted outside Scotland. The results of such a study in the Forth Valley in central Scotland are shown in Fig. 1*a*. The upper shoreline, formed at 6,800 yr BP, is a surface feature while the lower shoreline, formed at 9,600 yr BP, is a buried feature[12]. Both shorelines have corresponding sloping and essentially horizontal portions. Two parts of this area have been glacio-isostatically uplifted without significant tilting in the past 9,600 yr, while the remainder has been tilted. Furthermore, the older shoreline has two clear displacements, one of 1 m at the limit of the Loch Lomond (Younger Dryas) Advance, and one of nearly 1.5 m corresponding with a major fault: these displacements had ended by 6,800 yr BP (Fig. 1*a*).

In Glen Roy and vicinity in the Scottish Highlands, ice-dammed lakes existed during the Loch Lomond Stadial. We have recently levelled their fossil shorelines at 1,760 points. Measurements were made at the break of slope representing the former shoreline (junction of 'parallel road' and backing cliff) and were spaced, where possible, at 25–30-m intervals. Traverses were normally 4–5 km long and the average closing error was 0.011 m. Where peat was present probes 1–3 m apart were aligned perpendicular to the shoreline. This work is more detailed and accurate than any previously undertaken on shorelines of former lakes.

We find that the shorelines are in part horizontal and in part tilted while, occasionally, there are displacements of <2 m. Despite these variations each shoreline has a limited altitudinal range. Using the means for groups of measured points and, where linear regression analysis was possible, the calculated values for the ends of tilted lengths of shoreline, the highest shoreline of Glen Roy varies between 349.5 and 351.9 m, the middle shoreline between 324.5 and 326.8 m, and the lowest one between 260.1 and 262.4 m, ranges of 2.4, 2.3 and 2.3 m respectively. There is a major exception to these generalizations which we consider here.

On the north-west side of upper Glen Roy a large landslide has destroyed all three 'parallel roads' (Fig. 2). Immediately south-west of the landslide all three shorelines rise above their normal altitude for this general area by ~3 m: the highest shoreline attains 354.1 m, the middle one 327.7 m and the lowest one 263.9 m. The 'roads' are here cut into a steep slope (25–30°) composed of metamorphic rocks of the Eilde Flags Formation (Moinian). Drift cover is thin and is mainly weathered bedrock. South-west from the landslide linear depressions roughly parallel with the contours mark the upper edges of slipped masses of bedrock (Fig. 2): they appear to be clear evidence of downhill movement but occur even where levelling proves the 'roads' to have been uplifted most.

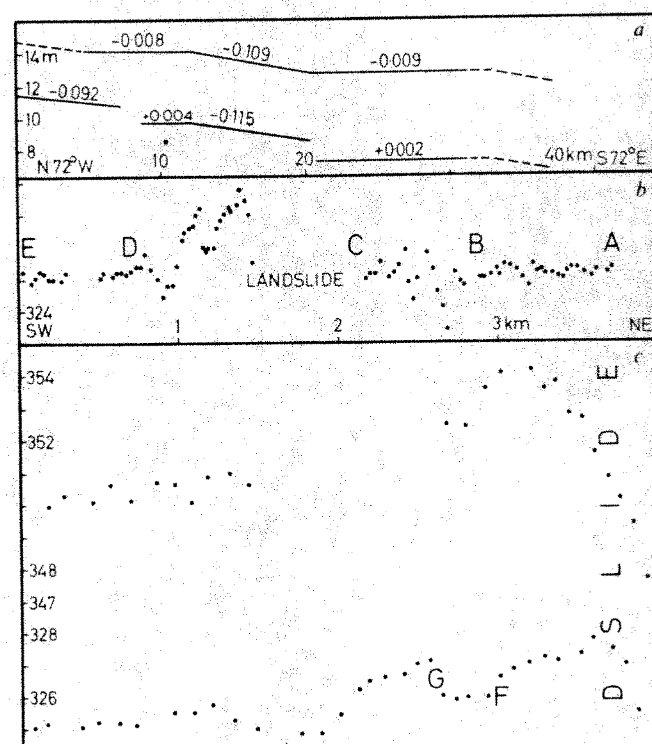

Fig. 1 Height–distance diagrams of dislocated shorelines. *a*, Western Forth Valley, gradients (in m per km). *b*, The middle shoreline of Glen Roy on both sides of the major landslide. *c*, All three Glen Roy shorelines south-west of the major landslide.

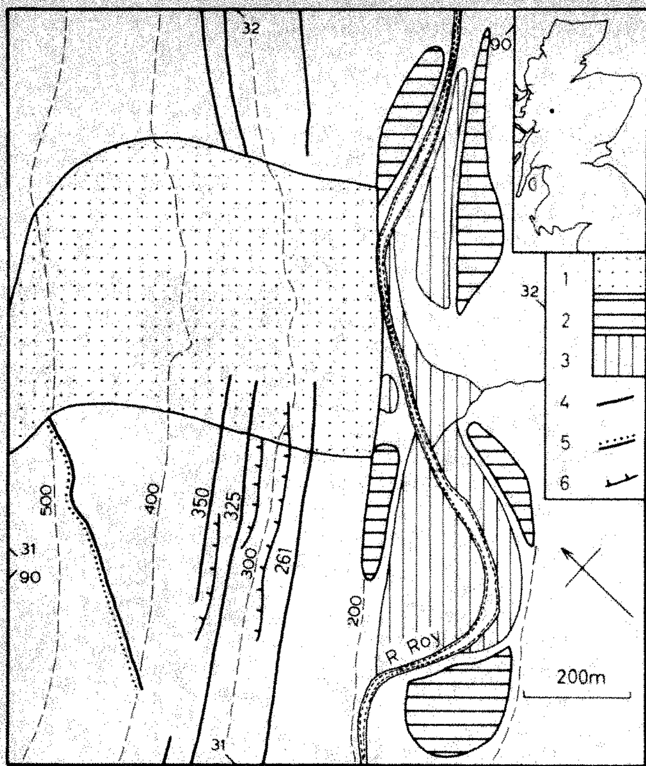

Fig. 2 The major landslide and other features. 1, Landslide; 2, part of the uniformly-sloping river terrace mentioned in the text; 3, other river terraces and floodplains; 4, 'parallel roads'; 5, inferred fault scarp; 6, upper edges of slipped masses of bedrock.

The middle shoreline, which is the best developed and sharply defined, is horizontal away from the major landslide: 16 levelled points in the south-west and 25 in the north-east (AB, DE, Fig. 1*b*) together average 325.1 m, the standard deviation being only 0.15 m. Between B and C the 'parallel road' is broken into several tilted portions: two of these rise to 0.7 m above shoreline altitude in the area of horizontality, indicating that BC is part of the uplifted area. South-west of the landslide the middle shoreline attains 2.6 m above its horizontal altitude. In the same locality the lowest shoreline attains 2.8 m above its altitude in the horizontal area and the highest shoreline 3.3 m above. All three 'roads' extend a short distance into the ground occupied by the major landslide, which has carried them down with it (Fig. 1*c*).

The point of maximal uplift on the highest shoreline lies upslope from the comparable point on the lowest shoreline. The culmination point of the middle shoreline is offset by 100 m: this difference is readily explained by the minor slips (for example, F and G, Fig. 1*c*) that have produced small but clear steps in the middle 'road'.

Localized uplift of the shorelines cannot be attributed to the landslide. Upward movement at the toe of a rotational landslide is well known: however, the Glen Roy feature is not a simple rotational slip and the toe is at the valley floor. Furthermore, the uplifted area extends hundreds of metres from the landslide. It is therefore most likely that crustal deformation occurred.

Pronounced uplift in a very small area suggests fracturing of the Earth's crust. Such fracturing is consistent with the presence of a linear bedrock ridge a few metres wide that slopes obliquely up the side of Glen Roy for a distance of 550 m (Fig. 2). Between the ridge and the valley side is a narrow depression that is up to 2 m deep despite being partly infilled by frost debris from the valley side and by peat. This feature is not a meltwater channel: the ridge is a clear positive feature standing above the adjacent ground (vertical aerial photographs reference O.S. 64:233, 032–033). Northwards the feature passes into the landslide. Southwards it begins to fade out before disappearing beneath frost debris that has moved downslope. Projected southwards the feature coincides exactly with the point where the middle shoreline begins to rise above its normal altitude (D, Fig. 1*b*). Part of the top 'road' is missing in the critical area and the bottom 'road' is here too poorly preserved to determine a relationship.

The linear nature of the ridge and associated depression and the evidence for uplift imply a fault. No detailed geological map of the area exists. Anderson[13] mapped a straight fault 10 km to the NNE the projection of which coincides with the Glen Roy feature. The bend in the presumed fault corresponds with a small re-entrant in the hillside suggesting, along with the ridge, the presence of a reverse fault: this is consistent with crustal compression associated with glacio-isostatic uplift. Fault movement could have caused earthquakes, thus accounting for the large landslide.

The uplift clearly post-dates formation of the 'parallel roads'. The relative date of termination of uplift is also established. When the lake was emptied, probably very rapidly by *jökulhlaup*[14], the new land surface encountered by the River Roy in the locally uplifted area was undulating, with large gravel fans alternating with lower ground. Initially the Roy cut into the fans and deposited the gravel thus obtained between them, producing a smooth profile now represented by a river terrace that extends intermittently along the whole length of the 2-km long uplifted area. The edge of the terrace is 110–170 m distant from the lowest shoreline. The standard deviation from a linear regression line ($r = 0.997$) of 41 levelled points on the terrace is 0.45 m. Hence pronounced differential uplift in this area had ceased by the time the terrace was formed. It is likely that the River Roy established this smooth profile shortly after lake drainage for the terrace is entirely in loose material (gravel) and, farther up the glen, was subsequently dissected by the Roy into a complex sequence of lower terraces. The major climatic amelioration that terminated the Loch Lomond Stadial occurred while the Roy ice-dammed lake stood at the highest shoreline. Hence the pronounced localized uplift occurred at the beginning of the Holocene.

Although minor earthquakes occur in Scotland today no related fault scarp has ever been detected. The country is essentially stable compared with the pronounced former instability implied by the Glen Roy evidence we have given. The latter is therefore attributed to glacio-isostatic uplift.

Our Glen Roy evidence thus shows that glacio-isostatic recovery can include abrupt localized uplift in an area now relatively stable. It adds to the Forth evidence (Fig. 1*a*) demonstrating differential movement of blocks of the Earth's crust. Because in both areas the dislocations post-date the Loch Lomond Advance, when glaciers were of limited extent, we suspect that larger movements occurred earlier during ice-sheet decay. The probability clearly exists that in Fennoscandia and North America, where ice sheets were far larger than in the British Isles, there are shoreline dislocations of even greater magnitude.

The NERC financed this research. Dr D. G. Sutherland criticized the draft of the paper.

Exotic terranes of western California

M. O. McWilliams

Geophysics Department, Stanford University, Stanford, California 94305, USA

D. G. Howell

US Geological Survey, Menlo Park, California 94025, USA

Numerous distinct geological terranes compose the North American Cordillera[1]; there may be as many as 50 terranes in California alone[2]. Critical to deciphering the history of Cordilleran tectonic assembly is an understanding of the displacement history of individual terranes. It is therefore important to know: (1) whether a terrane has undergone significant motion with respect to the stable craton (that is, whether it is allochthonous or exotic); (2) if so, when relative motion started and stopped; (3) from where an individual terrane originated; and (4) the nature of inter-terrane movements. We consider here the problem of determining whether the now-juxtaposed Salinian and Stanley Mountain terranes of California became amalgamated at or near their present position with respect to cratonic North America, or if they collided at a considerable distance from their present positions and were later accreted to North America as a composite package. The palaeomagnetic data that we present indicate that the latter was the case.

Terranes are fault-bounded geological entities of regional extent, each characterized by a geological history that is different from that of adjacent terranes. Such geological histories are determined from stratigraphical successions preserved within terranes, but in some cases this information is obscured owing to tectonic or sedimentological disruption or metamorphic overprinting. Composite terranes are produced by the amalgamation of two or more terranes. The southern Coast Ranges of California west of the San Andreas Fault consist of two composite tectonostratigraphical packages called the Salinian and Sur-Obispo terranes (Fig. 1). Basement rocks of the Salinian terrane are Middle and Upper Cretaceous granite plutons and older high-temperature metasedimentary rocks bounded on the west by the Sur-Nacimiento Fault. To the west lies the Sur-Obispo composite terrane, represented by the Stanley Mountain and San Simeon terranes. The Stanley Mountain terrane consists of Middle Jurassic ophiolite and an overlying thick sequence of Upper Jurassic to Upper Cretaceous forearc-basin strata. Structurally below the Stanley Mountain terrane is Franciscan mélange of the San Simeon terrane. The Stanley Mountain strata closely resemble, and are coeval with, the Great Valley sequence[3], which is typified by exposures along the west sides of the Sacramento and San Joaquin Valleys. Truncation by faults and unconformities disrupts the section in most places, but a nearly complete section of 4,000 m of Upper Jurassic and Cretaceous strata is exposed in the southeastern San Rafael Mountains[4]. These forearc-basin strata are demonstrably allochthonous with respect to Salinian basement, yet in late Cretaceous time the two terranes seemingly collided to form a new amalgamated terrane, as Campanian and younger sedimentary rocks of both terranes are petrographically identical and are characterized by non-marine horizons of locally derived granitic detritus[5,6] (Fig. 2). Several coherent packages of Upper Cretaceous arkosic strata in the San Simeon terrane may indicate continuity with the Salinian and Stanley Mountain terranes; however, equivocal sedimentary sequences which lap across these terranes are no older than early Tertiary.

Commencing in Campanian time with the paralic granite-grus lithofacies, the forearc took on a borderland-like configuration with detritus spilling into contrasting depositional settings on the newly juxtaposed terranes[6,7]. An episode of wrench faulting accompanied the suturing presumably along a now-distant margin of the Cordillera because Upper Cretaceous and Lower Tertiary strata contain numerous clasts of siliceous volcanic porphyries admixed with the granitic debris, yet such a volcanic provenance does not exist on either the Salinian or Stanley Mountain terranes.

Palaeomagnetic inclination data from Upper Cretaceous strata of the Salinian terrane indicate that deposition occurred as much as 2,500 km south of their present location (ref. 8; M. E. Williams, M. Schnapp and A. Cox, in preparation; D. E. Champion, personal communication). We report here new data which indicate a similar exotic origin for the Jurassic and Cretaceous rocks of the Stanley Mountain terrane.

To determine the palaeolatitude of the Stanley Mountain terrane in Jurassic time, samples of pillow basalt were collected at 10 sites spanning an 800 m section of ophiolite at Stanley Mountain (Figs 1, 2). Alternating field (a.f.) demagnetization of pilot specimens from each site yielded stable, well grouped magnetization directions at eight sites after removal of young secondary magnetizations of probable recent viscous origin; one example is shown in Fig. 3*a*. After partial demagnetization in peak alternating fields of 60–80 mT, the eight mean directions are well grouped and define an overall *in situ* mean direction $D = 053°$, $I = +54°$, $\alpha_{95} = 8°$. This direction is distinct from the present geomagnetic and axial dipole field directions for the sampling locality, as well as from any expected field direction for stable North America since early Mesozoic time[9]. A reasonable explanation for the *in situ* direction is that it represents a sampling of a primary Jurassic magnetization (TRM or high-temperature CRM) and should therefore be restored to palaeohorizontal attitude, thereby obtaining the palaeolatitude at which the rocks acquired their magnetization. If the magnetization is primary, the overall tectonically corrected mean direction is $D = 041°$, $I = -27°$, $\alpha_{95} = 8°$, corresponding to a palaeolatitude of $14 \pm 7°$. Structural attitudes of sedimentary rocks which immediately overlie the basalts were used as a palaeohorizontal reference indicator. If the age of the pillow basalt is 160 ± 5 Myr, as indicated by isotopic data from other Coast Range ophiolite samples[10], then a northerly or southerly

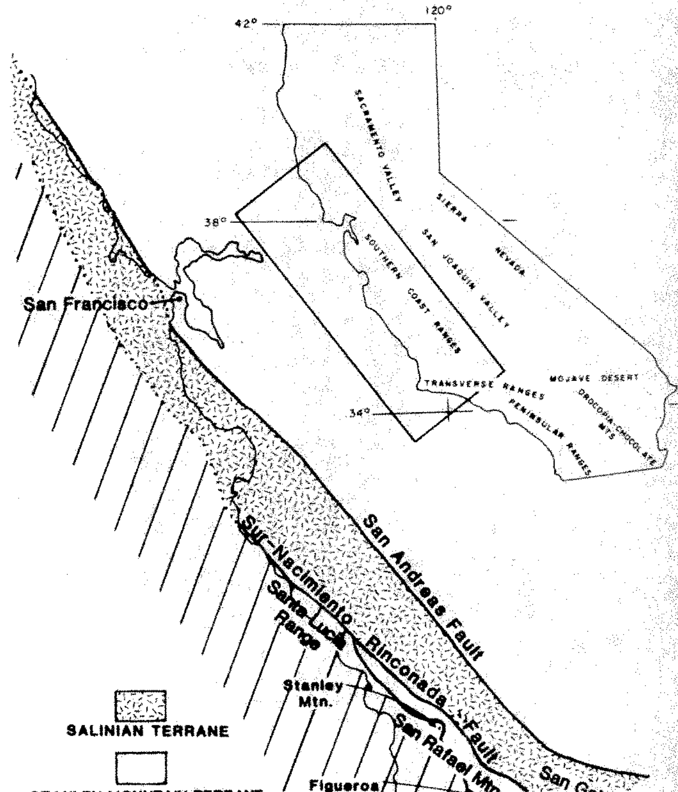

Fig. 1 Geographical sketch map of Stanley Mountain, San Simeon and Salinian terranes in western California.

0028-0836/82/200215—03$01.00

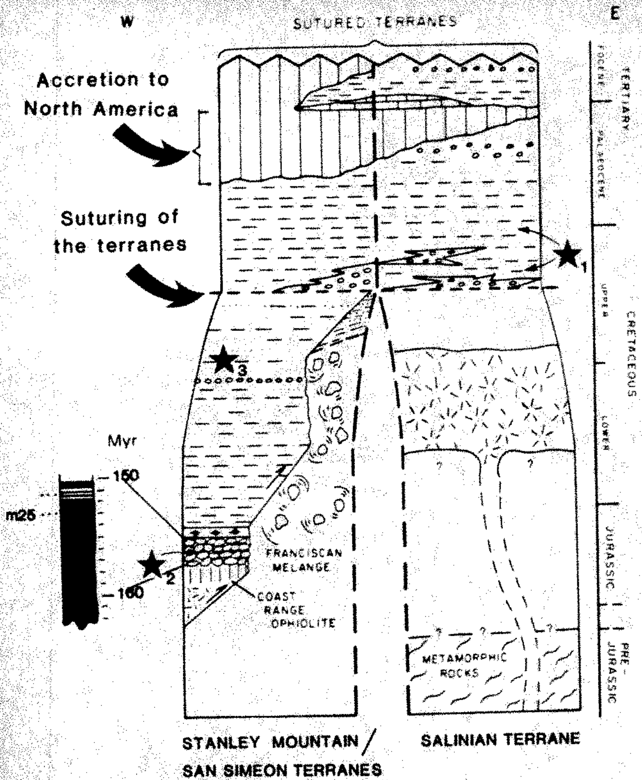

Fig. 2 Generalized stratigraphical columns for Salinian and Sur-Obispo composite terranes. Suturing of the two terranes was probably completed by the late Cretaceous, as equivalent strata lap onto both terranes after this time. ★, Stratigraphical positions of palaeomagnetic studies (*a*, D. E. Champion, personal communication; *b*, ref. 8 and M. E. Wilson, M. Schnapp and A. Cox, in preparation). The inset on the left is magnetic reversal time scale[11] (black = normal polarity).

palaeolatitude cannot be invoked, for the geomagnetic field was of mixed polarity at this time[11] (see reversal time scale inset, Fig. 2).

If the magnetization were of secondary origin and dated from Tertiary time, an exact tectonic correction would not be possible because the structural attitude at the time of remagnetization would be unknown. One possibility would be that the basalts acquired their magnetization after tectonic tilting and were subsequently rotated 50–60° clockwise about a vertical axis. At the locality where the samples were collected, the basalts form part of a steeply dipping homoclinal sequence, so that a fold test was not possible. There is no evidence, however, for Tertiary remagnetization by a thermal mechanism, for isotopic ages are not reset and reheating effects are not visible in hand specimen or thin section.

The sedimentary record indicates that the Stanley Mountain and Salinian terranes probably collided in the late Cretaceous. To determine the palaeolatitude of the Stanley Mountain terrane at approximately the time of collision, samples of Upper Cretaceous (Cenomanian–Santonian) flysch strata were collected at 10 sites in the San Rafael Mountains near Figueroa Mountain (Figs 1, 2). After a.f. demagnetization in peak fields up to 80 mT, a single stable component of magnetization was isolated (an example is shown in Fig. 3*b*). The overall *in situ* mean direction from these 10 sites is $D = 002°$, $I = +74°$, $\alpha_{95} = 10°$, which is significantly different from both the present geomagnetic field direction and the axial dipole field direction at the sampling locality, suggesting that it is not of recent origin. Also, this overall mean direction is significantly different from any geomagnetic field direction since early Mesozoic time derived from stable North America[9]. On tectonic correction to palaeohorizontal, the overall mean direction is $D = 023°$, $I = +12°$, $\alpha_{95} = 11°$. The minor decrease in overall precision accompanying this correction is not statistically significant and may be due to pre-magnetization slumping as noted in other palaeomagnetic studies of turbidites[8]. The slightly skewed distribution of site mean directions may be due to our inability to make exact tectonic corrections which compensate for this post-depositional slumping.

If the magnetization of these samples is primary and dates from the time of deposition or soon thereafter, the tectonically corrected inclination of $12 \pm 10°$ would correspond to a palaeolatitude of $6 \pm 5°$ (N or S). This range is slightly lower than the range of apparent palaeolatitudes from the Pigeon Point Formation on the Salinian terrane (ref. 8, and M. E. Wilson, M. Schnapp and A. Cox, in preparation), but if a Northern Hemisphere interpretation is invoked (Fig. 4), this might be expected, as the Pigeon Point strata are slightly younger (Campanian–Maestrictian). An alternative explanation for the palaeolatitude discrepancy could be that the suturing of the two terranes might not have been completed by this time.

The palaeomagnetic data shows that (1) the Salinian composite terrane lay in low ($21 \pm 7°$) palaeolatitudes[8] in Campanian–Maestrictian time, and occupied higher ($25 \pm 3°$) palaeolatitudes[10] in early Palaeocene time; (2) the Stanley Mountain terrane lay in slightly lower ($6° \pm 5°$) palaeolatitudes in Cenomanian–Santonian time, and occupied slightly higher ($14° \pm 7°$) palaeolatitudes at about 160 ± 5 Myr; either a north or south palaeolatitude is possible; (3) a simple displacement model (solid line in Fig. 4) would place the Sur-Obispo composite terrane at 14° S at 160 Myr, at 6° N at about 90 Myr and at 21° N at about 70 Myr, after colliding with the Salinian composite terrane; and (4) alternatively, the Stanley Mountain terrane could have occupied low northerly palaeolatitudes from Jurassic to Cretaceous time, beginning its major northward migration at about the time it collided with the Salinian terrane (dashed line in Fig. 4). Coupled with the geological arguments, these data indicate that the late Cretaceous collision of the two terranes occurred in low palaeolatitudes, far from the present California continental margin.

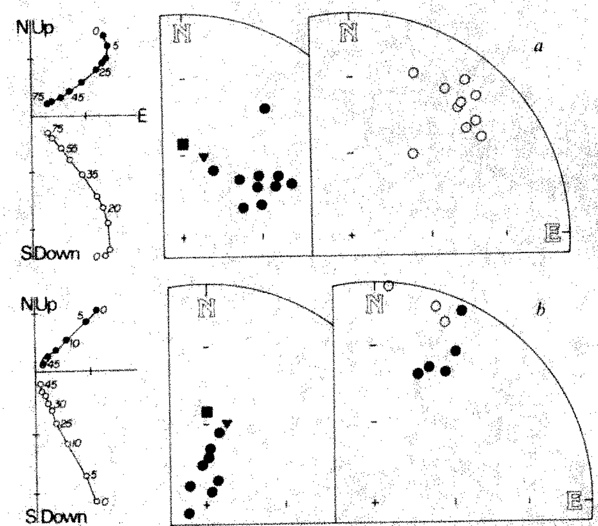

Fig. 3 *a*, Palaeomagnetic results from Stanley Mountain pillow basalts. Left: orthogonal vector projection of a.f. demagnetization experiment; circles represent projection of magnetization vector on the horizontal (●) or east–west vertical (○) plane; axis ticks 0.2×10^{-3} A m^{-1}. Numbers are peak a.f. treatment in units of 10^{-3} T. Centre: equal area projection of site mean magnetization directions after a.f. demagnetization. No tectonic correction is applied; each direction plotted is the average of six individually oriented samples. Solid symbols represent positive (downward) inclinations. ■ and ▼ are axial dipole field and present geomagnetic field directions respectively. Right: as in centre, but with magnetization directions restored to palaeohorizontal. Open symbols represent negative (upward) inclination. *b*, Palaeomagnetic results, Upper Cretaceous sedimentary rocks from Figueroa Mountain. Left: as above, axis ticks 0.1×10^{-3} A m^{-1}. Centre: site mean directions before tectonic correction; conventions as above. Right: site mean directions before tectonic correction; conventions as above.

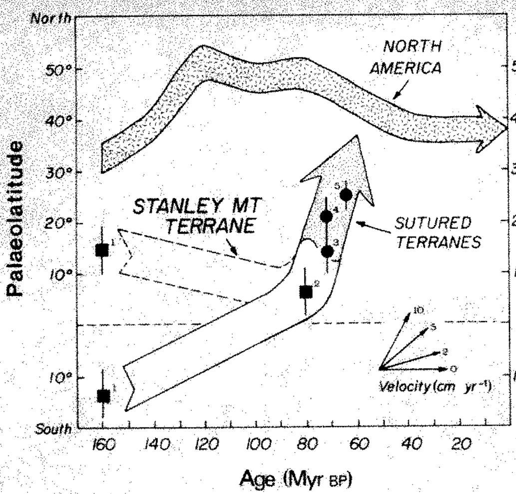

Fig. 4 Palaeolatitude of the Salinian and Stanley Mountain terranes as a function of time, compared with palaeolatitude of 'target area' on North America for present-day position, 35–39° north latitude. Stippled path represents the two terranes after suturing. The North American and Salinian/Stanley Mountain tracks intersect at ~50–55 Myr BP to allow for Eocene reconstruction of the Butano-Point of Rocks submarine fan system. ■, Data from Sur-Obispo terrane; ●, data from Salinian terrane. (1) and (2) are from this study; (4) from ref. 8; (3) from M. E. Wilson, M. Schnapp and A. Cox, in preparation; and (5) D. E. Champion, personal communication). Arrows in lower right give northward velocity in cm yr^{-1} for reference. The dashed and solid lines represent alternative palaeolatitudes for the Stanley Mountain terrane depending on the choice of magnetic polarity.

The classic sequence of events proposed for the evolution of the western Cordillera involves three general episodes[12-14]: (1) a late Jurassic to early Tertiary subduction regime with major deposition in an arc–trench gap configuration; (2) early Tertiary proto-San Andreas faulting and a borderland setting during an early to middle Tertiary episode of oblique subduction along a flattened Benioff–Wadati zone; and (3) continental margin transform faulting resulting in tectonic splintering and additional borderland development. If recent palaeomagnetic studies (ref. 8; M. E. Wilson, M. Schnapp and A. Cox, in preparation; D. E. Champion, personal communication), including our own, are accurate and basin analyses[4,6,7] correct, both the timing of events and nature of origin of the continental margin must be reinterpreted.

Analysis of the 1,500 m thick fluvio-deltaic sequence in the southeastern Stanley Mountain terrane indicates that the Stanley Mountain and Salinian terranes were probably attached by ~72 Myr BP. Thus the Stanley Mountain and Salinian terranes, both of which come from quite different parent terranes, must have travelled northwards together, despite the remarkable parallelism of Cretaceous depositional environments between the Stanley Mountain terrane and the Great Valley sequence of the Sacramento and San Joaquin Valleys. However, the Stanley Mountain/Salinian composite package was probably emplaced in California by the early Eocene, based on the inference that submarine fans sequences of this age[15] lap across these terranes and other terranes autochthonous to California.

The palaeomagnetic data presented here and elsewhere indicate a large northward component of relative plate motion along the western margin of North America during the Cretaceous and early Tertiary. Several late Mesozoic terranes presumably originated at the latitude of present-day Central America and moved northwards to the California area by late Palaeocene time. Plate motion reconstructions (ref. 16 and D. C. Engebretson, in preparation) demonstrate that Farallon–North America relative motion for most of the Cretaceous would have been largely orthogonal to a north-west trending margin of western North America. Kula plate motion relative to North America had a significant northward component at high latitudes, but owing to an Euler pole position in northwestern South America, Kula–North America relative motion in the Central American regions would also have been largely orthogonal (ref. 17 and D. C. Engebretson, in preparation).

Two possible ways to account for the northward shifting of terranes are immediately apparent[17]: (1) reconstruct the late Mesozoic Pacific basin plates including now vanished plate(s) whose configurations would account for the northward slip required by the palaeomagnetic data and for the episodic plutonism mapped all along the Cordillera, and/or (2) palinspastically restore Central America and the ancient Caribbean plate westwards to increase the distance from the Kula–North America Euler pole in late Mesozoic time, so that Kula plate motion could better account for the northward component of motion of the Stanley Mountain and Salinian terranes.

We thank Anne Demitrack, Brian Hausback, Bill Keller, Peter Lellis and Norman Sleep for assistance in sample collection, David Engebretson and Ben Page for editorial comments, and especially Michel Debiche and Anne Demitrack for many laboratory measurements. The research was supported by grant PRF-11405 from the Petroleum Research Fund of the American Chemical Society.

Implications of Palaeozoic phosphorites in the northern Sierra Nevada range

Robert J. Varga

Union Oil Research Center, PO Box 76, Brea, California 92621, USA

Marine phosphorites are known to occur within multiply deformed Ordovician/Silurian and Upper Devonian rocks of the northern Sierra Nevada range, California. Although the phosphatic sediments constitute a small percentage of total lithologies in the area, they provide unique information regarding the age and palaeogeographical setting of these rocks. The mode of occurrence of the Sierran phosphorites and their association with black shale and chert suggest that they may have formed along a continental margin which experienced strong equatorial or trade wind belt upwelling. Consideration of worldwide plate reconstructions for the early to middle Palaeozoic shows that the present western margin of North America was one of the few favourable sites for phosphate formation during this time period. Thus, the presence of marine phosphorites within Palaeozoic rocks of the northern Sierra Nevada is consistent with arguments which suggest that these rocks were deposited near the western margin of North America. Although considerable margin-parallel translations cannot be ruled out for these rocks, they do not appear to constitute a far-travelled microplate derived from a distant, trans-oceanic site.

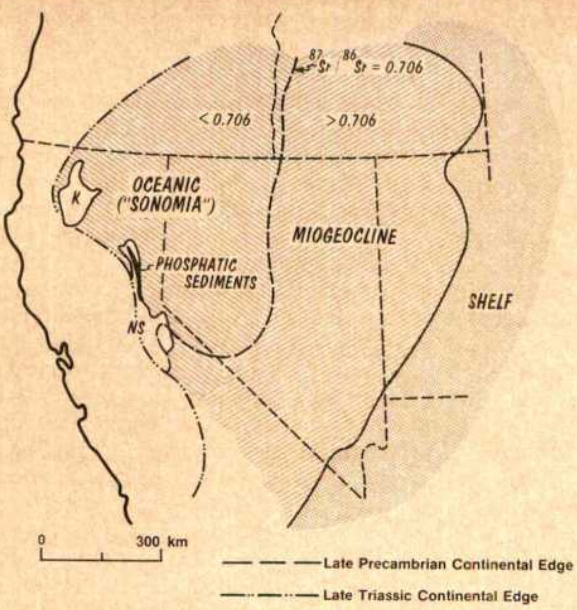

Fig. 1 Sketch map showing lower to middle Palaeozoic petrotectonic assemblages of the US Cordillera. Generalized outcrops of Palaeozoic strata in the northern Sierra Nevada (NS) and eastern Klamath Mountains (K) are shown with no pattern within 'oceanic' assemblage. Data from refs 19, 38, 44.

Phosphorite occurs within the pre-late Devonian (in part Ordovician/Silurian) Shoo Fly Complex (SFC) and late Devonian Elwell and Sierra Buttes Formations (EF and SBF, respectively) of the northern Sierra Nevada range. These formations and their phosphatic components crop out in an elongate, north-west-trending belt more than 150 km in length (Fig. 1). The SFC comprises predominantly siliciclastic sediments, in part of continental derivation[1], as well as minor limestone, dolomite and mélange[2,3]. Black shale, chert and intermediate to silicic volcanics of the SBF and EF[4] overlie the SFC with angular discordance[5–7] All three formations are multiply deformed[7–9] and were metamorphosed to lower greenschist facies at ~150 Myr (ref. 10). The SBF and EF constitute components of a middle Palaeozoic to early Triassic volcanic arc terrane which extends to the eastern Klamath Mountains of northern California[11].

Metamorphism and intense deformation has hindered interpretation of the depositional environments of Palaeozoic strata in the northern Sierra Nevada. As discussed below, such information is critical to the evaluation of their pre-Mesozoic palaeogeographical position. Thus, the presence of a unique sedimentary feature, such as phosphorite, assumes heightened significance. It is, therefore, of interest to compare the Sierran phosphorites with well-documented occurrences of marine phosphates about which some palaeoenvironmental generalizations can be made.

Phosphate within Palaeozoic rocks of the northern Sierra Nevada occurs principally as nodules, and to a lesser degree as lenses and angular fragments within foliated black shale and chert. Phosphate nodules (Fig. 2*a*) are generally round to sub-round and vary in size from ~0.5 to 2.5 cm. The nodules are black on fresh surface and weather to a light grey to white colour. The porous nodule surfaces often show a crude concentric pattern with inner layers composed of darker, more porous material than outer layers. Phosphatic lenses commonly accompany phosphate nodules (Fig. 2*b*). These lenses are up to 2.5 cm thick and 1 m in length. Angular fragments of phosphate, up to 0.5 cm in length, are ubiquitous associates of both phosphate nodules and lenses.

Phosphate nodules are composed of dark brown, cryptocrystalline, isotropic collophane (Fig. 2*c*) with inclusions of silica and pyrite. Slight differences in colour, transparency and quartz content define a crude, discontinuous banding towards the outer boundaries of most nodules. Every nodule examined contains a characteristic black, iron-rich outer surface which is up to 0.6 mm wide (Fig. 2*c*). Silica occurs as fine-grained intergrowths within the collophane matrix, as irregular masses up to 0.2 mm in size, and as recognizable biogenic remains (Fig. 2*d*). Well-preserved sponge spicules and radiolaria have been recovered by HCl dissolution of nodules from the EF[12] and SFC[7].

The average of four microprobe analyses of nodule interiors from the SFC is as follows: $P_2O_5 = 39.96\%$, $F = 3.56\%$, $CaO = 52.04\%$, $SiO_2 = 1.71\%$, $Cl{=}Sr{=}Na_2O{=}SO_3{=}MgO{=}K_2O <$ 500 p.p.m., total = 97.27% (the slightly low total could not be accounted for and presumably represents a small amount of structural OH^-, instrument calibration error, or both). CaO/P_2O_5 and F/P_2O_5 ratios in the SFC nodules have values of 1.30 and 0.09, respectively, which are close to the ratios

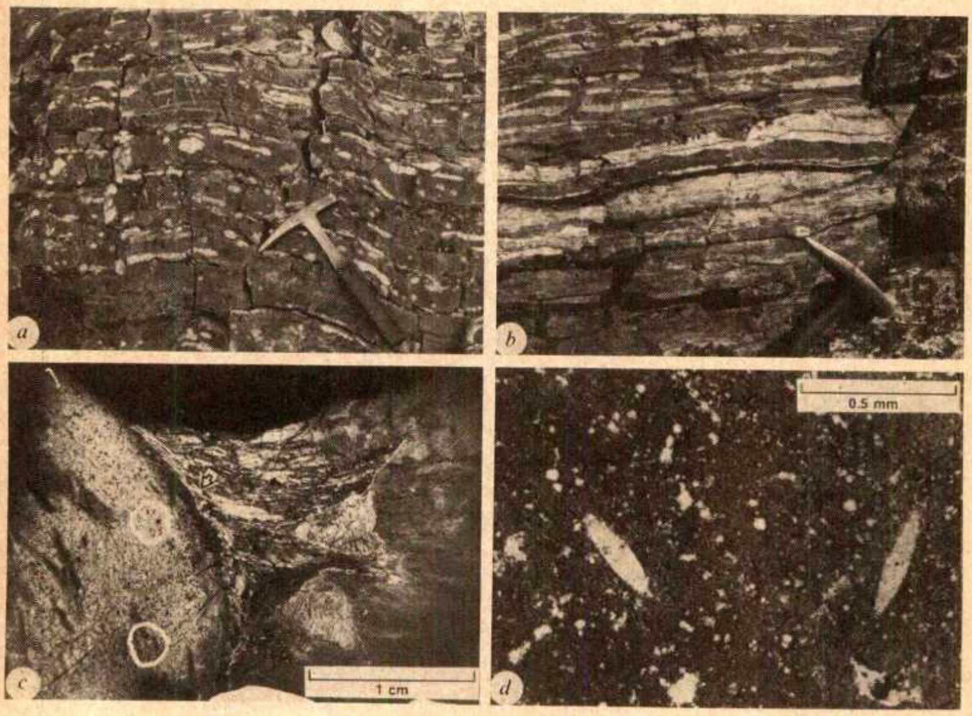

Fig. 2 *a*, Phosphate nodules (white areas) within black chert of the Elwell Formation. *b*, Phosphate lenses (white areas) and nodules (near hammer tip) within Shoo Fly Complex. *c*, Negative photograph of thin section showing the boundary between an undeformed phosphate nodule from the SFC (left side of photograph) and highly deformed black shale matrix. Note faint concentric banding within nodule and dark, iron-rich coating (light band in photo) on outer nodule surface (tip of arrow). Circled areas are probe sites. *d*, Sponge spicules(?) within SFC nodule.

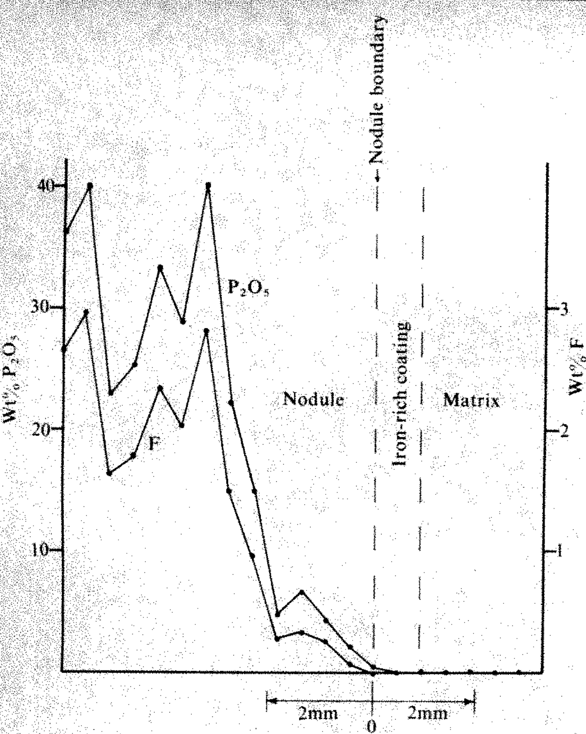

Fig. 3 Microprobe data from a 9.5-mm traverse across an SFC nodule–matrix boundary. Peaks and valleys in P_2O_5 and F contents show the relative abundances of apatite within the nodule. Areas of high apatite concentration correspond to layers of low included silica content. Iron-rich coating is seen as the dark band in Fig. 2*c* which separates matrix from nodule.

expected (1.32, 0.09) in unsubstituted fluorapatite, $Ca_{10}(PO_4)_6F_2$. CO_2 content was estimated using Gulbrandsen's[13] X-ray peak-pair method. By this method, CO_2 content of two SFC nodules and one EF nodule average $0.38\pm0.56\%$ and $0.74\pm0.56\%$, respectively. These estimates are consistent with a nearly ideal fluorapatite composition of the Sierran nodules.

The composition of the Sierran nodules is unusual in that most marine apatites contain 3–6% CO_3^{-2} substituted into the PO_4^{-3} site with the charge balanced by a variety of ions[14]. Post-depositional weathering, as a means of removing CO_2 and other components from the apatite structure[15], seems an unlikely mechanism to explain the apatite chemistry of the Sierran nodules. Outcrops from which the samples were collected for this study were quite fresh, having been scoured by alpine glaciers during the Pleistocene. Thus, the present chemistry of the nodules may represent either their original chemistry or the effects of chemical exchange during Jurassic dynamothermal metamorphism.

The origin of the concentric banding in Sierran phosphate nodules (Fig. 2*c*) is of interest because of the observation that many recent phosphorites contain films and layers of manganese[16]. Banding within an SFC nodule was investigated optically and by a 9.5-mm microprobe scan (Fig. 3) for P, F and Mn from the interior of the nodule to its outer edge. Weight percentages of both P_2O_5 and F, and thus apatite, show peak concentrations 3.3 and 5.6 mm from the outer boundary of the nodule with a drop in concentration in between. From 3.3 mm to the nodule boundary the concentration of apatite steadily decreases to zero with effectively no phosphorous or fluorine in the matrix. Mn was not present above detection limits (500 p.p.m.), anywhere along the microprobe traverse. X-ray fluorescence of the dark outer coating surrounding the nodule (Fig. 2*c*) showed it to be iron-rich with small amounts of titanium, calcium and potassium. Banding within nodule interiors thus corresponds to differences in apatite concentration. It is apparent optically that an increase in intergrown silica generally corresponds to decreases in apatite content. The sharp decrease in apatite content towards the nodule boundary is interpreted as indicating a steady drop in accretion of apatite during the waning stages of nodule growth.

The pre-Mesozoic position of Palaeozoic rocks of the northern Sierra Nevada with respect to North America has caused some debate[17]. The question is whether these rocks represent autochthonous or parautochthonous terranes which have been associated with the western margin of North America since the early Palaeozoic[7,11,18] or whether they represent components of a far-travelled island arc terrane, Sonomia (Fig. 1), which was sutured to North America in the Triassic[19]. Lack of faunal control and the absence of relevant palaeomagnetic data[10] preclude conclusive statements regarding the site of origin of these rocks. Thus, less direct petrological, sedimentological and structural arguments must be constructed[1,7].

The presence of marine phosphorites within the rock record of a particular region may have palaeogeographical implications if some analogy can be drawn between ancient and recent deposits. It is evident that many marine environments favourable to phosphate deposition in ancient oceans do not exist at present[13,16]. However, while the oceanic and biogeochemical conditions which existed during deposition of many ancient phosphorites remain largely unexplained, several recurrent observations lead to the following conclusions:

(1) When corrected for palaeomagnetic position, most recent and ancient phosphorites are found to have formed along the margins of continents in areas of oceanic upwelling at latitudes lower than 40°–50° (refs 20, 21).

(2) Phosphorites which form along the west coasts of continents ('west-coast type' deposits) in areas of trade wind belt

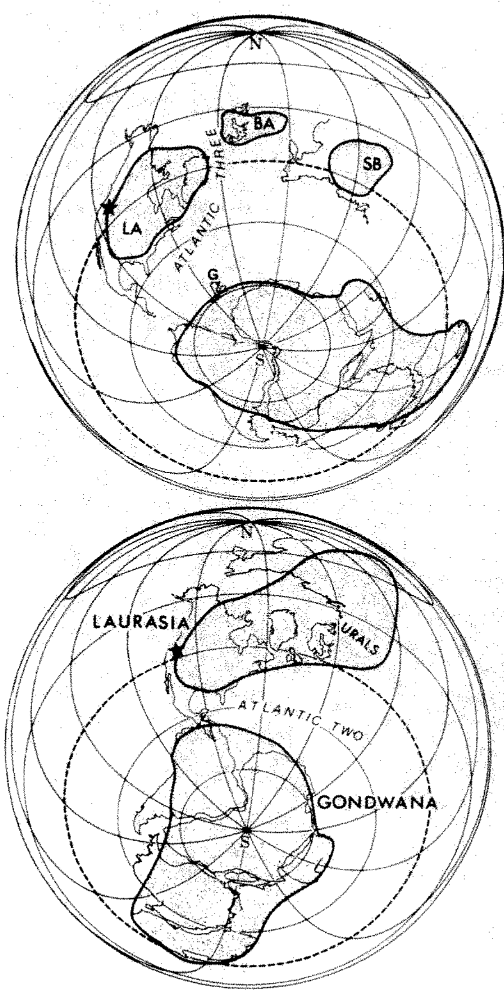

Fig. 4 Palaeomagnetic plate reconstructions for *a*, late Ordovician and *b*, late Devonian from ref. 34. ★, Present location of Sierran phosphorites with respect to North American Cordillera. Palaeoequators are shown as dashed lines.

upwelling[22-24] and those formed along continental margins bordering narrow, east–west seaways ('Tethyan-type' deposits)[25] in areas of equatorial upwelling[26] are typically associated with black shale and chert. Phosphate within west coast- or Tethyan-type deposits is generally nodular to pelletal in form.
(3) 'Florida-type'[27] or 'Chatham Rise-type'[28] phosphate deposits, which form along the east-facing margins of continents, are not generally associated with chert and black shale but typically occur within sandstone, limestone and dolomite[27,29,30]. Phosphate within Florida-type deposits is generally found in the form of pellets, pavements, sands and cobbles which show abundant evidence of enrichment by weathering, redeposition and replacement of limestone[30-32].

In form and lithic association phosphate deposits within Palaeozoic strata of the northern Sierra Nevada closely resemble west coast- or Tethyan-type deposits. Further, continentally derived sandstones within the SFC[1] imply relative proximity of the Sierran block to a continental mass during the early Palaeozoic. It is thus postulated that the Sierran phosphorites were deposited along the west-facing coast of a relatively large continental mass or, possibly, in a narrow east–west seaway between two continents during the early to middle Palaeozoic. By analogy with the world-wide distribution of modern and ancient phosphorites[20,21], the site of deposition would have been located at a latitude lower than 40°–50°. Water depths may have been in the range of 100–500 m (ref. 33).

Figure 4*a*, *b* shows the world-wide plate configuration as determined by Morel and Irving[34] for the general time period of phosphate deposition in the northern Sierra Nevada, approximately late Ordovician to late Devonian. The maps show that the west coast of North America was one of the few continental margins situated favourably throughout the early to middle Palaeozoic for formation of west coast-type phosphorites as most of the Gondwana continents were clustered about the South Pole. Other continental margins in positions favourable for west coast-type phosphate formation during the entire time period were the present north-west coast of Australia and northern India. The Palaeozoic stratigraphy and structural development of north-west Australia[35] and northern India[36] bear little resemblance to that of the northern Sierra Nevada[4,7,8]. Thus, neither of these sites is believed to represent a reasonable source terrane for a Sierran microplate. The maps also show that no narrow, equatorial seaways existed during the early to middle Palaeozoic, an observation consistent with the plate reconstructions of Scotese and others[37].

The present position of Sierran phosphorites near the western edge of the Cordillera is consistent with the palaeogeography of the North American continent during the early to middle Palaeozoic. If the northern Sierra Nevada was in its approximate position relative to North America during the early to middle Palaeozoic then the phosphorites would have lain at approximately lat. 5°–10° N during this time period. Schweickert and Snyder[38] concluded that an ocean as wide as the modern Atlantic may have existed off western North America by the Middle Ordovician assuming spreading rates comparable with those along the Mid-Atlantic Ridge and an upper Proterozoic (<850 Myr) rifting event[39]. The west-facing Palaeozoic margin of North America, at low latitudes and opposite an ocean sufficiently wide to develop circulatory gyres, was an ideal location to develop phosphatic sediments. It is thus not surprising to find phosphorites within Sierran strata if indeed they are indigenous to North America.

The hypothesis that Palaeozoic sediments of the northern Sierra Nevada were deposited on or near the Cordilleran margin of North America during the early to middle Palaeozoic has important tectonic implications. Specifically, this hypothesis is inconsistent with models which suggest that the northern Sierra Nevada represents part of a wholly exotic island arc terrane which was unrelated to North America until accretion during the Permo–Triassic Sonoma Orogeny[19]. Considerable translation of the northern Sierra Nevada along the continental margin[19] cannot be ruled out, however, as the entire west coast of North America could have received phosphate deposition (Fig. 4*a*, *b*). Though not conclusive, the present position of the northern Sierra Nevada within an area favourable for phosphate deposition during the early to middle Palaeozoic suggests a less complicated model wherein the Sierran phosphorites were deposited along the western margin of North America and have since experienced only limited translations. This model is consistent with the observations of other authors who have noted broad tectonic and stratigraphical similarities between Palaeozoic rocks of the Great Basin and the Sierra Nevada[1,4,7,11,38,40-43].

Temperature control of oxygen-isotope fractionation of cultured planktonic foraminifera

Jonathan Erez

The Hebrew University of Jerusalem, The H. Steinitz Marine Biology Laboratory, Eilat, PO Box 469, Israel

Boaz Luz

The Hebrew University of Jerusalem, Department of Geology, Jerusalem, Israel

The palaeotemperature equation of Epstein *et al.*[1] relates the oxygen-isotope composition of mollusc carbonate shells to the temperature in which it has been deposited. This equation has been applied extensively to derive palaeotemperatures and

other palaeoenvironmental parameters for the Pleistocene epoch, based on the isotopic composition of planktonic foraminifera in deep sea cores[2–11]. Recently, doubt has been expressed as to whether planktonic foraminifera fractionate oxygen isotopes according to the known palaeotemperature equation[12–18], and thus the validity of many palaeoenvironmental studies has been questioned. We present here experimental data demonstrating that planktonic foraminifera of the species *G. sacculifer* deposit calcite skeletons that have an oxygen-isotope composition very close to that predicted by the well-known palaeotemperature equation[1].

The oxygen-isotope composition of planktonic foraminifera in deep sea cores is a major tool in Pleistocene research. It serves to determine palaeotemperatures, palaeosalinities, sea-level changes, continental climatic conditions and provides accurate stratigraphy for the Pleistocene epoch[2–11]. These studies are based on the assumption that oxygen isotopes in planktonic foraminifera shells are fractionated according to the equation of Epstein *et al.*[1] that was determined experimentally for molluscs. Emiliani[2] tested this assumption by comparing the 'isotopic temperature' (the temperature calculated based on the isotopic composition of calcium carbonate), of planktonic foraminifera from superficial sediments, to the actual temperatures of the overlying seawater. He found a good fit between these temperatures and concluded that planktonic foraminifera can be used for palaeotemperature studies. This approach has been repeated on material from sediments with similar conclusions[6,10,19,20]. However, isotopic temperatures calculated for living planktonic foraminifera that were collected by plankton net tows were almost always significantly higher than those observed in the water in which they were collected[12–18]. It has been proposed that these nonequilibrium isotopic compositions are caused by introduction of metabolic CO_2 into the carbonate skeletons, a phenomenon that has been reported in other carbonate depositing organisms, including benthic foraminifera[21,22] and in part was attributed to metabolic activity of symbiotic algae[21]. Attempts to resolve the problems using foraminifera collected in sediment traps did not reach unequivocal conclusions[18,23], and thus palaeoclimatic determinations based on oxygen-isotope compositions of planktonic foraminifera became uncertain.

The ability to culture planktonic foraminifera in the laboratory[24] opened the possibility of resolving this problem experimentally. A detailed account of the entire experiment will be reported elsewhere[25]. Briefly, young (roughly 10-day old) individuals of the planktonic foraminifer *G. sacculifer* were collected from surface water in the Gulf of Eilat using plankton nets. Each individual was cultured in an 100-ml Erlenmeyer flask with 80 ml of filtered seawater and was fed daily by one newly hatched brine shrimp. The Erlenmeyer flasks were kept in temperature controlled baths where the deviations from the desired temperature did not exceed 0.1 °C (based on three daily accurate thermometer readings, and a continuous monitoring of temperature on strip chart recorder). Salinities were monitored every 2 days to ensure that there was no water evaporation. The growth of the foraminifera was monitored daily using an inverted microscope. All individuals considered in this experiment reached maturity and went through reproduction by producing gametes. The average initial weight of these foraminifers was ~5 μg per individual and the final weight was ~45 μg per individual. Thus ~90% of the carbonate shells was deposited in controlled conditions. A correction for the original (10% weight) isotopic composition was made using control groups for which the isotopic composition was determined separately. Each experiment lasted roughly 2 weeks; the range of experimental temperatures was between 14 and 30 °C, and in each run there were 2 or 3 different temperatures. Because only individuals that went through gametogenic reproduction were used for the final isotopic analysis, there was no need to clean the protoplasm from the shell. During the process of gametogenesis[24], the entire organic matter has been extruded naturally from the shell and the skeleton that is left behind is white, organic matter free and very similar to material from sediments. Yet before analysis the individuals were crushed in ethanol, dried, vacuum roasted for 30 min at 450 °C. The analysis was carried out according to the method of Shackleton[26] using a VG602 Micromass spectrometer. The water isotopic composition was determined according to the procedure of Epstein and Mayeda[27].

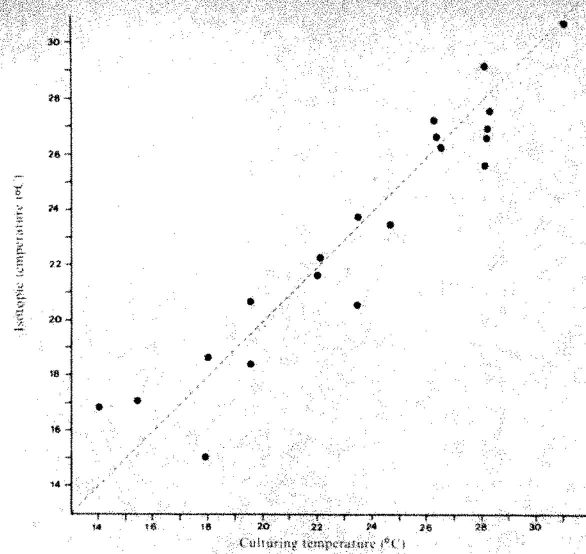

Fig. 1 The isotopic temperature calculated from the oxygen-isotope composition of the shell carbonate of the foraminifer *G. sacculifer* according to the modified equation of Epstein *et al.*[1] plotted against the actual temperature in which the foraminifers were cultured. The dashed line represents the ideal fit between the two temperatures having a slope of 1.0 and an intercept of 0. The best linear fit to the data is a line having slope and intercept of 1.01 and −0.07, respectively, having a correlation coefficient of $r = 0.95$. These experimental data demonstrate that *G. sacculifer* deposits its skeleton close to oxygen isotopic equilibrium, and that the common palaeotemperature equation for molluscs is applicable for this planktonic foraminifer.

The isotopic temperatures were calculated according to the equation of Epstein *et al.*[1] as modified by Craig[28]

$$pt = 16.9 - 4.2(\delta^{18}O_c - \delta^{18}O_w) + 0.13(\delta^{18}O_c - \delta^{18}O_w)^2$$

where pt is the isotopic temperature and $\delta^{18}O_c$ and $\delta^{18}O_w$ are the isotopic composition of the carbonate and seawater respectively.

The isotopic temperature and the actual culture temperature are compared in Fig. 1. A remarkable fit exists between the isotopic and the actual temperatures. The line of best fit using linear regression has the following parameters:

$$t = -0.07 + 1.01pt$$

where t and pt are the actual and the isotopic temperatures, respectively. The correlation coefficient (r) for this linear regression equals 0.95. Ideally, the intercept and the slope should have been 0.0 and 1.0, respectively. The values that we obtained (−0.07 and 1.01) are almost identical to those expected, and would cause only a slight deviation of <1% in palaeotemperature determinations in the range of 14–30 °C.

We therefore conclude that the planktonic foraminifer *G. sacculifer* fractionate oxygen isotopes with changing temperatures according to the modified equation of Epstein *et al.*[1] that was originally developed for molluscs. Accurate palaeotemperature determinations that are based on *G. sacculifer* isotopic composition should still take into consideration the isotopic composition of seawater and the vertical migration of this species during its ontogeny[12,23]. The nonequilibrium values that have been observed in plankton samples deserve further investigation, but it is not unlikely that they were caused by vacuum roasting of the samples before analysis, which was intended to remove organic contaminants.

Our experiment provides more data points to the palaeotemperature equation at the temperature range where it was lacking (14–30 °C) and substantiates the results of earlier palaeoenvironmental studies based on the oxygen-isotope composition of planktonic foraminifera.

We thank A. Szin and A. Shemesh for technical assistance.

IQ in Japan and the United States shows a growing disparity

Richard Lynn

Department of Psychology, The New University of Ulster, Coleraine, Co. Londonderry BT52 1SA, UK

Evidence from 27 samples indicates that the mean IQ in Japan is higher than in the United States by around one-third to two-thirds of a standard deviation. Analysis of results from the standardization in Japan in 1975 of the new revised version of the American Wechsler Intelligence Scale for Children shows that the Japanese–American disparity in mean IQ has increased during the twentieth century. Among the younger generation the mean Japanese IQ is approximately 111.

Several studies have indicated that the mean IQ is higher in Japan than in the United States and other advanced western nations[1,2]. The Japanese–American disparity has varied in different samples from 2 to 15 IQ points. The existing evidence suggests that the disparity is generally smallest among samples born in the earlier decades of the century, and greatest among young samples born more recently. Thus the mean IQ in Japan may have risen relative to that in the United States, producing an increasing disparity between the two populations.

Evidence to determine whether this is the case can be derived from the recent standardization in Japan of the revised version of the Wechsler Intelligence Scale for Children[3]. This test was constructed and standardized in the United States in the early 1970s and was standardized in Japan in 1975. Five of the performance subtests were retained unaltered in the Japanese standardization—Picture Arrangement, Object Assembly, Coding, Mazes and Block Design (in Block Design the last item in the Japanese version has been made slightly more difficult, thus making the test harder for the Japanese). The Digit Span subtest was also unchanged in the Japanese standardization, as in the previous standardizations of the Wechsler tests.

In Japan, the test was standardized on a representative sample of the child population consisting of 100 subjects at each age level from 6–16 yr. The standardization procedure in Japan followed that in the United States in matching the sample for socio-economic status to the total population. The mean raw scores of the Japanese samples at each age can be read off from the Japanese manual, and then converted to American scaled scores and the corresponding IQs ascertained from the American manual. Table 1 gives the mean Japanese scaled scores on the five performance subtests and on Digit Span, and the mean performance IQ derived from the five subtests. The overall mean performance IQ of this Japanese sample is 111 (relative to a mean American IQ of 100). 1,100 Japanese and 2,200 Americans were tested and the difference in mean IQ is clearly statistically significant. For individual tests for each year, a difference of one scaled point is statistically significant at the 0.01 probability level. The result evidently confirms previous estimations indicating that the Japanese mean IQ is higher than that in the United States.

Examination of the scores obtained by the Japanese on the six subtests given in Table 1 shows that the Japanese superiority is most pronounced in the tests of block design, mazes, picture arrangement and object assembly. The Japanese are less good on the digit span and coding tests. These results are broadly similar to those found in the Japanese standardization of the WISC and the WAIS. The consistency of this pattern of results suggests that the Japanese may be particularly strong on spatial ability.

Combining the results from the WISC-R with those of previous studies we have IQ data for 27 Japanese cohorts spanning almost seven decades. The series starts with the results for the WAIS for which the Japanese standardization sample was born around 1910 and concludes with the 6-yr-olds in the WISC-R born in 1969. Table 2 gives the mean IQs of the 27 cohorts in relation to their year of birth. It is clear that the Japanese cohorts born earlier in the century (1910–45) have a mean IQ of 102–105, whereas those born from 1946 to 1969 have a mean of 108–115. This suggests that the mean Japanese IQ has been rising relative to the American during the twentieth century. The secular trend is shown in Fig. 1, in which mean

Table 1 Japanese mean WISC-R scaled scores and IQs based on US norms

Age	Digit span	Picture arrangement	Block design	Object assembly	Coding	Mazes	Performance IQ
6	10.5	11.8	13.9	11.6	9.0	13.2	112
7	10.5	11.7	14.2	11.7	7.7	13.0	111
8	10.7	10.8	14.4	11.5	9.4	12.7	112
9	9.8	12.0	14.9	11.0	9.2	12.0	112
10	10.7	11.3	14.7	11.7	9.2	11.7	111
11	10.7	11.0	14.9	11.7	9.3	11.5	111
12	10.7	11.0	14.3	11.7	9.7	11.8	112
13	10.0	11.0	14.1	11.7	9.9	11.3	111
14	10.8	11.0	14.2	11.0	9.8	12.0	111
15	10.5	11.0	14.2	11.0	9.8	11.0	109
16	11.5	11.0	13.5	11.0	9.3	10.0	106

0028–0836/82/200222—02$01.00

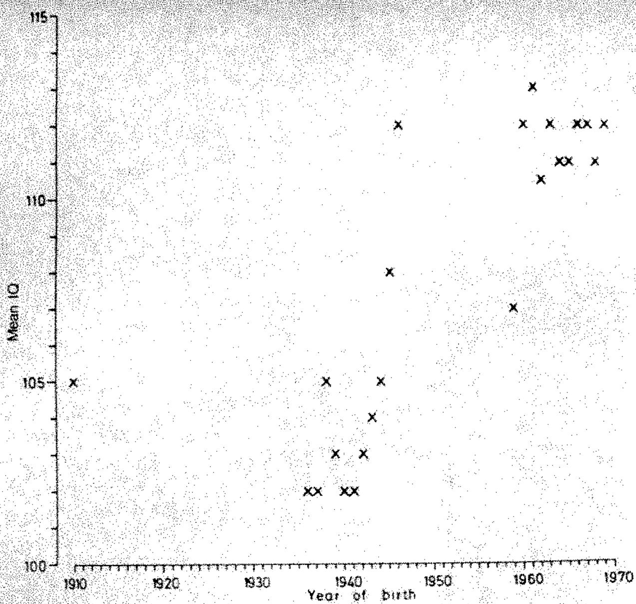

Fig. 1 Mean IQs of 23 Japanese cohorts showing a secular increase relative to a mean IQ of 100 in the US.

IQs for the same cohort are averaged to give a single mean (this applies to the four cohorts born during 1959–62).

The significance of the rising trend of the mean IQ in Japan can be tested from the correlation between mean IQ and year of birth. The product moment correlation is +0.76 and is statistically significant at $P<0.01$. The greatest discrepancy is in the value for 1910, which was derived from the WAIS and is based on only two of the performance subtests and digit span. It may therefore be subject to error. If this value is discounted, the cohorts born in the years 1936–46 have a mean IQ of 104.34, while those born in the years 1959–46 have a mean IQ of 111.20. The value of χ^2 for this difference is 10.83 and is statistically significant at $P<0.01$ (Yates' correction is applied).

Thus over the course of a generation the mean IQ in Japan has risen by ~7 IQ points. It seems doubtful whether a rise of this magnitude could be accounted for by a change in the genetic structure of the population. Instead, the explanation probably lies largely in environmental improvements. Comparison of the WISC and the WISC-R shows that the increase in IQ was present among 6-yr-olds. This indicates that it cannot be explained in terms of improvements in education and must be attributed to effects taking place before the age of six. Improvements in health and nutrition may be involved as it has been shown that the birth weight of Japanese babies has increased over the middle decades of the century[4].

Other advanced western nations, such as Britain, France, Belgium, Germany, Australia and New Zealand, all have mean IQs approximately the same as that in the United States[5]. At 111, the mean IQ in Japan is the highest recorded for a national population by a considerable order of magnitude. The effects of the high Japanese IQ of 111 can be illustrated as follows. Whereas Americans and Europeans have ~2% of their populations with IQs over 130, the Japanese have ~10% at this level. Among the population as a whole, 77% of Japanese have a higher IQ than the average American or European. Since intelligence is a determinant of economic success, as it is of success in many other fields, the Japanese IQ advantage may have been a significant factor in Japan's outstandingly high rate of economic growth in the post-World War II period.

Table 2 Mean IQs of 23 Japanese cohorts and their year of birth

Year of birth	Mean IQ	Test	Year of birth	Mean IQ	Test
1910	105	WAIS	1959	108	WPPSI
1936	102	WISC		106	WISC-R
1937	102	WISC	1960	115	WPPSI
1938	105	WISC		109	WISC-R
1939	103	WISC	1961	115	WPPSI
1940	102	WISC		111	WISC-R

Light experience and asymmetry of brain function in chickens

Lesley J. Rogers

Pharmacology Department, Monash University, Wellington Road, Clayton, 3168 Victoria, Australia

Asymmetry of brain function has been demonstrated for several non-human species[1], most clearly in the avian brain[2,3]. In the chicken, a single treatment of the left forebrain hemisphere during the first week of life after hatching with either cycloheximide or the putative neurotransmitter, glutamate, subsequently causes retarded visual and auditory learning, and elevated attack and copulation responses[3–5]. Similar treatment of the right hemisphere is without effect. The cellular mechanisms by which these pharmacological agents may alter brain development and so reveal lateralization have already been discussed in detail[6,7]. It is commonly assumed that lateralization of brain function in humans and other species is inherited either genetically[1,8] or cytoplasmically[9]. However, Rogers and Anson have suggested previously[3] that light experience may have an important role in establishing lateralization in the chicken forebrain, because after day 17 of incubation the embryo is oriented in the egg such that the left eye is occluded by the chicken's wing and body while the right eye is next to the air sac and exposed to light input (refs 10, 11 and J. V. Zappia and L.J.R., in preparation). Because the optic nerves decussate completely and most of the information reaching each tectum is processed by its ipsilateral forebrain hemisphere, it is possible that light entering the right eye stimulates developmental processes in the left hemisphere in advance of the right[3]. If so, chickens hatched from eggs incubated in darkness should fail to show functional asymmetry of the forebrain. I now report that this is indeed the case for asymmetrical control of attack and copulation.

Because all previous experiments demonstrating asymmetrical control of attack and copulation have used only male chickens hatched from eggs exposed to light during incubation[4,5], it was first necessary to ascertain that the same phenomenon occurred in females also hatched from eggs exposed to light, since chicks hatched in my laboratory were not sexed. As found for males, glutamate (500 nmol in 5 μl) treatment of the left hemisphere of female chicks on day 2 after hatching caused elevated attack and copulation (see ref. 4 for details of method), whereas those treated similarly in the right hemisphere behaved the same as untreated controls (Fig. 1).

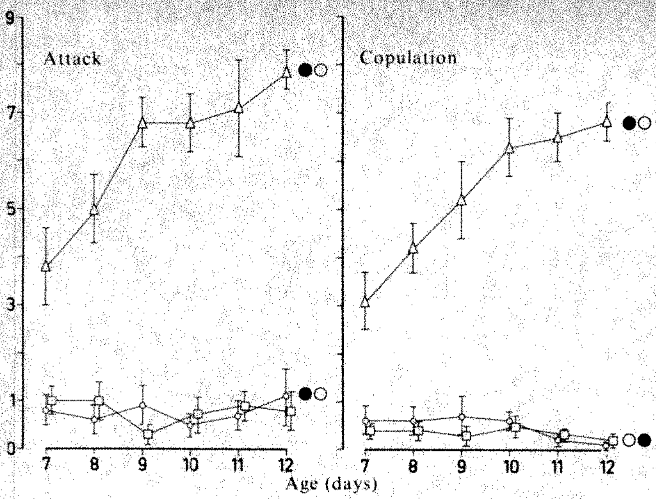

Fig. 1 Female chicks, supplied by a hatchery in which the eggs are exposed to light during incubation, have been tested for attack and copulation from days 7 to 12 of life. Daily mean scores with standard errors are presented. The behaviours are scored according to a rank ordering procedure (0–10) in standard tests using the moving hand as a stimulus[4]. Scores plotted on the y-axis rank from no response (0) to sparring with attack leaps for attack, and treading with pelvic thrusting for copulation. △ Represents females treated with glutamate in the left hemisphere, and on every day of testing their scores are significantly ($P<0.002$, U-tests) elevated above those for females treated in the right hemisphere (○), and untreated females (□). The pair of circles next to each graph represents the hemispheres, the hemisphere treated with glutamate being solid black. The other hemisphere is treated with normal saline. There were 8–10 animals in each group.

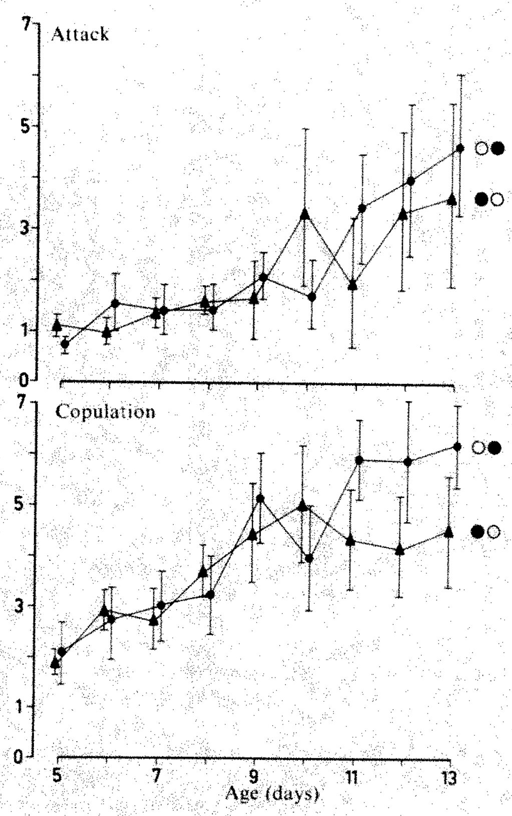

Fig. 2 Attack and copulation scores for chicks hatched from eggs incubated completely in darkness. Symbols as in Fig. 1; ▲, glutamate treatment in the left hemisphere ($n=15$); ●, glutamate treatment in the right ($n=10$).

Male and female chickens hatched from eggs incubated in darkness and treated with 500 nmol of glutamate on day 2 after hatching show no asymmetry of function for attack and copulation (Fig. 2). As the mean scores in Fig. 2 demonstrate, the chicks in both the left and right hemisphere treatment groups showed some elevation of attack and copulation scores.

In the chicken the first visually evoked tectal responses occur on day 17 of incubation. An electroretinogram of embryonic form can be detected and the first responses to light can be measured on day 18, and on day 19 the electroretinogram reaches its post-hatch form and light-evoked potentials are detected in the contralateral forebrain hemisphere[11,12]. Thus, it is during the last 5 days of incubation that light exposure should affect brain asymmetry, and this is in fact the case. In a matched control experiment, one batch of eggs was incubated in darkness for the first 16 days of incubation and then exposed to light of intensity varying between 100 and 500 lx during the last 5 days; another batch received the reverse treatment. The former treatment causes lateralization of atttack and copulation, the latter does not (see Fig. 3).

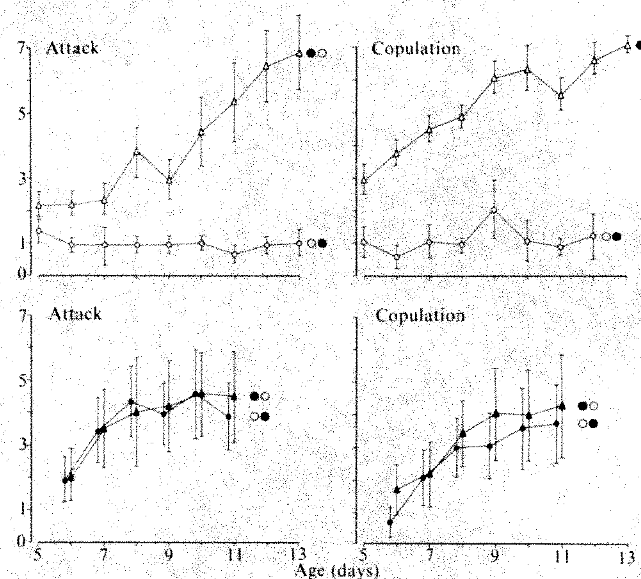

Fig. 3 The two graphs at the top present data for chicks hatched from eggs which were incubated in darkness for the first 16 days of incubation, and light from a heating bulb and overhead lamps (100–500 lx) during the last 5 days. The graphs at the bottom present data for eggs incubated in the reverse conditions ($n=8$–10 for each group). △, ▲, Treated with glutamate in the left hemisphere; ○, ●, treated in the right hemisphere.

In fact, 2 h of light exposure on day 19 of incubation are sufficient to establish asymmetrical control of attack and copulation (see Fig. 4). A sensitive period for this effect seems to have passed by the time the chick pips the egg shell on day 20 because no asymmetry for attack and copulation was present in chickens hatched from eggs exposed to light from the time of pipping onwards (~24 h).

As shown by the standard errors in the figures, the data for those groups of chickens hatched from eggs which had not received light exposure during the sensitive period were more variable than those of the lateralized groups ($P\leq 0.001$ for a comparison of the attack and the copulation scores on days 11 or 12 of all the lateralized versus non-lateralized chicks treated in the left hemisphere, and $P<0.05$ for both attack and copulation scores in a similar lateralized versus non-lateralized comparison of all those treated in the right hemisphere; Moses tests[13], $n=38$–48 for each group). Examination of the individual scores revealed that approximately half the chicks hatched from eggs kept in darkness during the sensitive period and then treated in the left hemisphere had consistently high scores for attack and copulation clustered around 7.0, while the other half had consistently low scores clustered around 1.0,

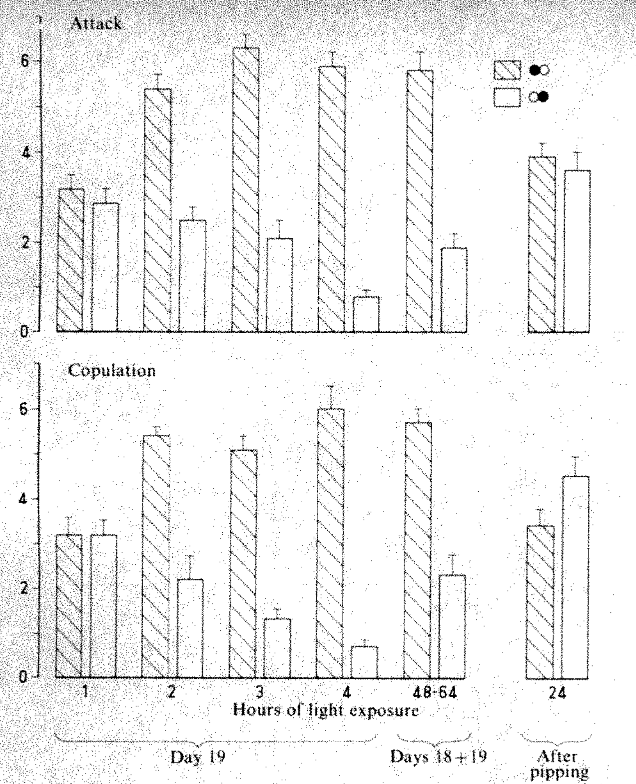

Fig. 4 Attack and copulation scores are given as overall means (±s.e.) calculated from scores recorded daily from days 6 to 11 of life. The symbols are as in Figs 1 and 2. Apart from the hours of light exposure indicated, the eggs were incubated in darkness. There is a significant elevation ($P<0.002$) in both scores for the left-treated groups (white columns) compared with the right-treated groups (black columns) after 2, 3, 4 and 48–64 h light exposure on day 19 of incubation, but not after 1 h on the same day or ~24 h from the time of pipping to hatching ($n=8$–12 for each group).

which suggests a bimodal distribution. This was also the case for chicks from eggs incubated similarly and treated in the right hemisphere. Further sampling will be necessary to confirm this (J. V. Zappia and L.J.R., in preparation), but it is possible that in the absence of light exposure before hatching individual chickens still have lateralized forebrain function, but that half are asymmetrical in one direction and half in the other direction, similar to pawedness in mice[14]. Light exposure during embryonic development may not generate lateralization in individuals, but synchronize the direction of lateralization in the population such that differences emerge between groups treated with glutamate in the left or right hemisphere.

On about day 19 of incubation, when the visual pathways between the tectum and the Wulst area of the forebrain are becoming functional, asymmetrical light input may synchronize the direction of functional asymmetry in the population, perhaps by stimulating blood flow to the left hemisphere in response to neuronal activity[15] and increasing protein synthesis[16] or some other metabolic process. The direction of asymmetry for attack and copulation therefore seems to be a consequence of the orientation of the embryo in the egg.

Denenberg[17] has reported that asymmetry of hemispheric function in the rat is enhanced by the experience of handling in early life. In this case environmental experience influences the degree of asymmetry, differing from the chicken data in which light experience seems to affect the direction but not the degree of asymmetry. However, both examples illustrate that interaction between genotype and experience determines the presence or form of functional asymmetry in the brain.

Is oxytocin an ovarian hormone?

D. Claire Wathes & R. W. Swann

Department of Anatomy, The Medical School, University of Bristol, Bristol BS8 1TD, UK

Oxytocin is a nonapeptide hormone produced by the hypothalamus and released from the posterior pituitary. It is cleaved from a large molecular weight precursor which is synthesized in cell bodies of hypothalamic magnocellular neurones and then packaged into membrane-bound granules[1]. During axonal transport the precursor is cleaved to produce oxytocin and an oxytocin-related neurophysin. Apart from its established roles in lactation and labour, oxytocin is thought to be an important regulator of the oestrous cycle; it causes luteolysis in cattle[2] and immunization against oxytocin increases the length of the ovine oestrous cycle[3]. McCracken[4] has proposed that oxytocin acts by stimulating prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) release from the uterine endometrium and that steroid hormones regulate $PGF_{2\alpha}$ secretion by altering the availability of endometrial oxytocin receptors[4,5]. Steriods may also have a direct influence on oxytocin release from the posterior pituitary, oestradiol-17β increasing and progesterone inhibiting oxytocin secretion in response to vaginal distension in the goat[6,7]. However, recent radioimmunoassay (RIA) measurements of peripheral oxytocin levels during the ovine oestrous cycle[8–10] consistently show that oxytocin and progesterone concentrations increase and decrease in synchrony during the luteal phase, reaching basal levels after luteolysis at a time when oestradiol-17β titres are known to rise[11]. Therefore, there may exist different controls of reflex release and basal secretion of oxytocin, and our discovery of large amounts of oxytocin within the ovine corpus luteum reported here may provide an explanation.

Peptides were extracted from ovine corpora lutea using the method developed by Walsh and Niall[12] for the isolation of porcine relaxin. The crude extract was applied to a Sephadex G-50 column. While testing the fractions from this column for relaxin-like activity in a rat uterine strip bioassay, it became apparent that some fractions were stimulatory rather than inhibitory. A similar finding has been reported previously in the cow[13]. The fractions were therefore measured by RIA for cross-reactivity with oxytocin (Fig. 1). A single peak of oxytocin-like immunoreactivity eluted between 330 and 400 ml in a position corresponding to that of synthetic oxytocin (Syntocinon. Sandoz). Dilution curves of material from this peak (henceforth referred to as luteal extract) showed parallelism with the oxytocin standard curve (Fig. 2). HPLC analysis of the extract revealed oxytocin immunoreactivity eluting in a position identical to that of synthetic oxytocin (Fig. 3).

Luteal extract was tested for oxytocin in two bioassays using concentrations calculated from the RIA results to correspond to the oxytocin standards. In a rat milk ejection assay, close

quantitative and qualitative agreement was achieved between the response to both luteal extract and oxytocin standard. In the rat uterine strip bioassay the estimated oxytocin-like activity approximated to one third of that measured by RIA but this discrepancy may have been due to the presence of a factor which inhibited uterine activity in the same Sephadex G-50 extract.

These data clearly indicate that the peptide extracted from the corpora lutea is authentic oxytocin. The yield of oxytocin from the ovaries of non-pregnant sheep was 2.6 μg per g of luteal tissue whereas the yield from pregnant sheep was only 34 ng per g. As the average weight of ovine corpora lutea is ~0.5 g and because there are normally 1–3 corpora lutea per animal, a non-pregnant ewe in the luteal phase of the oestrous cycle has ~2.6 μg of ovarian oxytocin. Lederis[14] calculated that the posterior pituitary and hypothalamus of the sheep together contained 18.2 μg oxytocin. Thus ovarian oxytocin represents

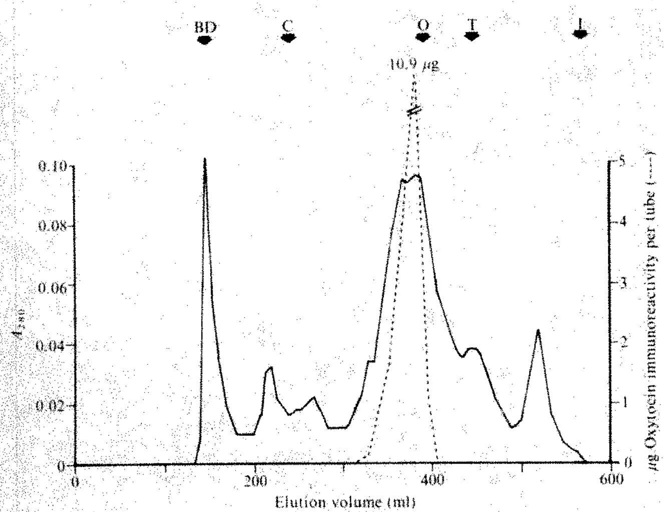

Fig. 1 Elution profile of a crude extract of 14.5 g ovine corpora lutea applied to a Sephadex G-50 (fine) column (120×2.4 cm) measured as absorbance at 280 nm. The eluant used was 0.1 M ammonium acetate *p*H 6.8 and the flow rate was 20.1 ml h^{-1}. Fractions (6.7 ml) were collected and lyophilized to remove ammonium acetate. The elution positions of various markers are shown: BD, blue dextran; C, cytochrome *c* (MW 12,300); O, oxytocin (MW 1,000); T, tyrosine (MW 181); I, ^{125}I. Paired fractions were assessed for oxytocin immunoreactivity by RIA. The rabbit antiserum used was raised against oxytocin coupled to thyroglobulin by the technique of Sofroniew *et al.*[24] and showed no significant cross-reaction with arginine-vasopressin, arginine-vasotocin or the rat neurophysins. ^{125}I-oxytocin, prepared by the chloramine-T method, was purified by chromatography on Sephadex G-25. The 4th International Standard for oxytocin (76/575) was used as a reference preparation.

~15% of the total hypothalamo-neurohypophysial store of hormone in the non-pregnant ewe during the luteal phase and ~0.2% during pregnancy.

Although it is possible that the presence of oxytocin in the ovary reflects its uptake from the blood, the high concentration of hormone suggests that it is synthesized there. However, proof of this hypothesis awaits the results of further experiments such as incorporation studies. If oxytocin is synthesized in a similar manner in the ovary and brain, one would also expect to find an ovarian neurophysin. We were unable to assay for ovine neurophysin but the Sephadex G-50 peak expected to contain molecules of molecular weight (MW) 10,000 (200–295 ml, Fig. 1) did contain small amounts of a component having the electrophoretic and HPLC characteristics of bovine neurophysin I.

Luteal oxytocin is probably not important for lactation in the ewe, as corpora lutea regress at parturition and a lactating ewe may not ovulate again for several months. Ovariectomized sheep can also deliver successfully, arguing against a role in parturition[15,16]. However, oxytocin measured in the peripheral

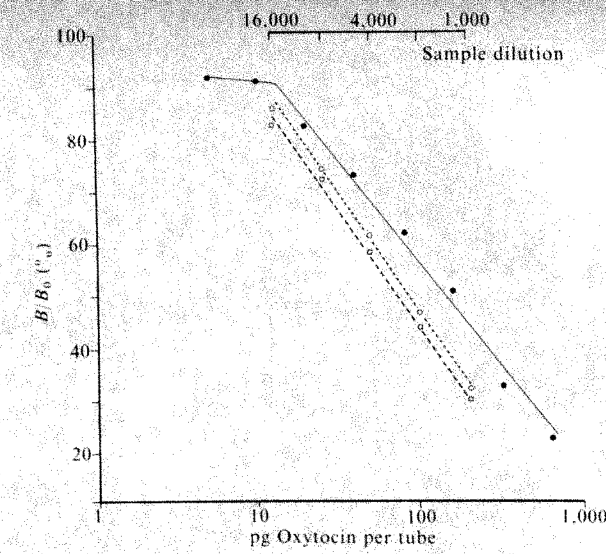

Fig. 2 Dilution curves for oxytocin standard (●) and two Sephadex-G50 fractions taken from separate extractions (○ and □). The ordinate shows bound ^{125}I-oxytocin (*B*) expressed as a percentage of ^{125}I-oxytocin bound in the absence of oxytocin (B_0). The slopes of the lines for the standards and samples did not differ significantly.

plasma during the oestrous cycle[8-10] could be of luteal origin as the increases and decreases in its concentration correspond to the waxing and waning of the corpus luteum. Additional evidence in support of this view is that ovariectomy leads to a decrease in circulating oxytocin[10] and that episodic release was not detected during seasonal anoestrus[9]. Circulating oxytocin concentrations also decline during pregnancy[8,9] corresponding to the much lower yield of oxytocin obtained from the ovaries of pregnant ewes in the present study.

The ovine corpus luteum is known to contain secretory granules, the release of which reaches a maximum in mid-cycle[17,18]. It has been suggested that these granules contain progesterone[17,19,20], but steroid secretion is not usually associated with granule formation and release. The present findings raise the possibility that these granules represent the ovarian

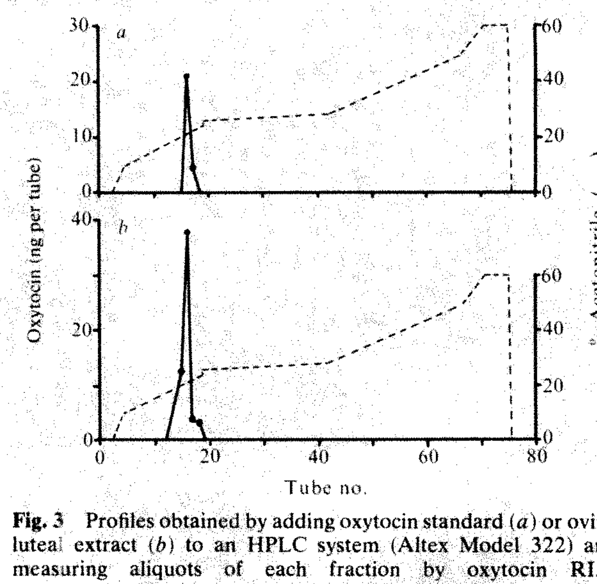

Fig. 3 Profiles obtained by adding oxytocin standard (*a*) or ovine luteal extract (*b*) to an HPLC system (Altex Model 322) and measuring aliquots of each fraction by oxytocin RIA. Chromatography was performed on a 5 mm (i.d.) × 10 cm stainless steel column packed in our laboratory with Hypersil ODS 5 μ. Samples were loaded and washed on to the column in 0.2 M Na_2HPO_4 *p*H 2.1 (adjusted with H_3PO_4) and eluted at a flow rate of 1 ml min^{-1} with an increasing gradient of acetonitrile (HPLC grade S, Rathburn). Fractions (1.2 ml) were collected. Vasotocin and arginine-vasopressin elute in tubes 11 and 12, respectively, using this gradient system.

oxytocin stores. Indeed another peptide hormone, relaxin, is packaged by the luteal cells into similar granules during pregnancy in the pig and rat[21,22].

The discovery of oxytocin in the corpus luteum raises a number of questions. If oxytocin were principally involved in the control of $PGF_{2\alpha}$ release at luteolysis, one would expect its concentration to peak shortly before the normal rise in $PGF_{2\alpha}$, but oxytocin levels decrease at about this time[8]. McCracken[4] has proposed that a rise in uterine oxytocin concentrations induced by oestradiol-17β is the first step in luteolysis but oestrogen levels similarly do not rise until progesterone concentrations have started to decline[23]. Thus the role of oxytocin during the oestrous cycle remains undetermined.

We thank Mr R. Jones, Miss J. Creek, Miss A. Moffatt and Mr P. Rees for technical assistance; S. D. Birkett for the radioimmunoassay; Dr J. A. Wakerley for the milk ejection experiment; Dr C. M. Wathes for the statistical analysis and Professors B. T. Pickering and D. G. Porter for their helpful discussions. The work was supported in part by grants from the ARC (AG 7/103), MRC (G8011540SA, G979/479) and the Wellcome Trust (9267/1.4P).

Note added in proof:
HPLC and RIA studies using bovine corpora lutea have shown that both oxytocin and bovine neurophysin I are present in the ovary in this species too.

Noradrenergic modulation of dendrodendritic inhibition in the olfactory bulb

C. E. Jahr* & R. A. Nicoll

Departments of Pharmacology and Physiology,
University of California, San Francisco, California 94143, USA

Noradrenaline containing fibres in the central nervous system (CNS) have been characterized in detail by histochemical techniques[1–3]. A particularly striking feature of this neurotransmitter system is its diffuse pattern of innervation. Although noradrenaline generally inhibits spontaneous activity of neurones[4–7], in a number of systems[5,8–10] it can actually enhance orthodromic excitatory responses. Enhancement of excitatory transmission through sensory relay neurones is consistent with the view that noradrenergic systems are intimately involved in such behaviours as arousal and attention[11]. However, the basis for this enhancement is unclear. Two proposed hypotheses are a facilitation of excitatory transmitter action[5] and a disinhibitory action in which noradrenaline inhibits inhibitory interneurones[8]. The olfactory bulb is ideally suited for studying the cellular action of noradrenaline because the neuronal circuitry is relatively simple. Using intracellular recording techniques we have now found that noradrenaline attenuates the inhibitory feedback onto relay neurones, thus facilitating their firing, while glutamate and aspartate augment the inhibitory feedback.

The olfactory bulb has two major cell types: mitral cells, which relay signals to the cortex and granule cells, which are inhibitory interneurones. The interaction between these two types of cells involves a reciprocal dendrodendritic inhibitory pathway[12–18]. Briefly, impulses in mitral cell dendrites release excitatory transmitter (probably aspartate[19]) onto the dendrites of granule cells which, in turn, release the inhibitory transmitter, γ-aminobutyric acid (GABA) back onto mitral cells. In addition, the olfactory bulb receives a massive input of centrifugal fibres[20], some of which contain noradrenaline[21]. As some of the centrifugal fibre synapses contain spherical vesicles similar to those found in mitral cells, the acidic amino acids glutamate and aspartate may also be neurotransmitters in centrifugal fibres. The observed close approximation of the centrifugal synapses to the reciprocal synapses suggests that they may act to change the gain of the reciprocal inhibitory pathway.

Standard intracellular recording techniques were used in the present study and are described in detail elsewhere[16,17]. Briefly, turtles (*Pseudemis scripta elegans*) were decapitated and the olfactory bulbs removed and hemisected. The superfusate was a modified Ringer solution buffered with Tris(hydroxymethyl)aminomethane to *p*H 7.4 and bubbled with 100% O_2. Experiments were performed at 19 °C. The olfactory nerves and mitral cell axons were stimulated with either concentric bipolar or bipolar needle electrodes. Drugs were applied in the superfusate or by iontophoresis. The placement of the tip of

the iontophoretic pipette in the external plexiform layer was facilitated by monitoring the focal extracellular field potentials with this pipette while it was being advanced through the tissue. The pipettes contained 1 M GABA (pH 4), 1 M sodium glutamate (pH 8) or 1 M sodium aspartate (pH 8).

Stimulation of the olfactory nerves or the mitral cell axons results in a complex of field potentials that can be recorded in the olfactory bulb. The largest wave recorded in the granule cell layer represents the excitation of granule cells[12-14]. Such stimulation results in a prolonged inhibition of the same wave evoked by a second identical stimulus. This paired pulse inhibition is an extracellular measure of the inhibitory postsynaptic potentials (i.p.s.ps) produced in a population of mitral cells that result from the activation of the dendrodendritic reciprocal synaptic pathway[13,14]. In all five experiments the addition of noradrenaline to the superfusate decreased this paired pulse inhibition (Fig. 1*a*), indicating that activation of the dendrodendritic inhibitory pathway was, at some point, decreased. This effect was more pronounced at moderate and high stimulus strengths (Fig. 1*b*). Noradrenaline also depressed the amplitude of the field potentials and therefore, in Fig. 1*a*, the stimulus strength was increased to evoke a conditioning response identical to that in the control.

It has been demonstrated with intracellular recording from mitral cells that the i.p.s.ps are GABA mediated, chloride dependent[16-18] and can be evoked by a single action potential in a mitral cell[16,17]. In the present experiments in control conditions, a number of mitral cells displayed successive spontaneous action potentials with intervening i.p.s.ps (Fig. 1*c*, top trace) which controlled the spontaneous action potential frequency. Thus, if the preparation was not stimulated, spikes occurred at a very regular interval which was determined by the amplitude and rate of decay of the i.p.s.ps. When the superfusate was switched to one containing noradrenaline (5–100 μM), both the i.p.s.p. following the spontaneous action potentials and the olfactory nerve-evoked i.p.s.ps (marked with arrows) were invariably shortened (Fig. 1*c*, bottom trace; $n = 11$). In addition, the peak conductance increase associated with the i.p.s.ps was decreased. The i.p.s.ps following spontaneous action potentials were also decreased in amplitude. In those cells which were not spontaneously firing action potentials noradrenaline had no effect on the membrane potential or conductance, although in some cells the threshold for spike initiation increased. This last effect might account in part for the depressant action of noradrenaline on the field potentials (see above) and the inhibitory effects reported *in vivo*[22].

The diminution of the i.p.s.p. could be due to the action of noradrenaline on either mitral or granule cells or both. As neither resting membrane potential nor membrane resistance of mitral cells was affected by nonadrenaline, its site of action might be on the granule cells, although it could exert its effects

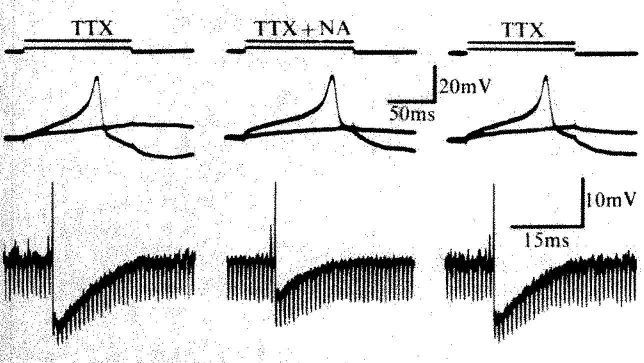

Fig. 2 Diminution of the i.p.s.p. in the presence of tetrodotoxin by noradrenaline. Top row: oscilloscope records of calcium spikes in tetrodotoxin (1 μM), after 15 min of superfusion with 100 μM noradrenaline, and after 23 min of washing in tetrodotoxin. Bottom row: simultaneous pen records of i.p.s.ps following calcium spikes. Resting potential was −60 mV throughout. The voltage calibration bar represent 1 nA for the current trace.

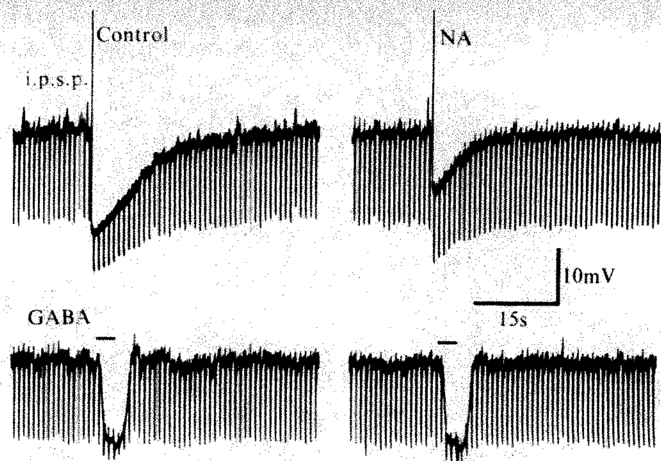

Fig. 3 Noradrenaline is not a GABA antagonist. The records on the left are the control i.p.s.p. (top) and control GABA response (bottom). The records on the right were obtained 24 min after the addition of noradrenaline (20 μM) to the superfusate. GABA was applied with a current of 80 nA. Resting potential was −54 mV throughout.

by blocking calcium entry (see refs 23, 24) into mitral cells. To examine this question further, the effects of noradrenaline were tested on mitral cell responses in the presence of tetrodotoxin. The calcium spikes that can be elicited in the presence of tetrodotoxin[15-17] were not reduced by concentrations of noradrenaline up to 100 μM while the i.p.s.p. was reduced substantially (Fig. 2; $n = 3$). Furthermore, this could be observed in cells in which spike threshold was unaltered.

Next, by iontophoresing GABA onto mitral cells we tested the possibility that noradrenaline might attenuate i.p.s.ps by blocking the action of the inhibitory transmitter. However, concentrations of noradrenaline that markedly reduced the size of the i.p.s.p. did not affect the iontophoretic GABA response (Fig. 3; $n = 4$). Thus, we conclude that the primary site of action of noradrenaline is on the granule cells. It has been reported that noradrenaline can enhance the action of GABA in the cerebellum[5]. We did not see such an enhancement, although small increases could have gone undetected. However, as shown above the overall effect of noradrenaline on synaptic inhibition in the olfactory bulb is depression.

In contrast to the actions of noradrenaline, iontophoretic glutamate enhanced the amplitude and duration of i.p.s.ps evoked by spontaneous action potentials (Fig. 4*a*; $n = 3$). This prolongation decreased the frequency of spikes without a change in spike threshold. When the iontophoretic current was increased, complete cessation of spontaneous action potentials occurred concomitant with a hyperpolarization of the membrane potential and a decrease in membrane resistence (Fig. 4*b*). Very short but intense ejections of glutamate resulted in fast hyperpolarizations associated with decreases in membrane resistance. Both effects outlasted the iontophoretic pulse and took the same form as i.p.s.ps (Fig. 4*c*). This hyperpolarizing action of glutamate could be observed in the presence of tetrodotoxin (Fig. 4*d*). However, after the addition of the GABA antagonist, bicuculline (Fig. 4*d*), or after blockade of synaptic transmission by cobalt, glutamate evoked a depolarization ($n = 8$). This indicates that the direct action of glutamate on mitral cells is a depolarization and suggests that, like the action of noradrenaline, glutamate acts on mitral cells primarily by modulating the release of GABA from granule cells.

Our observations suggest that noradrenaline and also enkephalin[25] decrease the i.p.s.p. recorded in mitral cells by acting on granule cells, causing them to release less GABA in response to the same stimulus. Glutamate and aspartate exert the opposite effect on granule cells. Based on extracellular recording techniques, McLennan[26] suggested that glutamate and noradrenaline might be acting in a similar way on granule

cells. The reason for this discrepancy is unclear. Noradrenaline may produce its disinhibitory effect by shunting or hyperpolarizing the granule cell membrane, thus attenuating excitatory input, or by interfering with excitation–release coupling[23,27]. Although a direct effect on the release process in mitral cells has not been completely ruled out, mitral cell calcium spikes are unaffected by noradrenaline, and thus any interference with release would presumably have to occur after calcium entry.

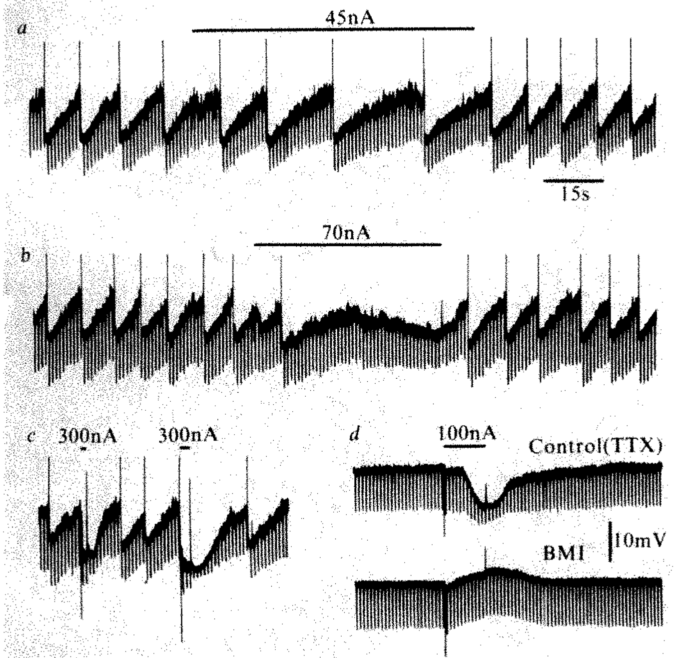

Fig. 4 Effect of glutamate on mitral cell i.p.s.ps and membrane potential. *a–c*, Iontophoretic applications of glutamate onto the same cell. Spike threshold was −57 mV throughout. *d*, Glutamate iontophoresis in a preparation perfused with tetrodotoxin (1 μM) before (top trace) and 20 min after the addition of 0.1 mM bicuculline methiodide (BMI) (bottom trace). Resting potential was −55 mV.

The hyperpolarizing action of glutamate and aspartate on mitral cells has been shown to result from the release of GABA from granule cells. This is presumably due to a depolarizing action of the amino acids on granule cells. The fact that doses of excitatory amino acid below that which caused the release of GABA still enhanced the evoked release of GABA suggests that subthreshold depolarization of granule cells facilitates excitation–secretion coupling. This result agrees with recent findings in invertebrate neurones[28].

In conclusion, it is proposed that noradrenaline, enkephalin and glutamate alter mitral cell excitability primarily by indirect actions; noradrenaline and enkephalin block GABA release from granule cells, whereas glutamate enhances GABA release. The granule cell, then, is the final common pathway on which the centrifugal fibres and their transmitter candidates exert presynaptic control and thereby modulate the flow of information through the olfactory bulb. Such a disinhibitory role for noradrenaline in a sensory pathway fits well into the proposed role of the locus coeruleus noradrenergic system in arousal[11], a behavioural state associated with enhanced neuronal responsiveness[29].

Differential release of serotonin and histamine from mast cells

Theoharis C. Theoharides, Philip K. Bondy*, Nikolaos D. Tsakalos† & Philip W. Askenase

Department of Internal Medicine, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA and

Exocytosis dependent on calcium and metabolic energy has been established as the mechanism for the release of membrane-bound secretory products from various exocrine, endocrine and neural cells[1]. This has also been shown to be the case in mast cells, which have been used increasingly as a model secretory system[2]. The secretory granules of mast cells contain several mediators[3], some of which, such as histamine, are known to participate in many immune reactions and allergic diseases[4,5]. Because of mast cell involvement in these clinical syndromes, as well as the role of histamine in gastric acid secretion[6] and possibly in brain pathophysiology[7], there has been great interest in the pharmacological modulation of histamine release from mast cells[8]. Serotonin is also stored in mast cell granules of several species but much less is known about its secretion. Because histamine and serotonin may have divergent functions in delayed hypersensitivity[4,9], we hypothesized that these amines could undergo differential release. We now report that the tricyclic antidepressant drug amitriptyline (Elavil) inhibits histamine release from stimulated mast cells while permitting the release of serotonin. In these conditions, exocytosis of secretory granules is largely prevented, but serotonin is released by an unknown process which still requires calcium and metabolic energy. The ability to secrete differentially expands the physiological potential of the mast cell, and suggests that release of serotonin may not always indicate mast cell secretion via exocytosis of secretory granules.

Rat peritoneal mast cells were collected, purified (90% purity) and incubated as described previously[10]. Mast cells that had been preincubated with ^{3}H-serotonin to load them with this releasable amine[11] and then incubated with amitriptyline (10^{-7}–10^{-4} M) for 5 min showed depressed histamine release

Effect of amitriptyline on mast cell release of histamine and serotonin. Mast cells (90% purity, 10^6 cells ml^{-1}) were first incubated in HEPES-buffered Locke's solution[10] with 5 μCi ml^{-1} ^3H-serotonin (29.8 Ci $mmol^{-1}$; NEN) for 1 h at 37 °C, and were then incubated (10^5 cells per tube) with 0–10^{-4} M amitriptyline for 5 min, followed by an additional 5 min incubation with compound 48/80 (1 μg ml^{-1}) or 30 min incubation with anti-ovalbumin hybridoma IgE antibody (1:1,000 dilution) and ovalbumin (Ag, 100 μg ml^{-1}) in the presence of phosphatidylserine (100 μM). The histamine released was assayed fluorometrically[38] while the serotonin released was measured by liquid scintillation counting[11], both in duplicate portions. Ruthenium red (0.005%) staining of mast cells was performed as described previously[14]. Spontaneous release was 1.8% for serotonin, 3.6% for histamine. Results represent the mean ± s.d. of five separate determinations.

but nearly unaltered serotonin release when stimulated either nonspecifically with the classic mast cell secretagogue[12] compound 48/80 (1 μg ml^{-1}) or immunologically by addition of 1:1,000 dilution of mouse ascites fluid from an IgE antibody-secreting hybridoma[13] and antigen (ovalbumin, 100 μg ml^{-1}) in the presence of 100 μM phosphatidylserine (Table 1). When experiments were performed with unpurified peritoneal cells (10% mast cells), higher concentrations of amitriptyline were required to permit differential release. Exocytosis of secretory granules was identified by selective staining with ruthenium red which, by virtue of its relative inability to cross the plasma membrane and its high affinity for proteoglycans of the secretory granule core, binds to and stains only those granules exposed to the extracellular fluid[14]. This assay showed that depression of histamine release by amitriptyline was accompanied by a substantial reduction in apparent granule exocytosis (Table 1). To examine the requirements necessary for the release of serotonin but not histamine, mast cells were preincubated with either EDTA (5×10^{-3} M for 2 h) or antimycin A (10^{-6} M) and 2-deoxyglucose (5×10^{-4} M) for 30 min followed by amitriptyline and then compound 48/80, or IgE and antigen as before. With calcium depletion or deprivation of metabolic energy, serotonin failed to appear in the supernatant (Table 2). Thus, differential release of serotonin seemed to be calcium and energy dependent.

Although histamine release has been the traditional measure of mast cell secretion, release of radiolabelled serotonin—presumably incorporated into mast cell granules from the extracellular medium—has been used increasingly as an alternative means of quantifying mast cell secretion because of its simplicity and sensitivity, and because it has so far been shown to parallel the release of histamine[11,15–17]. However, our results indicate that serotonin can be released in the absence of substantial histamine secretion, and in the absence of demonstrable exocytosis of secretory granules. To exclude the possibility that differential release was solely due to an unknown ability of exogenous radiolabelled serotonin to bind to some location from which it could be displaced without exocytosis of secretory granules, we used a HPLC system to assay endogenous (preformed and granule-stored) serotonin both in supernatants and in cell pellets of mast cells stimulated to secrete by compound 48/80 in the presence of amitriptyline (10^{-4} M). In conditions where there was only ~11% release of histamine and 19% staining by ruthenium red (Table 2), there was ~67% release of endogenous serotonin. These results show that activation of mast cells in the presence of amitriptyline resulted in similar release of both exogenous and endogenous serotonin.

Data from three previous studies suggest that serotonin may indeed be secreted differentially from mast cells[18–20]. Other studies have reported that different mast cell secretory products may be packaged either in distinct granules or in other cytoplasmic components from which they may be mobilized separately[21–22]. However, as serotonin and histamine are both thought to be stored in the secretory granules of mast cells, it is necessary to postulate a mechanism whereby serotonin, and not histamine, could be transported from the granules to the cell exterior. It is possible that in some circumstances serotonin may be preferentially moved from the secretory granules to another compartment, perhaps in small cytoplasmic vesicles from which it may then be secreted by energy- and calcium-requiring exocytosis. There is some evidence that serotonin is present in the cytoplasm of mast cells[23,24], and a transport system for serotonin that involves a specific serotonin binding protein released by exocytosis together with serotonin has been demonstrated in the nervous system[25]. Furthermore, a vesicular transport mechanism has recently been identified in guinea pig basophils[26], and we have identified proteins in rat basophil leukaemia cells and mast cells that bind serotonin[27]. We suggest that specific serotonin-binding proteins, perhaps in cytoplasmic vesicles, may be involved in differential release by mast cells.

The ability of amitriptyline to inhibit histamine release (which has also been shown in human basophils[28]) and to permit differential release of serotonin, may be partly related to its ability to inhibit phosphatidylinositol turnover[29], which has been linked to the cascade of events involved in mast cell secretion[30]. This differential release contrasts with the explosive release of many mast cell granule constituents that is commonly seen in allergic and immediate hypersensitivity disease mechanisms, and is often used to raise doubts about the physiological usefulness of such a dramatic reaction[31,32].

Our present finding, that there may be a way of triggering the selective release of mast cell mediators, is also supported by recent *in vivo* work. In these experiments, immunized mice were challenged with antigen and developed skin swelling responses associated with mast cell degranulation, release of serotonin and formation of gaps between endothelial cells[33]. However, mice treated with pargyline—another drug permitting differential secretion from mast cells[34]—showed no mast cell degranulation but had skin swelling and evidence of

Effect of energy or calcium deprivation on differential release of serotonin in the presence of amitriptyline (10^{-4}M) and in response to either compound 48/80 (1 μg ml^{-1}) or IgE antibody plus appropriate antigen as described in Table 1 legend. Mast cell viability was tested with the Trypan blue (0.04%) exclusion method and was >94%. Results represent the mean ±s.d. of five separate determinations.

serotonin-induced gaps between endothelial cells[35]. These results, with the recently demonstrated ability of mast cells to secrete individual granules in well localized areas of their plasma membrane[36,37], indicate that mast cells could participate in previously unrecognized functions, some of which may be involved in syndromes that are alleviated by antidepressant agents.

H-2K-, *H-2I*- and *H-2D*-restricted hybridoma contact sensitivity effector cells

M. Minami, K. Okuda, M. E. Sunday & M. E. Dorf

Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115, USA

Mice primed with 4-hydroxy-3-nitrophenylacetyl-*O*-succinimide (NP-*O*-Su) generate hapten-specific T cell-mediated contact or cutaneous hypersensitivity (CS) responses[1]. Analysis of the effector T cells mediating these *in vivo* responses suggested that multiple T-cell subpopulations were involved[2]. It has not been possible previously to separate these cell populations physically by conventional means. Therefore, to separate these cells and to provide a uniform source of CS effector cells for future analyses, we hybridized the CS effector cell population with AKR-derived BW5147 thymoma cells. We now describe five *H-2*-restricted hybridoma T-cell clones isolated from this fusion. Each hybridoma possesses hapten-specific CS activity and four also cross-react with 4-hydroxy-3-nitrophenylacetyl (NP) derivatives. Two of the hybridoma clones are specific for NP associated with *H-2I* gene products; two others for NP associated with *H-2D* products; and one for NP associated with *H-2K* gene products.

C57BL/6 mice were immunized with 2 mg NP-*O*-Su; 6 days later T cells were prepared from the regional lymph nodes as previously described for the enrichment of Ts_3 suppressor cells[3]. The hybridization procedure has been reported elsewhere[3], in fact the same series of hybridoma cells were used to screen for CS and suppressor cell activity. The hybridoma colonies were screened for CS reactivity by injecting 10^5 irradiated cells (2,000 R) together with either 40 μg of NP–bovine serum albumin (BSA) or 5×10^5 NP-coupled C57BL/6 spleen cells into the left footpad. Maximal antigen-specific swelling responses occurred 24–48 h after injection.

The specificity of five CS reactive hybridoma clones is demonstrated in Table 1. Two types of NP-reactive hybridoma cell lines were distinguished. The B6-CSI-15 and B6-CSI-78 lines demonstrated significant footpad swelling responses when given together with NP-coupled proteins (for example, NP–bovine γ-globulin, NP–BGG), but failed to respond when transferred with carrier protein (BGG) alone. Similar NP-specific swelling responses were noted when the hybridoma cells were injected with other NP-coupled proteins, including NP–BSA (Table 3) and NP–keyhole limpet haemocyanin (KLH) (data not shown). However, these hybridoma lines failed to give NP-specific responses when administered with NP-coupled syngeneic C57BL/6 spleen cells. In contrast, the B6-CSK-21, B6-CSD-35 and B6-CSD-52 hybrids demonstrated NP-specific swelling responses when transferred with NP-coupled C57BL/6 spleen cells, but failed to respond to trinitrophenyl (TNP)-coupled C57BL/6 spleen cells or NP-coupled proteins. Significant levels of footpad swelling were elicited after local injection of as few as 10^3 hybridoma cells plus antigen. Injections of 10^4 or 10^5 hybridoma cells resulted in larger swelling responses, while injection of 10^6 cells gave swelling responses only slightly larger than those induced by 10^5 cells. In contrast, when 10^3–10^6

Table 1 Specificity of hybridoma CS effector cells

Hybridoma cell line	Challenge antigen NP–BGG	NIP–BGG	BGG	NP-cells	NIP-cells	TNP-cells
BW5147	0.3±0.9	1.0±0.6	0.3±0.3	1.5±0.6	NT	NT
B6-CSI-15	8.3±1.7*	6.0±0.6*	0.6±0.3	0.8±0.6	NT	NT
B6-CSI-78	8.3±1.5*	7.3±1.5*	0.3±0.3	1.5±0.9	NT	NT
BW5147	0.9±1.3	NT	NT	0.3±0.7	0.3±0.3	1.3±0.7
B6-CSK-21	0.9±0.6	NT	NT	8.0±0.6*	10.0±0.6*	0.3±0.3
B6-CSD-35	0.9±0.9	NT	NT	8.3±0.3*	0.6±0.3	0.0±0.6
B6-CSD-52	1.3±0.6	NT	NT	8.3±0.3*	8.7±0.9*	1.3±0.9

1×10^5 irradiated BW5147 cells or hybridoma cells were mixed with 40 μg NP–BGG, NIP–BGG, BGG, or 5×10^5 NP-, NIP-, or TNP-conjugated C57BL/6 spleen cells, and these were then injected into the left footpad of C57BL/6 recipients in 25 μl Hanks' balanced salt solution. Footpad swelling, measured as the difference in footpad thickness between the left and right footpads 24 h after antigenic challenge, is recorded in units of 10^{-3} cm. The groups each contain 4–5 mice. NT, not tested.

* Significant swelling response ($P<0.01$).

B6-CSI-78	98	98	74	3	2	4	3	0
B6-CSK-21	98	98	74	7	2	3	2	2
B6-CSD-35	100	98	73	6	2	2	1	0
B6-CSD-52	98	7	78	5	2	2	0	0
B6-Ts$_1$-3	98	5	84	0	53	31	0	0

Monoclonal hybridoma anti-Thy-1.1, -Thy-1.2 (NEN) and -I-A^b antibodies (Dr T. Springer, Sidney Farber Cancer Institute, Massachusetts), conventional anti-H-2D^b ((A × 18R)F$_1$ anti-B10) and anti-I-J^b (5R anti-3R) alloantisera, guinea pig anti-NP^b and anti-CGAT idiotypes, and polyvalent guinea pig anti-mouse immunoglobulin antisera (prepared as detailed elsewhere[6]) were used, together with predetermined optimal concentrations of rabbit complement, to lyse the hybridoma cells. The results are expressed as per cent specific lysis and represent pooled results from 2–6 experiments. Less than 15% lysis is considered insignificant. The B6-Ts$_1$-3 T-cell hybridoma line was used as a control. Characterization of monoclonal Ts$_1$ suppressor cells is detailed elsewhere[6]. CGAT is the common idiotype on anti-GAT antibodies[10].

hybridoma cells were given intravenously (i.v.) and the mice were challenged with antigen in the footpads, no swelling response was observed (data not shown). This may be due to the failure of the hybridoma cells to properly migrate to the site of antigenic challenge. However, note that the use of a local transfer system has limitations: as helper[4] and killer[4,5] T cells can also induce delayed inflammatory responses, it is difficult to determine whether these hybridoma cells are CS effector cells or represent hybridomas derived from distinct T-cell subsets. This may be a semantic problem[2].

Previous reports[1,2] have indicated that NP-specific CS effector cells derived from Igh^b-bearing C57BL/6 mice cross-reacted with NP derivatives such as 4-hydroxy-5-iodo-3-nitrophenylacetyl (NIP). To evaluate the fine specificity of the CS reactive hybridoma clones isolated, they were injected with either NIP-derivatized proteins or cells. As shown in Table 1, four of the five hybridomas demonstrated significant levels of NIP cross-reactivity. Previous analyses of the C57BL/6-derived NP-*O*-Su-induced CS effector cell population did not reveal a non-NIP-cross-reactive population[1,2] but these previous experiments involved adoptive transfers of a heterogeneous population of *H-2*-restricted cells. Thus the presence of some NIP-cross-reactive clones in the heterogeneous population probably prevented detection of other non-cross-reactive clones.

To further distinguish between these hybridoma clones, the cells were phenotyped by microcytoxicity testing[6] using antisera reactive with *Thy-1-*, *H-2-* and *Igh-V*-encoded determinants derived from the C57BL/6 parental strain. The AKR (*H-2^k*, *Igh^d*)-derived BW5147 thymoma cells and the NP-specific suppressor T-cell hybridoma line B6-Ts$_1$-3 of C57BL/6 (*H-2^b*, *Igh^b*) origin, were used as controls. All the lines carried the BW5147-derived Thy 1.1 marker (Table 2), as shown by the high percentage of lysis observed after treatment with monoclonal anti-Thy-1.1 antibody and complement. Most of the hybridoma clones also carried the Thy-1.2 marker derived from the spleen cell donors. The B6-CSD-52 and B6-Ts$_1$-3 lines were exceptions—this may be due to the loss of the chromosome carrying the *Thy-1.2* gene[7,8]. All the C57BL/6-derived hybridomas specifically reacted with anti-H-2D^b antisera. However, none of the hybridomas demonstrated significant reactivity with monoclonal anti-I-A^b or conventional anti-I-J^b antibodies[9]. The cytolytic activity and specificity of the anti-I-J^b antisera described previously[6] were confirmed by testing the I-J^b-bearing B6-Ts$_1$-3 hybridoma suppressor line.

To evaluate the nature of the antigen receptor on these hybridomas, the cells were tested for reactivity with guinea pig anti-NP^b idiotypic antisera[6]. Control guinea pig anti-idiotypic antisera directed against a different idiotypic determinant associated with anti-GAT (poly(Glu^{60}Ala^{30}Tyr^{10})) antibodies[10] and polyvalent guinea pig anti-immunoglobulin antisera were used as controls. Only the B6-CSI-15 and the control B6-Ts$_1$-3 hybridoma lines demonstrated specific lysis with anti-NP^b antisera. All cloned sublines of B6-CSI-15 also demonstrated <50% lysis with anti-NP^b antisera, suggesting that the idiotypic receptor is poorly expressed. Similar findings were reported for the idiotypic receptors on suppressor cell hybridomas[11]. In addition, note that only one of the four hybridoma lines which cross-reacted with NIP hapten (Table 1) carried detectable levels of NP^b-related idiotypic determinants, indicating that at the T-cell level, NIP cross-reactivity does not correlate with the presence of NP^b idiotypic determinants. These results are also consistent with data which indicate that B6-derived CS effector cells are generally not susceptible to complement-mediated lysis with anti-NP^b antisera (unpublished data).

The hybridoma CS effector lines were further distinguished by evaluating the genetic restrictions of activation. The B6-CSI-15 and B6-CSI-78 hybridoma lines only demonstrated NP-specific reactivity when transferred into I-A^b-bearing recipients (Table 3). Thus, transfer of B6-CSI-15 and B6-CSI-78 cells together with NP–BSA yielded significant footpad swelling responses in I-A^b-bearing C57BL/6 and B10.A(5R) recipients, but not in strains lacking an *I-A* subregion derived from the *H-2^b* haplotype. In contrast, when B6-CSK-21 cells were transferred together with NP-coupled syngeneic spleen cells, footpad

See Table 1 legend for protocol. Recipients received 5×10^5 syngeneic hapten-modified spleen cells.

swelling responses were noted only in C57BL/6, B10.A(5R) and B10.MBR recipients. Thus, the activity of the B6-CSK-21 hybridoma cell line is restricted by genes in the *H-2K* region. Finally, the C57BL/6-derived B6-CSD-35 and B6-CSD-52 hybrids demonstrated NP-specific responses only in *H-2D*- (and *H-2I*-) compatible C57BL/6 and B10.A(2R) recipients.

The present series of *H-2K*-, *H-2I*- and *H-2D*-restricted T-cell hybrids are specific for the same haptenic determinants. Although all the hybrids are NP-specific, the B6-CSI lines do not react with NP-coupled cells and the B6-CSK and B6-CSD lines fail to respond to NP-coupled proteins. This may reflect the interaction requirements for activation of *H-2I*-restricted hybridomas by cells which process and present antigen, while the *H-2D*- or *H-2K*-restricted cells may be activated by a different kind of antigen association[2,12,13]. These data support the hypothesis that activation of the *H-2K*- and *H-2D*-restricted effector CS hybridoma cells is macrophage-independent, as are the interactions of cloned or hybridoma cytolytic T effector cells[14-16].

The series of NP-specific hybridomas isolated and described here provides a very useful tool for analysing antigen receptors on T cells. Further analysis of these hybridoma lines may help to elucidate T-cell function, including analysis of the signals required for cellular activation; comparisons of the products released after antigen activation and determining whether these cells mediate multiple T-cell functions (for example, whether *H-2I*-restricted hybrids may provide helper activity or whether the *H-2K/D*-restricted cells function as killer T cells). Experiments are being done to address these issues.

Failure of killed *Listeria monocytogenes* vaccine to produce protective immunity

Carl Heinz Wirsing von Koenig & Horst Finger

Institute of Hygiene and Laboratory Medicine, Municipal Hospital, D-4150 Krefeld, FRG

Herbert Hof

Institute of Hygiene and Microbiology, University of Wuerzburg, D-8700 Wuerzburg, FRG

We report here experiments which, in contrast to recently published data[1,2], suggest that protection against lethal doses of viable *Listeria monocytogenes* cannot be achieved by previous injection with killed *Listeria* vaccine neither by adding macrophage-blocking agents such as dextran sulphate nor by using C3H/HeJ mice having inborn macrophage defects. This discrepancy can be explained by the ineffective killing of bacteria at 56 °C, resulting in injection of small numbers of viable bacteria; such doses are normally subinfective and do not provide immunity. Blocking of the macrophage system by dextran sulphate[3], however, or use of C3H/HeJ mice with inborn macrophage defects[4] renders these doses fully infective, hence providing subsequent protective immunity[5].

L. monocytogenes, serotype 4b, was cultured in tryptose broth at 37 °C for 16 h. The virulence of the strain was maintained by continuous passage in mice of the same strain as used for the experiments. Viable counts of bacteria in broth, dilutions and spleen homogenates were determined using 10-fold dilutions on to agar. Dilutions, where necessary, were made in sterile 0.9% phosphate-buffered saline (PBS) *p*H 7.2.

Using the protocol of van der Meer *et al.*[2], the bacterial suspensions were incubated at 56 °C for 60 min to kill the bacteria. Then the suspensions were diluted to a final concentration of 5.0×10^8 bacteria ml^{-1}. In the first experiment, 0.2 ml of this dilution (1.0×10^8 bacteria) was injected intraperitoneally (i.p.) into female NMRI (Han) mice (Central Institute for Laboratory Animals, Hannover), aged 8–12 weeks. The animals were divided into two groups; one group received an additional i.p. injection of 50 mg dextran sulphate 500 (DS 500) per kg body weight 1 day before infection (Pharmacia). Viable counts of the bacterial suspensions revealed in five independent experiments, between 7.5×10^1 and 8.0×10^2 *L. monocytogenes* per ml, resulting in infective doses between 1.5×10^1 and 1.6×10^2 bacteria per mouse. The time dependence of bacterial killing at 56 °C is shown in Table 1.

The time course of infection of mice was followed by counting bacteria in spleen homogenates at different times after infection. As can be seen from Fig. 1, 1.6×10^2 bacteria per mouse did not result in detectable viable bacteria in the spleens, without further treatment. Challenge of these animals 1 week later with an i.p. injection of $20\times LD_{50}$ (lethal dose for 50% of the population, 4.5×10^5) *L. monocytogenes* led to the death of all animals during the subsequent 5-day observation period. Figure 1 shows that the second group of mice, which were treated with the macrophage blocking agent DS 500, became infected after i.p. injection of only 1.6×10^2 bacteria. The course of infection resembled the normal course of experimental listeriosis[6]. Subsequent challenge of these animals with $20\times LD_{50}$ of viable *L. monocytogenes* revealed protective immunity as only one of eight animals died within the period of observation.

The second experiment used C3H/HeJ and C3HeB/FeJ, male mice (24–28 g; Jackson Laboratories), which have an 'intrinsic adjuvant' (ref. 1). Earlier studies have shown that C3H mice belong to a group of mouse strains that are susceptible to infection with *L. monocytogenes*, a phenomenon thought

Table 1 Killing of *Listeria monocytogenes* at 56 °C

Incubation time (min)	Viable bacteria per ml
0	3.5×10^9
30	2.8×10^6
40	2.8×10^2
50	8.0×10^1
60	1.2×10^2
70	2.0×10^1
80	0
90	4.0×10^1
100	0

L. monocytogenes serotype 4b were grown at 37 °C for 16 h in tryptose broth. The broth was incubated in a 56 °C waterbath then chilled to 4 °C before the viable count was performed.

0028–0836/82/200233—02$01.00

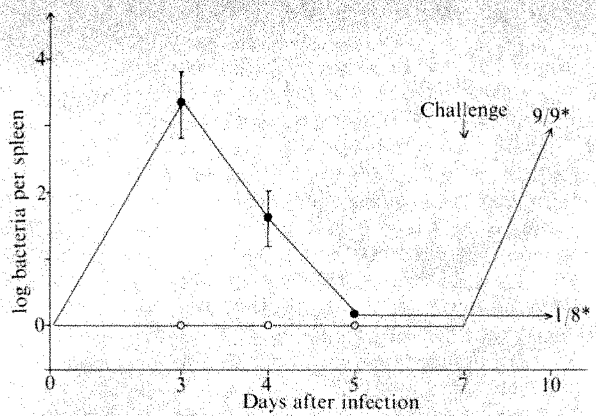

Fig. 1 Course of infection with *Listeria monocytogenes* in DS 500-treated mice. Female NMRI mice were injected i.p. with 1.6×10^2 viable *L. monocytogenes*. ○, Animals given no additional treatment; ●, animals injected i.p. with 50 mg DS 500 per kg body weight on day 1 before infection. Seven days later, all mice were challenged with $20 \times LD_{50}$ (4.5×10^5) viable *L. monocytogenes* i.p. Each point represents the mean ±s.e.m. of five spleens. * Proportion of animals dead at end of observation period.

to be mediated by a single autosomal gene, *Lr*[7]. The HeJ substrain of C3H mice has a macrophage defect[4] which renders it highly susceptible to facultative intracellular parasites such as *Salmonella typhimurium*[8]. Consequently, the i.p. LD_{50} was 4.0×10^3 *L. monocytogenes* compared with 2.3×10^4 for C3HeB/FeJ mice. Both mouse strains were infected with a suspension of bacteria produced as described above. The doses of viable bacteria were fully infective for C3H/HeJ but not for C3HeB/FeJ mice, resulting in induction of protective immunity in the former in the same manner as that shown for DS-500-treated NMRI mice.

We then repeated the experiments using injections of *L. monocytogenes* killed by incubation at 70 °C for 60 min. The killed bacteria were unable to produce immunity or to increase the nonspecific resistance to infection in both DS-500-treated NMRI and in C3H/HeJ mice. We therefore conclude that blocking or impairment of the mononuclear phagocyte system by either DS 500 or *Bordetella pertussis* organisms[9,10], or by inborn defects as in the C3H/HeJ mouse substrain, renders normally subinfective doses of *L. monocytogenes* fully infective, which can be clearly demonstrated by a drastically reduced mean lethal dose. Animals surviving this infection, however, possess a strong protective immunity based on the interaction of T-lymphocytes and macrophages.

These experiments stress the importance of a functionally active macrophage system for resistance against facultative intracellular parasites. Contrary to the findings of van Dijk[1] and van der Meer[2], our experiments suggest that injection with a killed *Listeria* vaccine is unable either to provide protective immunity or to increase nonspecific resistance to infection.

Directed effector cells selectively lyse human tumour cells

Charles B. Simone

Clinical Pharmacology Branch, Division of Cancer Treatment, National Cancer Institute, Bethesda, Maryland 20205, USA

Classical antibody-dependent cellular cytotoxicity (ADCC) involves effector cells that mediate damage of antibody-coated targets. Classical ADCC is probably responsible, at least in part, for *in vivo* allograft rejections, resistance to viral infections, parasite destruction and the rejection of tumours[1,2]. Like complement[3,4], human effector cells mediate damage by creating a pore or channel in the target membrane, but the channel created by effector cells is 2.5 times larger (functional diameter ~165Å) than the channel formed by complement[3,5]. Classical ADCC is inhibited by low concentrations of immune complexes which compete with target-bound antibody for effector cell Fc receptors[6]. Because many clinically important diseases, such as certain cancers and systemic infections, have been shown to result in circulating antigen–antibody complexes, it seems likely that these immune complexes might inhibit the ADCC component of host defense mechanism in these diseases. A major advantage to the host might result from the attachment of antibody to effector cells first; either via the Fc receptor[7], which is a weak interaction; by antibody 'associating' with effector cells[8], which is very transient; or by binding antibody to the cellular membrane of effector cells[9]. Here I report the specificity of such antibody-directed ADCC effectors for antigen-bearing targets *in vitro*.

Antibody can be attached to effector cells by incubating them together in the presence of polyethylene glycol (PEG) and spinning them through a mixture of phthalate oils (see Table 1 legend). Using radiolabelled antibody, it can be shown that 150,000 antibody molecules can be attached to each effector cell (neutrophil) by this technique (data not shown). Also, no radiolabelled antibody is detected for up to 24 h in supernatants of directed effectors incubated at 37 °C; or for up to 6 h in the plasma of mice (five animals) which were injected intravenously with directed lymphocytes (data not shown). The effects of

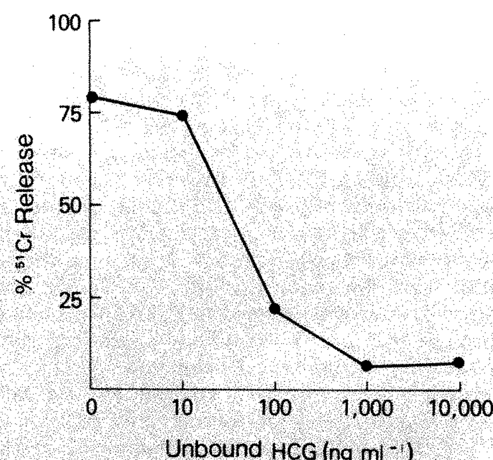

Fig. 1 Effect of unbound HCG on directed effector cell action on ^{51}Cr-labelled JEG-3 cells. 7.5×10^5 ^{51}Cr-labelled -3 cells in RPMI 1640 medium were suspended with 5% fetal calf serum in flat-bottom microtitre wells with indicated amounts of unbound HCG. Anti-HCG-directed effector cells were introduced into the well to a total volume of 200 µl and the plate was gently rotated for 10 min, then incubated for 5 hr at 37 °C. ^{51}Cr release was assayed as before. Controls were effector cells treated with PEG and phthalate oils without antibody, which yielded 7–10% ^{51}Cr release at all points of unbound HCG.

Classical ADCC				
2×10^6 PBLs	+	96	68	68
1×10^6 Neutrophils	+	93	72	76

Human resealed erythrocyte ghosts containing CF were made as described earlier[3]. Intact RBCs and MCF-7 cells were TNP-modified and ^{51}Cr-labelled. Samples were counted in a γ-counter. Monolayers of each target were made on the bottom surface of flat-bottom microtitre wells as previously described[3]. Freshly separated human granulocytes and lymphocytes were obtained as described previously[3] and used for classical and directed ADCC. They were washed three times and resuspended in balanced salt solution (BSS)–HEPES to a final concentration of 5×10^7 cells per ml. 'Directed' ADCC effector cells were prepared as follows. Affinity-purified rabbit anti-TNP IgG was mixed with effector cells. 12% of 20,000-molecular weight PEG (Fisher Scientific) in BSS–HEPES was immediately added, bringing the total mixture to $1\ mg\ ml^{-1}$ immunoglobulin in 6% PEG. The mixture was incubated for 90 min at 0 °C and then 250 μl aliquots were layered over 800 μl of a phthalate oil mixture (dibutyl phthalate:bis-(2-ethylhexyl)phthalate, both from Eastman Chemicals, Rochester; 1.5:1 v/v) in 1.5 ml Beckman microcentrifuge tubes and sedimented in a Beckman Microfuge B at 9,360 g for 4 min. Cells can be separated from the incubation medium without an aqueous wash because the oil mixture is less dense than the cells and more dense than the medium. The supernatant and entire oil mixture were recovered by aspirating them from the tubes. The cells were washed five times using BSS-HEPES and resuspended to the original concentration of 5×10^7 cells per ml. Control effector cells* were treated with PEG and the phthalate oils as above but without antibody. The microtitre wells were all refilled with BSS-HEPES and the desired reaction components (effector cell, antibody) were added to a final volume of 200 μl. The plates were centrifuged at 250 g for 10 min and incubated at 37 °C for 3 h; then 100 μl aliquots were withdrawn from each well and fluorescence or ^{51}Cr release determined. The total releasable marker was determined by the marker released by 1% Triton X-100. Samples were run in duplicate and agreement between the duplicates was within 15%.

classical ADCC were compared with those of 'directed' ADCC (Table 1) using trinitrophenyl (TNP)-modified targets. Peripheral blood lymphocytes (PBLs) or neutrophils were added to anti-TNP-coated targets (classical ADCC), or effector cells with attached anti-TNP antibody ('directed' ADCC) were added to TNP labelled targets. The three targets used were TNP-resealed human erythrocyte ghosts containing carboxyfluorescein (CF), TNP–^{51}Cr-labelled intact human erythrocytes and TNP–^{51}Cr-labelled MCF-7 cells, a human breast cancer cell line[11]; each was put in separate microtitre wells. Effector cells alone or effector cells treated with PEG and the phthalate oils but without antibody produced minimal background release from each target, showing that the PEG and phthalate oil treatment *per se* does not cause target damage. Directed effector cells can mediate marker release from a membrane model (erythrocyte ghosts), intact erythrocytes and even from human breast cancer cell MCF-7. These results are comparable with those seen when classical ADCC methods are used. Hence the attachment of antibody to effector cells using this technique does not inhibit cell-mediated killing.

The specificity of the directed cytotoxic effector cells was assayed by placing two antigenically distinct targets in the same microtitre well: TNP-modified ghosts containing CF and human choriocarcinoma cell line, JEG-3 (gift of Dr Saul Rosen), labelled with ^{51}Cr. The JEG-3 cell line secretes human chorionic gonadotropin (HCG) at a rate of 7,290 IU per 10^9 cells per day; hormone secretion can, however be blocked by antibody against HCG[12]. If anti-TNP-directed-effector cells are used, very high CF release from the TNP-modified ghost population is observed and there is minimal background ^{51}Cr release from the ^{51}Cr-labelled JEG-3 cells (see Table 2). However, if anti-HCG-directed effector cells (anti-HCG antibody given by Dr Hans Hager, Hoffmann-LaRoche) are used, then ^{51}Cr release is high and CF release is minimal, indicating that the JEG-3 cells are killed and the TNP–ghosts are not damaged. The specificity of directed ADCC is comparable with that of classical ADCC. When soluble immune complexes (HCG–anti-HCG) were added to microtitre wells containing 10^6 JEG-3 cells before 10^6 anti-HCG-directed neutrophils, there was 36% ^{51}Cr net release after 4 h of incubation compared with 40% net release using the same system but without immune complexes. This was in contrast to only 7% ^{51}Cr net release from 10^6 JEG-3 cells which were treated with anti-HCG first, then with immune complexes, then 10^6 effector neutrophils. Hence immune complexes do not significantly inhibit directed ADCC but do inhibit classical ADCC.

JEG-3 cancer cells were chosen as targets because the anti-HCG-directed effector cell–JEG 3 system may be a model clinically relevant to human testicular cancer. It is of interest, therefore, to determine whether unbound HCG (analogous to circulating HCG in a patient with testicular cancer) interferes with the lysis of JEG-3 cancer cells mediated by anti-HCG-directed effector cells. Figure 1 shows that $\geq 1{,}000\ ng\ ml^{-1}$ unbound HCG almost totally prevents anti-HCG-directed effectors from lysing ^{51}Cr-labelled JEG-3 cancer cells, probably by binding to the anti-HCG antibody attached to the effector cells. Whereas 100 $ng\ ml^{-1}$ of unbound HCG allows partial ^{51}Cr release, 0 or 10 $ng\ ml^{-1}$ of unbound HCG does not interfere with killing.

Recently, Miller *et al*[13] treated a T-cell leukaemia patient with systemic anti-Leu 1 antibody and a clinical response, albeit transient was demonstrated. Several difficulties encountered in that patient, including clearance of antibody and dosage, might be avoided in future human *in vivo* therapy if the technique described here was used. Hence the anti-human Leu 1 (Becton Dickinson) reagent was used to see whether it would effect lysis of targets *in vitro* after it had been attached to effector cells in the conditions already described (Table 3). Freshly separated PBLs were ^{51}Cr-labelled and divided into two groups, one of which was TNP-modified. When anti-TNP-directed effectors were put into either group, there was significant ^{51}Cr release from the TNP-modified PBLs and only background ^{51}Cr from the unmodified PBL targets. When anti-human Leu 1-directed

Table 2 Directed compared with classical ADCC using anti-TNP or anti-HCG and their action on targets

Effectors	Anti-TNP: TNP-ghosts %CF release	Anti-TNP: JEG 3 cells %^{51}Cr release	Anti-HCG: TNP-Ghosts %CF release	Anti-HCG: JEG 3 cells %^{51}Cr release
Directed ADCC				
2×10^6 PBLs +antibody	83	8	6	47
1×10^6 Neutrophils +antibody	92	7	7	53
Classical ADCC				
2×10^6 PBLs +antibody	92	7	8	49
1×10^6 Neutrophils +antibody	90	8	8	54
No antibody	TNP–Ghosts	JEG cells		
2×10^6 PBLs	11	7

2×10^6 PBLs*	13	8		
1×10^6 Neutrophils*	14	8		

4×10^5 TNP-modified erythrocyte ghosts containing CF and 4×10^5 ^{51}Cr-labelled JEG-3 cells were suspended together in flat-bottom microtitre wells in RPMI 1640 medium. Desired components were then added and marker release assayed after 5 h incubation at 37 °C. Directed effector cells were made as before and control effector cells* were treated with PEG and phthalate oils without antibody. Anti-HCG is affinity-purified rabbit IgG.

Table 3 ADCC effector cells directed with anti-TNP or anti-Leu 1 antibodies and their effects on TNP-^{51}Cr-labelled PBL or ^{51}Cr-labelled PBL targets

Effector cell Treatment	% ^{51}Cr release TNP-^{51}Cr-PBLs	^{51}Cr-PBLs
Directed ADCC		
1×10^6 Neutrophils*	15	11
1×10^6 Neutrophils+anti-TNP	74	12
1×10^6 Neutrophils+anti-Leu 1	61	56
Classical ADCC		
1×10^6 Neutrophils*	10	13
1×10^6 Neutrophils+anti-TNP	71	13
1×10^6 Neutrophils+anti-Leu 1	59	62

Freshly separated PBLs were ^{51}Cr-labelled and divided into two groups, one of which was TNP-modified. 7.5×10^5 PBLs of each group were put in separate microtitre wells and suspended in 0.1 M BSS–HEPES and desired components were added to a total volume of 200 µl. Directed effectors were made as before and other control effectors* were treated with PEG and phthalate oils but without antibody. After incubation for 5 h at 37 °C, 100 µl supernatant aliquots were removed and ^{51}Cr content assayed.

effector cells were used, ^{51}Cr was released from each group, but slightly less than the amount seen for the anti-TNP-directed effector cell TNP–PBL reaction. Presumably this is because only the T-cell subpopulation is attacked when anti-human Leu 1 reagent is used, whereas T cells, B cells and null cells are attacked in the TNP–PBL group when anti-TNP is used. Classical ADCC results are comparable.

The technique of using PEG and phthalate oils to attach antibody to freshly separated effector cells results in the specific lysis of cells bearing the target antigen. The lysis is specifically blocked by soluble antigen. Soluble immune complexes do not inhibit directed ADCC. The degree of specific target lysis of human cancer cells and model targets using these directed effector cells is comparable with the lysis produced with classical ADCC techniques. The phthalate oils are completely washed off directed effector cells and these cells cause no adverse reactions *in vivo* (mice and one human). With the advent of monoclonal antibodies, this technique makes it theoretically possible to cause the destruction of targets *in vivo* (tumours, infectious agents) provided the antibody–antigen system is well defined. The absolute amount of non-human antibody given to a patient using this technique (and hence the risk of serum sickness and anaphylactic reactions) should be much less than that amount of antibody passively administered to patients with certain tumours and Gram-negative sepsis[14]. Trials using passive administration of non-human antibody in an attempt to produce human tumour regression have been limited[13,15–17] because recent evidence shows that cell-mediated rather than humoral immunity is important in tumour resistance[18,19] and that passive antibody may enhance tumour growth[20]. I have shown here that human effector cells can be selectively directed to lyse human cancer cells and not other adjacent cells.

I thank Drs A. S. Fauci, D. Longo, C. Myers and F. Abramson for helpful comments.

Kinetics of induction and molecular size of mRNAs encoding human interleukin-2 and γ-interferon

Shimon Efrat, Shlomo Pilo & Raymond Kaempfer

Department of Molecular Virology, The Hebrew University – Hadassah Medical School, 91 010 Jerusalem, Israel

T-cell growth factor (TCGF), or interleukin-2 (IL-2), and immune or γ-interferon (IFN-γ) are lymphokines possessing powerful immunoregulatory properties. IL-2 is essential for the *in vitro* proliferation and maturation of certain classes of T lymphocyte[1,2], particularly cytotoxic[3,4] and helper[5] T cells, and also activates natural killer cells[6]. IFN-γ is considerably more active than IFN-α and -β as activator of natural killer cells and as antiproliferative agent, relative to its antiviral activity[7–11]. As a step towards understanding the regulation of expression of these proteins, we report here the induction of mRNA species encoding IL-2 and IFN-γ in mitogen-stimulated normal human lymphocytes and their expression in *Xenopus laevis* oocytes. On microinjection, distinct species of mRNA sedimenting at 10–10.5S and 13–13.5S direct the synthesis and secretion of active IL-2 and IFN-γ respectively. A second species of IL-2 mRNA is consistently revealed, sedimenting at 13–13.5S and comprising about 20% of the total IL-2 mRNA activity. During induction, an initial concomitant rise in IL-2 and IFN-γ mRNA activities is followed promptly by a concomitant decline in the rate of their accumulation.

We used human tonsils as a convenient source of large amounts of lymphocytes. Cultivation of these cells in the presence of phytohaemagglutinin (PHA) leads to the induction of IL-2 (Fig. 1*a*). IL-2 activity is detectable in the medium by 8 h and accumulates at an increasing rate until about 24 h, when a distinct decline in the rate of accumulation is observed. The kinetics of IFN-γ induction by PHA in the same culture (Fig. 1*b*) are remarkably similar to those of IL-2. Inclusion of the tumour promoter 12-*O*-tetradecanoyl phorbol 13-acetate (TPA) together with PHA enhances both IL-2 and IFN-γ levels in the medium throughout the induction period, but even with TPA present, the rate of accumulation of IL-2 and IFN-γ begins to decline after 20–24 h.

We isolated mRNA from cells that had been cultured for 12 h with PHA and microinjected it into *X. laevis* oocytes. As detailed in Fig. 2 legend, this mRNA directed extensive synthesis of IL-2. About 80% of the expressed IL-2 activity was recovered from the surrounding medium, showing that the mRNA directed both synthesis of active IL-2 and its secretion from oocytes. The mRNA preparation also directed the synthesis of active IFN-γ, the bulk of which was secreted (see Fig. 2 legend).

Table 1 *p*H sensitivity of IFN-γ and IL-2 activities in oocyte medium

	Culture medium	10S mRNA	13S mRNA
IFN-γ(U ml^{-1})			
*p*H 7.2	2,560	<40	220
*p*H 3	<40	<40	<40
IL-2 (c.p.m.)			
*p*H 7.2	35,500	42,500	5,800
*p*H 3	29,200	38,400	7,800

Half the incubation medium of groups of 10 oocytes, injected with 10S or 13S mRNA as described for Fig. 3, was dialysed for 16 h against phosphate-buffered saline at *p*H 3 and then for 2 h against buffer at *p*H 7.2. The other half of the incubation medium was dialysed for 18 h against buffer at *p*H 7.2. Aliquots of 24 h-LCM were treated similarly. Assays were performed as described in Fig. 2 legend.

The kinetics of appearance of mRNA for IL-2 and for IFN-γ in lymphocytes stimulated by PHA, as followed by microinjection into oocytes, are illustrated in Fig. 2. Accumulation of IL-2 mRNA activity begins after 4 h and follows a sigmoid course, with a sharp decline in the rate of accumulation at ~16 h. IFN-γ mRNA activity follows a remarkably similar time course (Fig. 2). Comparison with Fig. 1 shows that the levels of mRNA encoding both IL-2 and IFN-γ reach near maximal values well before these activities appear in the medium in significant amounts.

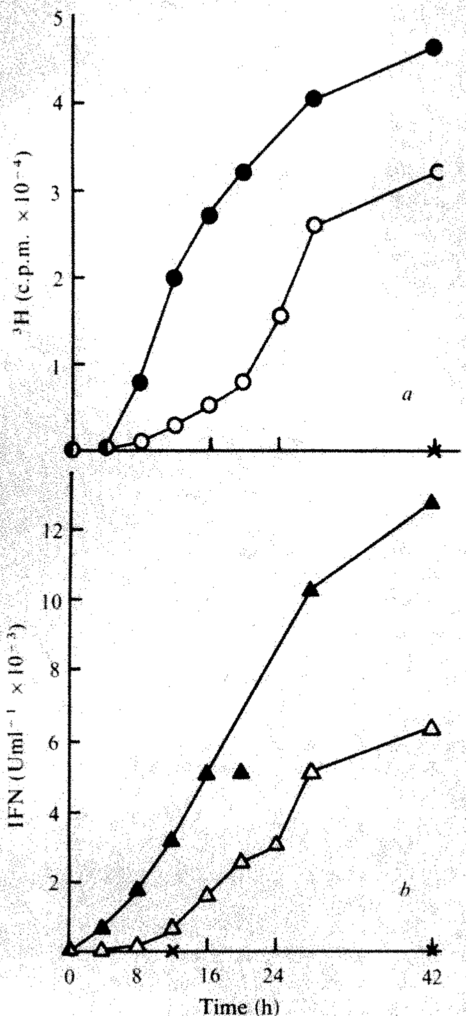

Fig. 1 Kinetics of induction of IL-2 (*a*) and IFN-γ (*b*). Tonsils from otherwise healthy donors were disrupted mechanically and cultured at 4×10^6 cells per ml in RPMI 1640 medium supplemented with 2 mM glutamine, 10 mM minimum essential medium (MEM) non-essential amino acids, 100 mM MEM Na-pyruvate, 10 mM HEPES buffer *p*H 7.2, 5×10^{-5} M 2-mercaptoethanol, 2% fetal calf serum (FCS), antibiotics and 0.4% (v/v) PHA-P (Difco) (○, △). TPA (Sigma) was added to 10 ng ml^{-1} (●, ▲). ×, Mitogen-free controls. At the indicated times, aliquots of the cultures were centrifuged and supernatants were passed through 0.22 μm filters and frozen. *a*, IL-2 activity was assayed by incubating 50 μl of serial dilutions made in culture medium containing 10% FCS with 50 μl of medium containing 2×10^4 assay cells in round-bottom microtitre wells for 48 h at 37 °C. Assay cells were human peripheral blood lymphocytes that had been cultured for at least 1 week in IL-2-containing medium and then incubated without IL-2 for 24 h. Each well received 1 μCi of ^{3}H-thymidine (83 Ci mmol^{-1}) in 10 μl of culture medium at 42 h. The cells were collected on filters and radioactivity in DNA was monitored. Values plotted are for 1:32 dilutions. Values for zero-time cultures, which represent background assay activity of PHA or PHA and TPA, were <500 c.p.m. *b*, IFN-γ was assayed by inhibition of the cytopathic effect of mengovirus in human amnion cells. Confluent cells in microtitre wells were incubated with 50 μl of serial dilutions of the assay fluids in RPMI 1640 medium for 8 h and then infected with 3–5 plaque-forming units (PFU) per cell of mengovirus in 50 μl of medium. After 1 h, the cells were washed and incubated with medium containing 2% FCS for about 24 h before they were stained with Gentian violet. An internal laboratory standard of human IFN-γ and an IFN-α reference standard were included; 1 U of IFN-γ corresponds to about 2.5 IU of IFN-α. The interferon activity was abolished by dialysis against phosphate-buffered saline, *p*H 2.

To estimate the molecular size of IL-2 and IFN-γ mRNAs, mRNA extracted from lymphocytes stimulated for 16 h with PHA was centrifuged through an isokinetic sucrose gradient. In Fig. 3*a*, arrows denote the positions of *Escherichia coli* rRNA and rabbit globin 9S mRNA markers. Microinjection of RNA from individual gradient fractions revealed two peaks of IL-2 mRNA activity, a major one (IL-2A) sedimenting at 10–10.5S and comprising ~80% of the activity, and a minor one sedimenting more rapidly, at 13–13.5S (IL-2B).

Figure 3*b* depicts a sedimentation velocity analysis of mRNA purified from cells stimulated for 16 h with both PHA and TPA and illustrates the synthesis of both IL-2 and IFN-γ directed by individual gradient fractions. Again, IL-2 mRNA activity sedimented in a major peak at 10S and a minor one at 13S, while IFN-γ mRNA activity sediments in a single peak at 13S that directs high levels of IFN-γ synthesis on microinjection into oocytes. The expression of IFN-γ mRNA in these experiments is at least an order of magnitude higher than that described in previous studies[12,13] estimating its size at 15S and 18S respectively. IFN-γ encoded by co-sedimenting mRNA might depress DNA synthesis[11] in the IL-2 assay cells, in which case the amount of the 13S IL-2 mRNA species would be an underestimate. Alternatively, the overlap of the IL-2B and IFN-γ mRNA peaks at 13S suggests that IFN-γ may induce IL-2 in the cells used for the IL-2 assay. To examine these alternatives, we dialysed the medium of oocytes injected with 10S and 13S mRNA at *p*H 3 before testing for IL-2 activity. Such treatment effectively eliminates IFN-γ activity but does not affect the IL-2 activity of the two mRNA peaks (Table 1). We conclude, therefore, that the IL-2B mRNA sedimenting at 13S is expressed independently of IFN-γ.

Inclusion of TPA in the culture medium does not influence the relative abundance of the two IL-2 mRNA peaks, but increases by severalfold the specific activities of the IFN-γ mRNA (see Fig. 2) and IL-2 mRNA species (Fig. 3). The higher levels of induction observed when TPA is present (Fig. 1) are thus reflected by increased mRNA activity.

The mRNA species described here were derived from normal human lymphocytes, avoiding abnormal phenomena that may be associated with transformed cell lines[14]. The ability of IL-2 to stimulate the proliferation of T cells was assayed in cultured human peripheral blood lymphocytes comprising >90% T cells, as judged by rosetting with sheep erythrocytes. These cells are IL-2 dependent and die within 48 h when cultured without this factor. At the time of assay, such cells responded only very weakly to PHA or TPA. Although crude IL-2 preparations may contain B-cell growth factor[15] activity in addition to TCGF, the activity observed in our experiments stimulated extensive DNA synthesis in cells that were essentially pure T lymphocytes, thus defining the activity as IL-2.

The expression of human IL-2 mRNA in *X. laevis* oocytes and the secretion of active IL-2 from these cells made it possible to analyse the levels of IL-2 mRNA activity during the course of induction. Mitogenic stimulation of lymphocytes leads to an initial increase in IL-2 mRNA activity that quickly levels off (Fig. 2). The decline in rate of accumulation of IL-2 mRNA activity agrees well with the decline in rate of IL-2 accumulation observed in the culture medium (Fig. 1). It is thus likely that the capacity of an IL-2 producer cell to form active IL-2 mRNA is limited and that a refractory period may follow, similar to that observed for IFN-β induction[16]. The kinetics of appearance of both IFN-γ (Fig. 1) and IFN-γ mRNA (Fig. 2) are remarkably similar to those for IL-2. The levelling off of mRNA activities observed in Fig. 2 could be caused by the cessation of mRNA synthesis, by the accumulation of mRNA encoding post-transcriptional repressors, or by both. Gullberg *et al.*[17]

have shown that the IL-2-forming capacity of mouse splenocytes declines ~20 h after exposure to mitogen. The present findings support the concept that the induction of IL-2 and IFN-γ in lymphocytes is regulated at the level of transcription.

Finally, our results reveal that IL-2 mRNA is composed of two distinctly sedimenting molecular species (10S and 13S). The mRNA had been treated with dimethyl sulphoxide (DMSO) and heated before centrifugal analysis. This and the observation of a single mRNA peak for IFN-γ, as opposed to two for IL-2, do not support the interpretation that the 13S IL-2 mRNA peak is due to aggregation. This finding probably reflects the existence of more than one gene (or class of genes) encoding IL-2 activity, as has been observed for IFN-β[18,19], although an alternative mRNA processing pathway could also explain the results. The sedimentation coefficient of 10–10.5S for the major IL-2A mRNA species corresponds[20] to a nucleotide length of 610–680 bases. Assuming a minimum of 200 nucleotides for the 5'-leader and 3'-untranslated region, including poly(A), the IL-2A mRNA species can thus encode 135–160 amino acids, corresponding to proteins with molecular weights (MWs) of 14,800–17,600 and more if some side chains are modified. This estimate agrees well with the MW of 15,000 reported for IL-2 (refs 21, 22). The minor IL-2B mRNA species and IFN-γ mRNA correspond to a length of 1,060–1,150 nucleotides and accordingly can encode 31,000–35,000 of unmodified protein. These values are in accord with recent estimates of 20–25,000-MW for IFN-γ[23].

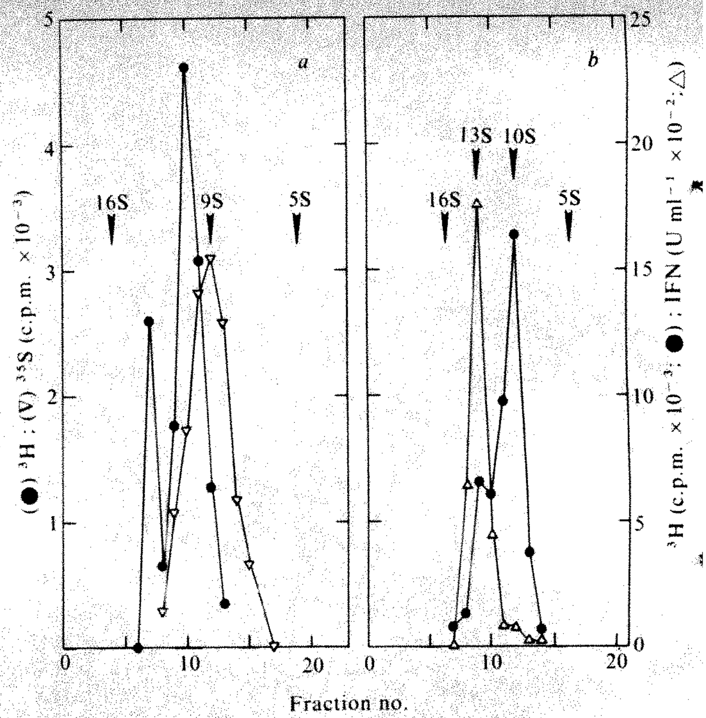

Fig. 3 Sedimentation velocity analysis of IL-2 and IFN-γ mRNAs. Total poly(A)-containing RNA was prepared from lymphocytes cultured for 16 h with PHA (*a*) or PHA and TPA (*b*) as described for Figs 1 and 2. The mRNA (160 μg in *a* and 80 μg in *b*) was heated in water for 90 s at 95 °C, rapidly cooled and centrifuged through 5–17.7% isokinetic sucrose gradients (5 ml) in 10 mM Tris-HCl, *p*H 7.4, 1 mM EDTA and 0.15 M NaCl. RNA from individual fractions was ethanol-precipitated, dissolved in 10 (*a*) or 5 (*b*) μl of water, and microinjected into 10 oocytes as described for Fig. 2. After incubation, the oocyte medium was assayed for IL-2 (●) and IFN-γ (△), as described for Fig. 1. Values for IL-2 are at a 1:4 dilution; at this dilution, standard 24 h-LCM gave 19,000 c.p.m. Assay backgrounds were as for Fig. 2. The concentration of microinjected RNA in the 10S peak fraction of IL-2 was 0.25 (*a*) and 0.21 (*b*) mg ml^{-1}. Parallel gradients contained *Escherichia coli* rRNA A_{260} markers (arrows) or rabbit globin mRNA, monitored for translation activity[27] by incorporation of ^{35}S-methionine (∇).

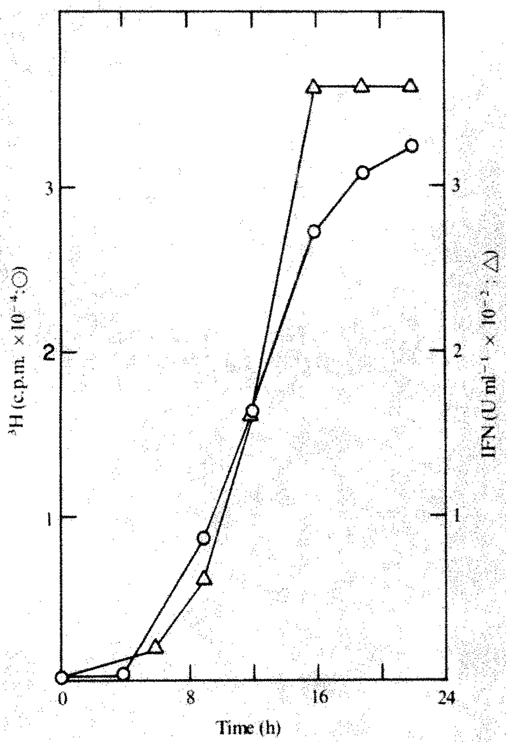

Fig. 2 Kinetics of appearance of IL-2 (○) and IFN-γ (△) mRNA activities in stimulated lymphocytes. Tonsillar lymphocytes were cultured with PHA as described for Fig. 1. At the indicated times, total RNA was extracted by the guanidinium thiocyanate-CsCl method[24]. The RNA was passed twice over oligo(dT)-cellulose, the second time after incubation for 5 min at 55 °C in 90% DMSO[25]. Poly(A)-containing RNA was dissolved in water at a concentration of 2 mg ml^{-1}. Oocytes were each injected with 50 nl of mRNA and incubated for 40 h at 21 °C in groups of 10 with 0.1 ml Barth's medium containing 10^{-4} M phenylmethylsulphonylfluoride[26] (buffer A). Aliquots of incubation medium from each group of oocytes were assayed for IL-2 and IFN-γ activities as described for Fig. 1. Values of IL-2 activity are for 1:4 dilutions. At this dilution, a standard lymphocyte-conditioned medium prepared after 24 h of culturing with PHA (24 h-LCM), gave a count of 30,000 min^{-1}; incubation medium from uninjected oocytes or from oocytes injected with Barth's medium gave <300 c.p.m. background activity. Medium and homogenate (prepared in 0.1 ml of fresh buffer A and cleared by centrifugation) from oocytes each injected with 100 ng of mRNA prepared at 12 h were assayed for IL-2 and yielded 16,400 c.p.m. and 4,400 c.p.m. respectively. When assayed for IFN-γ, these yielded 160 and 25 U ml^{-1} respectively; uninjected oocytes or oocytes injected with Barth's medium gave no detectable background activity. Interferon activity was abolished by dialysis against *p*H 2 buffer.

We thank Dr E. Kedar for helpful discussion and assay cells, Dr H. Soreq for advice on microinjection, and S. Marsh, A. Yeheskel and E. Chriqui for assistance. This work was supported by a grant from the Robert Szold Foundation.

The *LSP-2* gene and a 5′ flanking sequence are independently expressed in *Drosophila melanogaster*

Barry Yedvobnick* & Michael Levine†

* Department of Biology and
† Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut 06511, USA

The positions of nucleotide sequences involved in the stage- and/or tissue-specific expression of structural genes in higher organisms are largely unknown. One might predict, however, that closely linked genetic loci which are not coordinately controlled will contain regulatory sequences in close proximity to the respective coding regions. During the third instar of larval development in *Drosophila melanogaster*, the hormone ecdysterone augments the expression of several genes in fat body tissue, one of which is the structural gene coding for larval serum protein-2, *LSP-2*[1–5]. Although *LSP-2* transcripts are detected only in third-instar larval fat bodies, a genomic clone containing the *LSP-2* gene (clone *104*) hybridizes to poly(A)$^+$ RNA prepared from other tissues. We have now analysed clone *104* for other coding regions. Three transcripts, designated *T1*, *T2* and *T3*, hybridize within the 12.5 kilobases (kb) of DNA flanking the 5′ end of the *LSP-2* coding region. The *T1* coding region is separated from the 5′ end of the *LSP-2* coding region by no more than 2.5–3.5 kb. In contrast to the dramatic increase in the level of *LSP-2* transcript induced by ecdysterone in third-instar larval fat bodies, the *T1* transcript remains below the detectable level, indicating that expression of the two coding regions is not coordinately regulated.

A restriction map for clone *104* (Fig. 1 and ref. 3) shows the cleavage sites of *Eco*RI, *Sal*I and *Bam*HI endonucleases and the relevant fragments generated by digesting *104* DNA with either a combination of *Eco*RI and *Sal*I (fragments 1–5) or *Bam*HI (fragments 6–12). The map location of the 5′ terminus for *LSP-2* mRNA was determined by S_1 nuclease digestion[6]. The results of this analysis indicate that the 5′ end of the *LSP-2* coding region is 1.8 kb from the *Sal*I cleavage site in the coding region (Fig. 1). However, we cannot rule out the possibility that the *LSP-2* gene has an intervening sequence which separates a small segment of mRNA coding information from the bulk of the gene. The 1.8 kb value is therefore a minimum estimate.

The initial tests for identifying transcripts that hybridize to *104* DNA involved digestion of the DNA with either a combination of *Eco*RI and *Sal*I or *Bam*HI, separation of the DNA fragments by electrophoresis in agarose gel, transfer of the fragments from the gel to a sheet of nitrocellulose and hybridization with ^{32}P-labelled RNA probes (Fig. 2). Intense hybridization to the fragments containing the *LSP-2* coding region (fragments 2, 3, 9, 12) was detected with the fat body RNA probe but not with the oocyte, gastrula or late embryonic RNAs, in agreement with earlier results indicating that the *LSP-2* gene is expressed specifically in third-instar larval fat bodies[2]. Hybridization was also detected with all four RNA probes to fragments in the region flanking the 5′ end of the *LSP-2* coding region (fragments 1, 4, 7, 8, 11); fragments 7 and 2 hybridized very weakly with fat body and gastrula RNAs respectively; however, the bands are not visible with the autoradiographic exposures shown in Fig. 2. Hybridization to fragment 11 was visible with the fat body RNA probe with shorter exposures. No hybridization was detected with any of the RNA probes to DNA fragments containing sequences flanking the 3′ end of the *LSP-2* coding region.

The transcripts hybridizing with *104* DNA were further characterized by electrophoresis of poly(A)$^+$ RNA from late embryos and total RNA from fat bodies in agarose gel, transfer of the fractionated RNA to nitrocellulose paper and hybridization with ^{32}P-labelled *104* DNA probes (Fig. 3). When intact *104* DNA was used as the probe, a single transcript correspond-

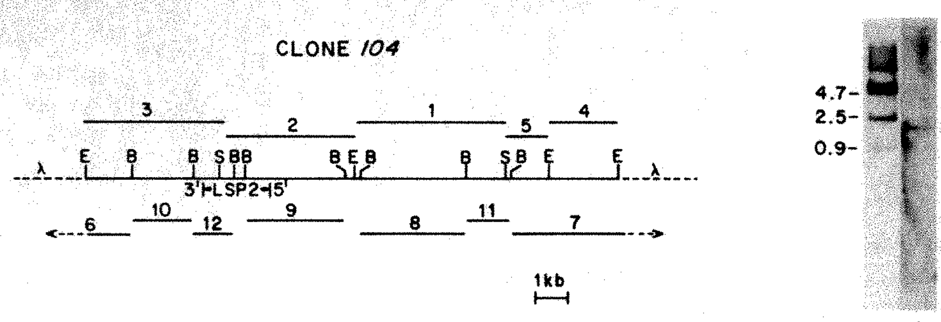

Fig. 1 Restriction map of clone *104*. The clone was isolated from a library of Charon-4 phages containing randomly sheared fragments of *Drosophila* DNA from strain *Canton-S*[12], using as probe poly(A)$^+$ RNA from late third-instar larval fat bodies[1,3]. The restriction map shows the positions in *104* DNA of the endonuclease cleavage sites for *Eco*RI (labelled E), *Sal*I (labelled S) and *Bam*HI (labelled B)[3]. The relevant fragments produced by digestion of *104* DNA with both *Eco*RI and *Sal*I are labelled 1–5, and by digestion with *Bam*HI are labelled 6–12. The location of the 5′ terminus of *LSP-2* mRNA was determined by hybridizing fat body RNA with purified fragment 2 DNA, removing the single-stranded regions by digestion with S_1 nuclease[6] and measuring the size of the remaining RNA–DNA hybrid by electrophoresis in agarose gel. Fragment 2 was purified after electrophoresis in 0.8% agarose gel of an *Eco*RI/*Sal*I digest of *104* DNA, electroelution of the fragment into hydroxyapatite[13] and recovery of the fragment from hydroxyapatite with 1 M sodium phosphate buffer *p*H 7; the purified fragment was dialysed at 4°C against 10 mM Tris/1 mM EDTA *p*H 7.6, precipitated with 95% ethanol and dissolved in 25 μl of a solution containing 0.4 M NaCl/0.04 M PIPES *p*H 6.4/1 mM EDTA/80% formamide[6]. The hybridization reaction was started by dissolving 100 μg total fat body RNA, heating the solution at 67 °C for 10 min and then incubating at 52 °C for 3 h to allow hybrids to form. The solution was then diluted into 10 vols of ice-cold S_1 nuclease reaction buffer and digested with 10 U of S_1 nuclease at 37 °C for 35 min, as described by the manufacturer (BRL). The digestion was stopped and the hybrids precipitated with 95% ethanol in the presence of 10 μg tRNA. The precipitate was electrophoresed in a denaturing agarose gel, transferred to nitrocellulose paper, hybridized to ^{32}P-labelled *104* DNA (specific activity 10^8 c.p.m. μg^{-1}) and autoradiographed, as previously described[3]. The resulting autoradiographs are shown beside the restriction map; lane *a* is a control containing an *Eco*RI/*Sal*I digest of total *104* DNA, lane *b* contains the S_1 nuclease-resistant RNA–DNA hybrid formed with fragment 2. The exposure for *a* was 3 days, for *b* 10 days.

0028–0836/82/200239—03$01.00

ing in size to the *LSP-2* mRNA was detected in fat body RNA but not in embryonic RNA, consistent with earlier results[2]; three other transcripts were detected in the embryonic RNA, of 2.6, 2.2 and 1.6 kb and designated *T1*, *T2* and *T3* respectively. The regions of *104* DNA homologous to each of the three transcripts were identified by using purified *Eco*RI fragments of *104* DNA as individual probes. Fragment 1, which contains the *LSP-2* coding region and 3.5 kb flanking the 5′ end of the coding region, hybridized with the *LSP-2* transcript in fat body RNA and with the *T1* transcript in embryonic RNA; fragment 2 hybridized with transcripts *T1*, *T2* and *T3*; and fragment 3 with only *T3*. The doublet in the lane containing embryo RNA in Fig. 3*b* is probably the result of residual ribosomal RNA in the poly(A)$^+$ RNA preparation. These bands appeared when the blot was hybridized to several probes unrelated to clone *104*. Members of several other laboratories doing similar analyses have found similar, nonspecific bands at the ribosomal RNA position (personal communications).

To investigate whether *T1*, *T2* and *T3* were encoded by separate sequences or shared homology, three additional DNA fragments homologous to *Eco*RI fragment 2 were hybridized to the embryonic RNA blot of Fig. 3 (data not shown, see Fig. 3 legend). We observed that *Eco*RI fragments 2a and 2b were homologous to both *T1* and *T2*, whereas *T3* was homologous

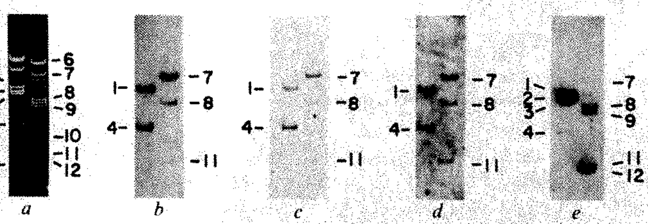

Fig. 2 Regions of *104* DNA that hybridize with RNA from oocytes, embryos and larval fat bodies. Samples containing 1.5 μg of *104* DNA were digested with either a combination of *Eco*RI and *Sal* I or *Bam*HI, separated in 1% agarose gel and transferred to nitrocellulose paper[3]. The paper was prehybridized with 0.75 M sodium chloride/0.075 M sodium citrate/50% formamide/0.2% SDS/0.5 mg ml^{-1} *Escherichia coli* rRNA at 41 °C for 2 h in sealed plastic containers, and the ^{32}P-labelled poly(A)$^+$ RNA probe was added and the reaction continued for 48 h; the RNA was labelled with [γ-^{32}P]ATP and T4 polynucleotide kinase[1], yielding specific activities of 0.5–1.5 × 10^7 c.p.m. μg^{-1}. The paper was washed by shaking for several hours at 41 °C in 0.75 M sodium chloride/0.075 M sodium citrate/50% formamide and then at room temperature in 0.75 M sodium chloride/0.075 M sodium citrate for 30 min. After a 1-min rinse in 0.3 M sodium chloride/0.03 M sodium citrate, the washed paper was wrapped in Saran plastic and autoradiographed for 3–7 days. *a*, Staining pattern with ethidium bromide; *b–e*, autoradiographic patterns btained with poly(A)$^+$ RNA probes from the following sources: *b*, stage 14 oocyte; *c*, gastrula; *d*, late (12 h) embryo; *e*, fat bodies from late third-instar larvae. In all the gels, the left lane contained the *Eco*RI/*Sal*I digest and the right lane contained the *Bam*HI digest of *104* DNA. The positions of the relevant bands are labelled as in Fig. 1.

to *Eco*RI 2c. As probe sequences separated by at least 4 kb are homologous to the 2.6-kb *T1* transcript, the DNA sequences encoding *T1* must be interrupted by at least one intervening sequence. The relationship between the *T1* and *T2* transcripts is uncertain, although the data are consistent with the coding of *T2* by a subset of the *T1* coding region. Additional tests for hybridization of the *LSP-2* and *T1* transcripts with restriction fragment *Eco*RI 1a from *104* DNA place the proximal terminus of the *T1* coding region 2.5–3.5 kb from the 5′ end of the *LSP-2* coding region (data not shown).

Based on the proximity of sequences encoding *LSP-2* and *T1*, we determined whether or not *T1* transcription was augmented during *LSP-2* expression in the fat body. Samples containing poly(A)$^+$ RNA from late embryos and fat bodies were electrophoresed in agarose gel, transferred to nitrocel-

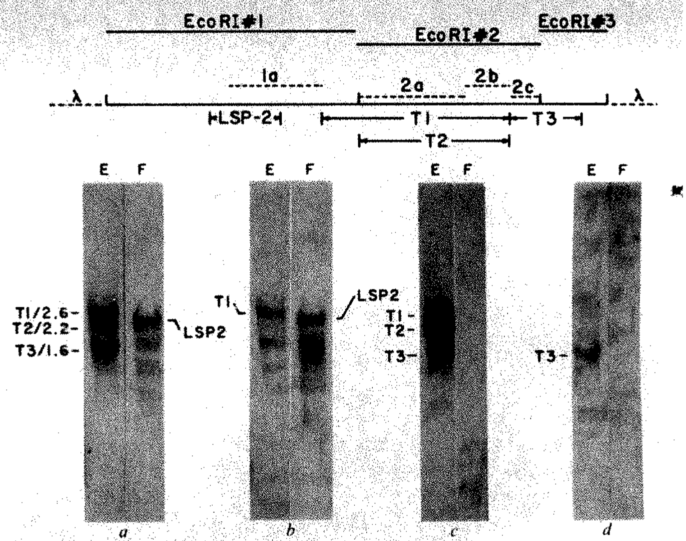

Fig. 3 Identification of transcripts from embryos and larval fat bodies that hybridize with *104* DNA. Samples containing either 23 μg poly(A)$^+$ RNA from 12 h embryos or 10 μg total RNA from late third-instar larval fat bodies were glyoxalated, electrophoresed in an agarose gel and transferred to nitrocellulose paper[3,14]. Hybridizations were done with *Eco*RI fragments of *104* DNA purified by the following procedure. An *Eco*RI digest of *104* DNA was electrophoresed in 1% agarose gel, using low-melting point agarose (BRL), and the DNA bands were detected by staining the gel with ethidium bromide; the bands containing the *Eco*RI fragments of *Drosophila* DNA were cut from the gel and heated at 65 °C for 20 min, and then 100 μl 10 mM Tris-HCl *p*H 7.6/1 mM EDTA containing 15 μg tRNA was added. The solution was brought to 0.2 M sodium acetate and shaken with an equal volume of phenol at 65 °C. The aqueous phase was shaken again with phenol at room temperature; the nucleic acid was precipitated from the aqueous phase in 95% ethanol. Each fragment was labelled by nick-translation, and the labelled probes were hybridized with the RNA transferred to nitrocellulose paper. The hybridizations were done successively using the same paper, with a regeneration step after each hybridization to remove the preceding probe[14]. Probes: *a*, total *104* DNA; *b*, *Eco*RI fragment 1; *c*, *Eco*RI fragment 2; *d*, *Eco*RI fragment 3. E lanes contain late embryo poly(A)$^+$ RNA, F lanes contain total fat body RNA. The map positions of additional probes used in this analysis (1a, 2a, 2b, 2c) are indicated by the dotted lines above the *Drosophila* DNA insert in clone *104*. The results from these hybridizations are explained in the text; the data are not presented. The map positions of the genes encoding *T1*, *T2* and *T3* are indicated by the lines below the *Drosophila* DNA insert.

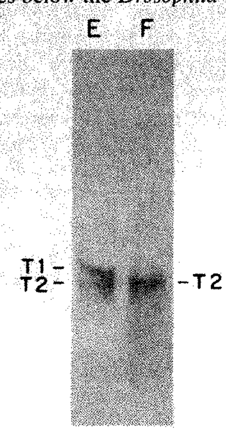

Fig. 4 Test for transcripts *T1* and *T2* in embryonic and fat body RNA. Samples containing 15 μg poly(A)$^+$ RNA from late (12 h) embryos or 12 μg of poly(A)$^+$ RNA from late third-instar larval fat bodies were denatured, electrophoresed in agarose gel and transferred to nitrocellulose paper[3,14]. The *Bam*HI fragment 8 (see Fig. 1) was purified as described for the *Eco*RI/*Sal*I fragment 2 of Fig. 1, ^{32}P-labelled by nick-translation, hybridized to the RNA on nitrocellulose paper, and the paper was then autoradiographed for 3 days. Lane E contains embryonic RNA, lane F contains fat body RNA.

lulose and hybridized to ^{32}P-labelled *Bam*HI fragment 8 (Fig. 4). As predicted, this probe hybridized to the *T1* and *T2* transcripts present in the embryo RNA preparation, whereas only the *T2* transcript was detectable in the fat body sample. When the nitrocellulose filter was regenerated and hybridized to a probe containing the *LSP-2* coding region, the fat body RNA preparation hybridized ~90 times more strongly than the embryo RNA at the position of the *LSP-2* transcript (data not shown). Thus, despite a dramatic increase in the level of *LSP-2* transcript in late third-instar larval fat body tissue, the *T1* transcript does not accumulate.

There is no proof that the sequences encoding the *T1*, *T2* and *T3* transcripts are those flanking the *LSP-2* coding region. *T1*, *T2* and *T3* could be transcribed at other genomic sites, yet possess significant homology with clone *104* sequences. This is unlikely, however, because (see refs 2, 3, 7): (1) when genomic DNA was digested with several restriction endonucleases, electrophoresed in agarose gel and transferred to a nitrocellulose filter, after hybridization to ^{32}P-labelled clone *104* DNA the only bands detected on the filter were those predicted from the restriction endonuclease map of clone *104*. (2) *In situ* hybridizations of tritium-labelled clone *104* DNA to salivary gland chromosomes have revealed only a single site of hybridization, the *LSP-2* locus. Thus, the *T1*, *T2* and *T3* transcripts are probably encoded by the region flanking the *LSP-2* gene. As *T1* transcripts are undetectable in third-instar larval fat body tissue, it seems that the factors which increase the expression of the *LSP-2* gene act locally, rather than regionally. This situation is very similar to the regulation of sequences encoding yeast histones[8], *D. melanogaster* cuticle proteins[9] and the enzyme dopa decarboxylase of *D. melanogaster*[10]. This is particularly interesting since the transcription of *LSP-2* seems to be augmented by the steroid hormone ecdysterone[3,5]. DNA transformation studies have shown that sequences required for hormonal response can be closely linked to the coding regions they regulate[11]. In the case of the *LSP-2* gene, the position of sequences encoding *T1* may delimit the regulatory regions.

Male and female mouse DNAs can be discriminated using retroviral probes

Sandra J. Phillips, Edward H. Birkenmeier, Robert Callahan* & Evan M. Eicher

The Jackson Laboratory, Bar Harbor, Maine 04609, USA
* Laboratory of Cellular and Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Only two markers have been identified for the mouse Y chromosome: a gene that determines the male transplantation antigen (H-Y)[1] and sequences homologous to a satellite DNA originally isolated from a heterogametic female snake[2]. To investigate the molecular organization of the murine Y chromosome and to understand its role in sex determination, more Y-specific sequences and genes must be identified. We have now compared restriction digests of DNAs from female and male mice using hybridization probes representing two different classes of murine retroviruses. Some viral DNA-containing fragments were present in male but not female DNAs. The male-specific fragments varied in copy number from 1 to as many as 100, and we estimate that in some *Mus* species, as much as 3% of the Y chromosome is composed of retrovirus-related sequences. To our knowledge this is the first report of (1) an association of retrovirus-related sequences with a mammalian Y-chromosome and (2) many copies of retrovirus-related sequences on the same chromosome.

DNAs were prepared from male and female mice representing six distantly related inbred strains of *Mus musculus* and three other *Mus* species[3]: *Mus poschiavinus*, *Mus spretus* and *Mus caroli*. *M. poschiavinus* and *M. spretus* were included because they interbreed with laboratory strains and *M. caroli* because its karyotype is virtually identical to that of *M. musculus*[4].

*Eco*RI digests of mouse DNAs were blotted onto nitrocellulose[5] and hybridized to the long terminal repeat (LTR) of a *M. musculus* amphotropic retrovirus[6]. The LTR sequence, which shares homology with the AKR ecotropic virus LTR[7], was isolated from unintegrated proviral DNA and subcloned in pBR322. This probe was chosen because it represents terminal viral DNA sequences and detects fusion fragments composed of viral and adjacent cellular sequences. Approximately 50 fragments in *M. musculus* DNA hybridize to the LTR (Fig. 1*a*, lanes 1–12), and they probably represent many of the endogenous type C retroviral genomes known to exist in *M. musculus*[8]. In the four inbred strains BALB/cWt, C57BL/10J, NZB/B1NJ and SM/J, a 5.5 kilobase (kb) *Eco*RI fragment was present in male but not female DNA (Fig. 1*a*, lanes 1–4, 7, 8, 11, 12). The relative intensity of this band suggested that it is present in one or a few copies. This dimorphic fragment was not observed in DNA from AKR/J and DBA/2J strains (Fig. 1*a*, lanes 5, 6, 9, 10).

Restriction fragments containing DNA sequences related to the LTR were weakly detected in the closely related species *M. spretus* (Fig. 1*a*, lanes 13, 14) and *M. poschiavinus* (Fig. 1*a*, lanes 15, 16). No male-specific bands were evident. DNA from the more distantly related species *M. caroli* did not hybridize with this probe, which is consistent with previous results[9,10].

A different hybridization pattern was observed when a sequence representing another class of endogenous xenotropic type C retrovirus was used to analyse these same DNAs (Fig. 1*b*). This class (designated type C-I) has been isolated from all species of *Mus* tested, except *M. musculus*, and can be distinguished from other laboratory strains of retroviruses both immunologically and on the basis of nucleic acid sequence homology[10–12]. A C-I virus (designated M720) was isolated from *M. cookii* tissue culture cells and used to infect FEC cells. A clone of unintegrated circular proviral DNA was prepared. In *M. musculus* (Fig. 1*b*, lanes 1–12) and *M. poschiavinus* (Fig. 1*b*, lanes 15, 16), this clone of the entire *M. cookii* type C-I proviral genome hybridized to at least four fragments (14.5, 11.8, 7.5 and 4.3 kb) in male DNAs that were not present in female DNAs. Because the sum of the sizes of the male-specific bands is larger than a viral genome (8.5 kb), we conclude that these four bands are derived from more than one type C-I endogenous virus genome. The relative intensity of hybridization of these fragments to M720 suggests that each is present in multiple copies. Usually multiple-copy fragments represent

0028-0836/82/200241—03$01.00

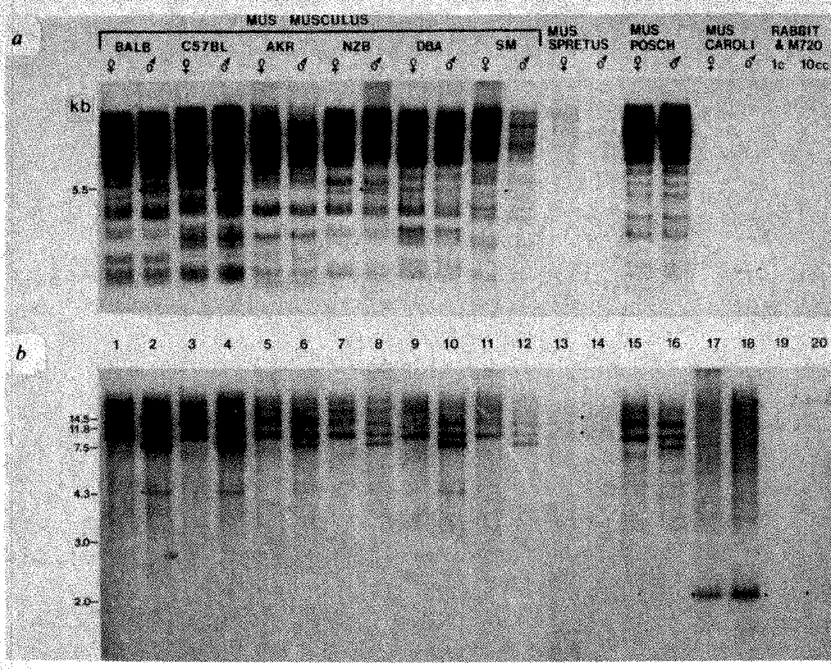

Fig. 1 Detection of sexually dimorphic retrovirus-related *Eco*RI restriction fragments in genomic mouse DNAs. Genomic DNAs were prepared from individual livers of inbred male and female siblings (lanes 1–12) or from closely related animals (lanes 13–18). DNAs (4 μg) were digested with *Eco*RI, separated by electrophoresis in 1% agarose and transferred to nitrocellulose[5]. Probes were prepared by nick-translation to a specific activity of $1\text{–}3\times10^8$ d.p.m. ^{32}P per μg DNA[25]. Filters were incubated at 70 °C in the presence of 6 × SSC for 16 h, and washed extensively at 52 °C in 0.1 × SSC, 0.05% SDS. Hybridizing fragments discussed in the text are denoted by ■ and the sizes of those fregments are given on the left of each panel. In *a*, mouse DNAs were probed with a pBR322 clone of the LTR of an amphotropic retrovirus from *M. musculus*[6]. Resolution was increased by exposing for 10 days to Kodak XAR film without intensifying screens. In *b*, the same DNAs were probed with a pBR322 clone of proviral DNA (M720) from a xenotropic retrovirus from *M. cookii*. Exposure was for 1 day at room temperature. Abbreviated strain and species names include BALB/cWt (BALB), C57BL/10J (C57BL), AKR/J (AKR), NZB/B1NJ (NZB), DBA/2J (DBA), SM/J (SM) and *M. poschiavinus* (MUS POSCH).

internal viral sequences, because flanking cellular restriction sites are presumed to be heterogeneous[13]. If all the *Eco*RI sites generating these multiple-copy fragments are internal viral restriction sites, then we are observing at least one unusually large (>14.5 kb) retrovirus genome. Alternatively, one or more conserved *Eco*RI sites flanking 'normal-sized' viral genomes could generate multiple-copy fragments larger than the viral genome itself.

The number of M720 cirus-related sequences in male DNA from *M. musculus* was estimated by mixing cloned M720 proviral DNA with rabbit DNA at levels representing 1 or 10 copies of provirus DNA per cellular genome (Fig. 1*b*, lanes 19, 20). One copy of M720 proviral DNA per genome is barely detectable when hybridized with itself (lane 19). Ten copies of the viral genome are detectable, but the intensity is approximately one-tenth of that observed with the M720 male-specific fragments shown in Fig. 1*b*, lanes 1–12. From these and other results (data not shown) we conclude that there are ~100 copies of M720 related sequences in males from *M. musculus* inbred strains and *M. poschiavinus*.

Male-specific M720-related fragments were detected in *M. spretus* DNA (Fig. 1*b*, lanes 13, 14); however they hybridize less intensely with the probe than those identified in *M. musculus* male DNA (Fig. 1*b*, lanes 1–12). Whether this reflects a lower copy number or less homology is unresolved. Restricted cellular DNA from *M. caroli* also hybridized with M720 proviral DNA. Although *M. caroli* DNA does not appear to contain male-specific sequences unique to the M720 proviral genome, it does contain a 2.0 kb internal *Eco*RI fragment characteristic of the provirus (Fig. 1*b*, lanes 19, 20). We conclude that the M720-related sequences in the *M. caroli* genome are structurally more closely related to M720 than to related sequences in the other *Mus* species tested. In addition, the overall conserved pattern of the M720-related bands in *M. musculus* and *M. poschiavinus* DNAs is in striking contrast to the strain specificity observed with the LTR probe. These results are consistent with the previously noted conservation of the type C-I endogenous retrovirus-related sequences in cellular DNA from all species of *Mus*[10,12].

The presence of many copies of M720-related sequences on the Y chromosome of some *Mus* species can be explained in several ways. One hypothesis is that one or more independent viral integration events occurred in or near a specific sequence present many times on that chromosome. However, there is no evidence for site-specific integration of retroviruses[14]. Second, multiple copies of a viral genome could have resulted from successive intrachromosomal recombination events. Such a model has been proposed to explain the presence of five copies of the avian leukosis retrovirus genome on a single chicken chromosome[15,16], and would explain the presence of 100 copies of M720-like virus sequences on the mouse Y chromosome. Third, we could be observing the result of amplification of a Y-chromosomal element containing virus-related sequences. The conserved pattern of M720-related dimorphic restriction fragments in *M. musculus* and *M. poschiavinus* suggests that either the integration or amplification event(s) responsible for multiple copies occurred recently in evolutionary terms, or these sequences have been conserved relative to other species. If conservation is responsible, these sequences may have a functional role. The role is not, however, sex determination, because mice that carry a *M. poschiavinus* Y chromosome (as well as the typical M720 male-specific fragments) can develop external female genitalia and ovaries[17]. It may be significant that males of several inbred strains have been shown to express a protein related to a type C virus envelope protein (gp70) in the epididymis and ductus deferens[18,19].

It remains to be demonstrated that the LTR and M720-related patterns of sexual dimorphism represent sequences from the Y chromosome. Although these sequences are present only when a Y chromosome is present, it is possible that the fragment dimorphism is a result of amplification of an autosomal or X-chromosomal sequence. Hybridization *in situ* will provide direct evidence.

We have shown that probes representing dispersed repetitive elements, such as retroviruses, are valuable tools for analysing large genomes. On Southern blots they can effectively reduce the complexity of the murine genome from 1×10^6 *Eco*RI fragments to ~50 fragments. Just as we have used retroviral probes to identify sequences from the Y chromosome, retroviral probes have been useful as molecular markers for identifying regions of the genome where deletions or insertions have occurred[20].

The Y chromosome is unique in the mammalian genome in that it is perpetually monosomic. With the exception of the region that pairs with the X chromosome during meiosis[21], opportunities for recombination with other chromosomes are precluded. Markers such as these virus-related sequences offer a means to study the evolution of this chromosome, which may differ from that of the rest of the genome. Because the Y chromosome represents 2% of the haploid male genome[22,23] (size = 1.5×10^9 base pairs)[24], the M720-related male-specific sequences would represent 3% of the chromosome [(100 copies × 8,500 base pairs/0.02 × 1.5 × 10^9) × 100]. The high concentration of virus-related DNA on the Y chromosome poses

many intriguing questions. Are these viral sequences present as a result of 'poor housekeeping' by the monosomic Y chromosome? Is the Y a 'target' chromosome for retrovirus integration or amplification? Are retroviral sequences involved in the function of this unusual chromosome?

Messenger RNA of infectious pancreatic necrosis virus is polycistronic

P. P. C. Mertens* & P. Dobos

Department of Microbiology, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Infectious pancreatic necrosis virus (IPNV) is an economically important fish pathogen. The virus particles contain two large segments of double-stranded (ds)RNA[1–4], which encode four different intracellular primary gene products[5,6]. The smaller genome segment ('B') encodes the largest of these four proteins and the larger genome segment ('A') encodes the other three by a mechanism which does not seem to involve post-translational cleavage of a large precursor polypeptide *in vivo*[7]. Previous results[8,9] have indicated that only two species of mRNA are produced, one from each genome segment[8], and that one of these viral mRNAs (that produced from segment B; ref. 7) is monocistronic. The other mRNA, which is transcribed from segment A (ref. 7), encodes three proteins, which may be produced by a mechanism involving multiple initiation and termination sites for translation, rather than post-translational cleavage[5–7]. To distinguish between these two possible mechanisms, we have studied the translation *in vitro* of the denatured IPNV genomic dsRNA segments. We report here that the mRNA transcribed from genome segment A is polycistronic.

IPNV particles are icosahedral with a diameter of 60 nm. The dsRNA genome is bi-segmented (segments A and B of molecular weight (M_r) 2.5×10^6 and 2.3×10^6, respectively[1–4]; see Fig. 1*A*).

* Present address: The Animal Virus Research Institute, Pirbright, Woking, Surrey GU24 0NF, UK.

Three size classes of IPNV-specific polypeptides are synthesized in the same relative proportions throughout the infectious cycle, starting 3 h after infection[5]. These primary gene products are designated ICPs (infected cell proteins) and have molecular weights of 105,000 (105K), 62K, 31K and 29K (Fig. 1*C*[5,7]). Of these four proteins, three subsequently undergo post-translational cleavage: (1) the 62K protein is cleaved via a 60K intermediate, to generate the major capsid protein VP54 (Fig. 1*D*); (2) part of the 31K internal virion protein is cleaved during maturation to generate a 29K polypeptide, and both

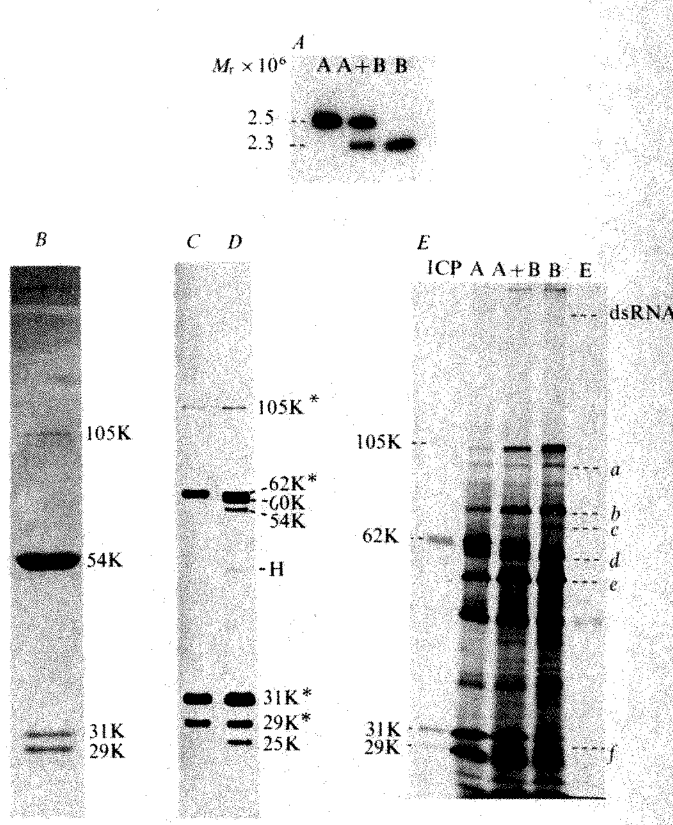

Fig. 1 Polyacrylamide gel electrophoresis of IPNV dsRNA, purified virus proteins, virus-specific proteins synthesized in infected cells, and protein products derived by translation *in vitro* of denatured IPNV dsRNA. Purified virus was digested with proteinase K and the genome segments were separated by electrophoresis in 10% polyacrylamide slab gels[10,17]. The bands were detected by autoradiography (a small amount of ^{32}P-labelled dsRNA was added to the original sample), sliced out and electroeluted from the gel slices using methods published elsewhere[10]. *A*, a small amount of each fractionated genome segment was subjected to analytical gel electrophoresis followed by autoradiography to check its purity and homogeneity (note that due to trailing, segment A was contaminated with segment B). The molecular weights were computed from their electrophoretic mobilities relative to reovirus (Dearing 3) dsRNA run in parallel wells. *B*, proteins of purified IPNV analysed in 10% polyacrylamide slab gel followed by staining with Coomassie blue using procedures published elsewhere[17,18]. *C*, *D*, autoradiograms of labelled virus-specific polypeptides analysed in 11% polyacrylamide slab gels. Infected CHSE cell monolayers were UV-irradiated 3 h after infection to reduce the cellular background and the cultures were labelled with ^{35}S-methionine 6 h after infection at 20 °C for 1 h (*C*) or 4 h (*D*) as described previously[5,6]. The molecular weights of virus-specific proteins were computed from their electrophoretic mobilities relative to unlabelled standards run in parallel. H indicates residual host protein; the four primary gene products are marked with asterisks. *E*, cell-free protein synthesis was carried out in nuclease-treated rabbit reticulocyte lysates (NEN), primed with denatured dsRNA segments, in the presence of ^{35}S-methionine. 2 μg of dsRNA were precipitated in ethanol, washed with ether, dried and denatured in 2 μl of dimethyl sulphoxide at 55 °C for 15 min, then 100 μl of the complete reaction mixture was added and incubation was continued at 37 °C for 1 h. The products of translation were analysed using 11% polyacrylamide slab gels followed by autoradiography. ICP, labelled infected-cell proteins, synthesized in UV-irradiated CHSE cell cultures from 6 to 8 h after infection. A, *in vitro* translation products from dsRNA segment A; A+B, *in vitro* translation products from segments A and B; B, *in vitro* translation products from segment B; E, endogenous products of translation (no RNA added). The approximate molecular weights of the major products are indicated. *a–f*, The major products from incomplete translation of segment B. (Note the location of ^{32}P-labelled dsRNA near the top of the gel.)

0028–0836/82/200243—04$01.00

precursor (VP31) and product (VP29) are found in the virion[6] (Fig. 1*C*); (3) the only non-structural protein, 29K, is slowly degraded into small polypeptides via a 25K intermediate[6] (Fig. 1*D*). The 105K protein is synthesized in small quantities and is incorporated into virions (VP105) without apparent changes in molecular weight (Fig. 1*B–D*). Peptide mapping has shown that the four primary gene products have different amino acid sequences[6].

Using hybrid viruses of two parental serotypes, it has been shown that genome segment B encodes ICP 105K and A encodes the other three primary gene products[7]. The question arises as to how three unrelated proteins are produced from a single large genome segment. We considered the following possible mechanisms: (1) post-translational cleavage of a large, precursor polypeptide; (2) transcription of subgenomic mRNAs from genome segment A; (3) transcription of genome-length mRNA containing multiple initiation and termination sites for protein synthesis.

Several studies have provided evidence against mechanisms 1 and 2[5,6,8,9]. For example, we have been unable to detect polyprotein precursor(s) in IPNV-infected cells by pulse-chase experiments or by using amino acid analogues, protease inhibitors, $ZnCl_2$ or supra-optimal temperatures[5] (experiments with pactamycin also gave negative results; P.D., unpublished results). In addition, the relative molar ratios of the primary gene products indicated that the frequency of their synthesis was inversely related to their molecular weights, suggesting that they are the products of different cistrons[5]. Furthermore, during intracellular replication of IPNV, only two species of genome-length 24S viral mRNAs were synthesized, which hybridized to the two genome segments[8]. The virion-associated polymerase was shown to synthesize *in vitro* two species of single-stranded (ss)RNA which were the same and which co-migrated during electrophoresis with the species of viral message synthesized *in vivo*[9]. Thus no discrete subgenomic mRNAs were detected either *in vivo*[8] or *in vitro*[9].

To investigate the third possible mechanism (that is, multiple initiation and termination sites on a single mRNA species), we used an *in vitro* protein synthesizing system. Denatured virion dsRNA was used to provide translation templates[10] in rabbit

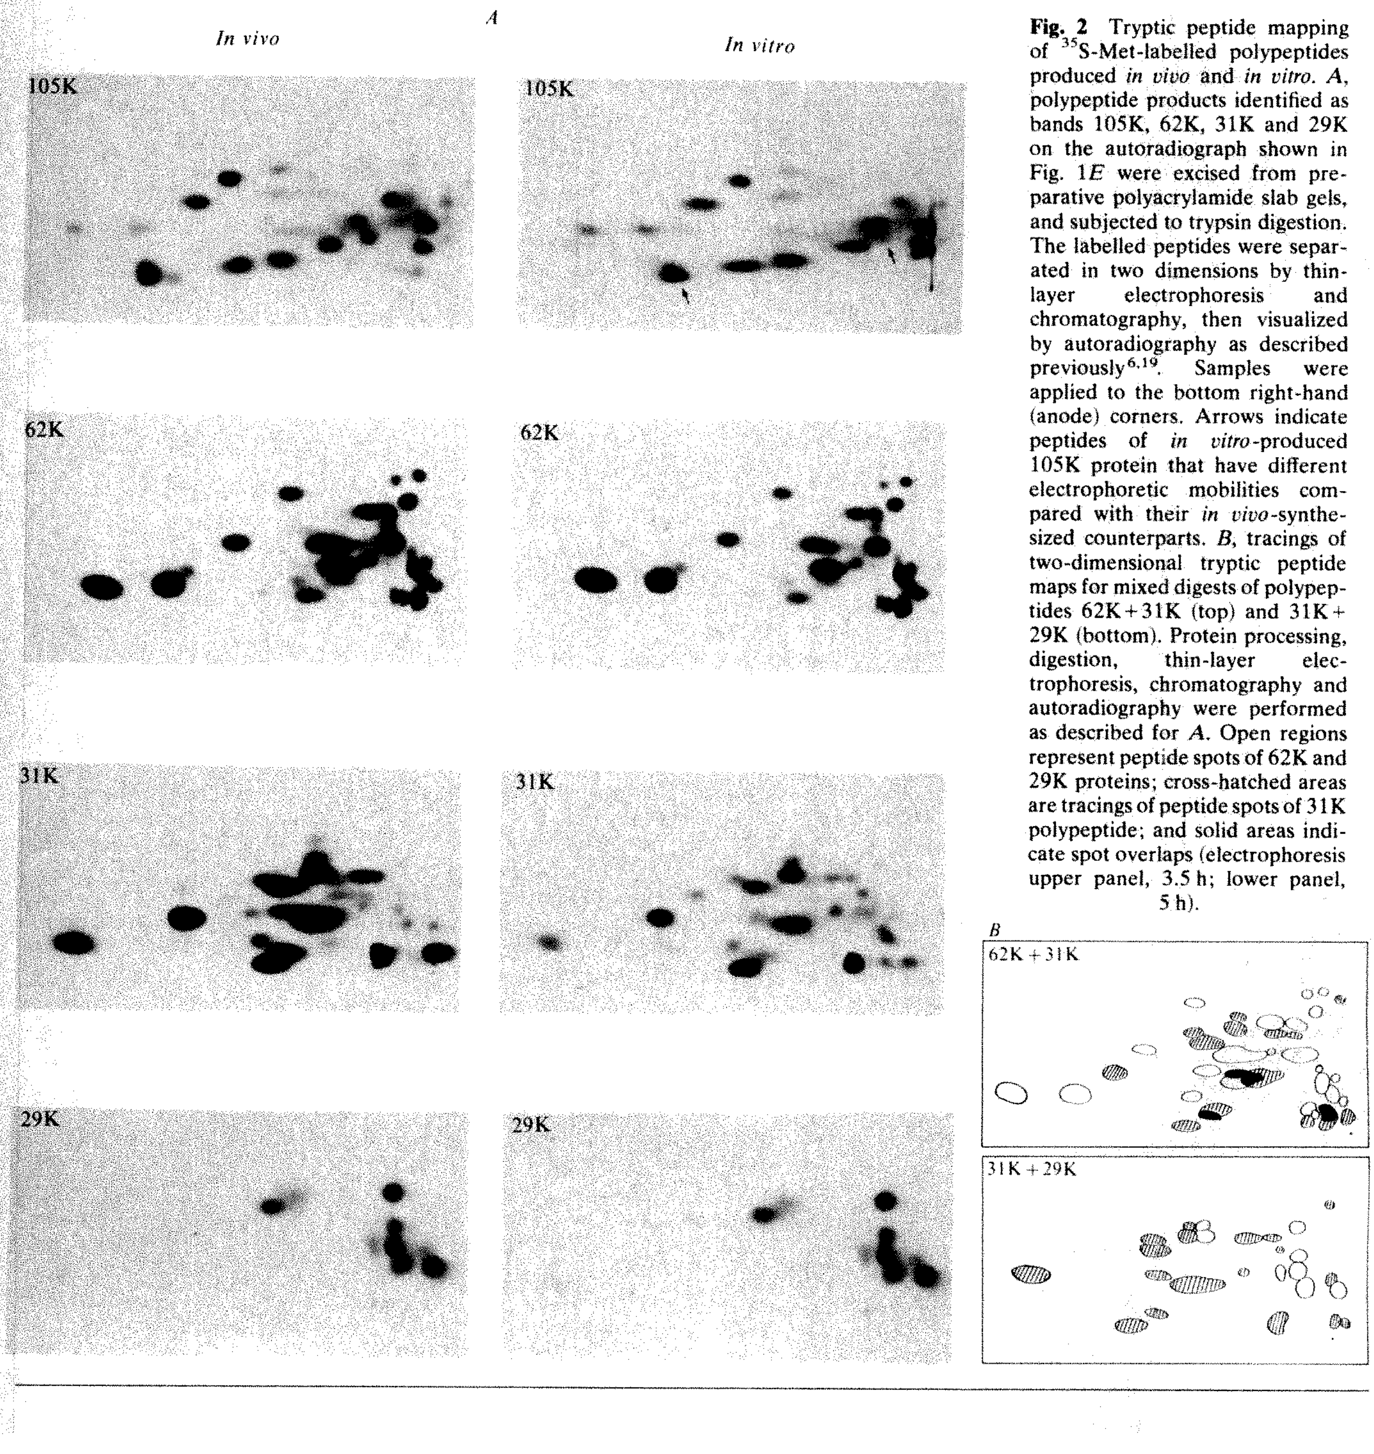

Fig. 2 Tryptic peptide mapping of ^{35}S-Met-labelled polypeptides produced *in vivo* and *in vitro*. *A*, polypeptide products identified as bands 105K, 62K, 31K and 29K on the autoradiograph shown in Fig. 1*E* were excised from preparative polyacrylamide slab gels, and subjected to trypsin digestion. The labelled peptides were separated in two dimensions by thin-layer electrophoresis and chromatography, then visualized by autoradiography as described previously[6,19]. Samples were applied to the bottom right-hand (anode) corners. Arrows indicate peptides of *in vitro*-produced 105K protein that have different electrophoretic mobilities compared with their *in vivo*-synthesized counterparts. *B*, tracings of two-dimensional tryptic peptide maps for mixed digests of polypeptides 62K+31K (top) and 31K+29K (bottom). Protein processing, digestion, thin-layer electrophoresis, chromatography and autoradiography were performed as described for *A*. Open regions represent peptide spots of 62K and 29K proteins; cross-hatched areas are tracings of peptide spots of 31K polypeptide; and solid areas indicate spot overlaps (electrophoresis upper panel, 3.5 h; lower panel, 5 h).

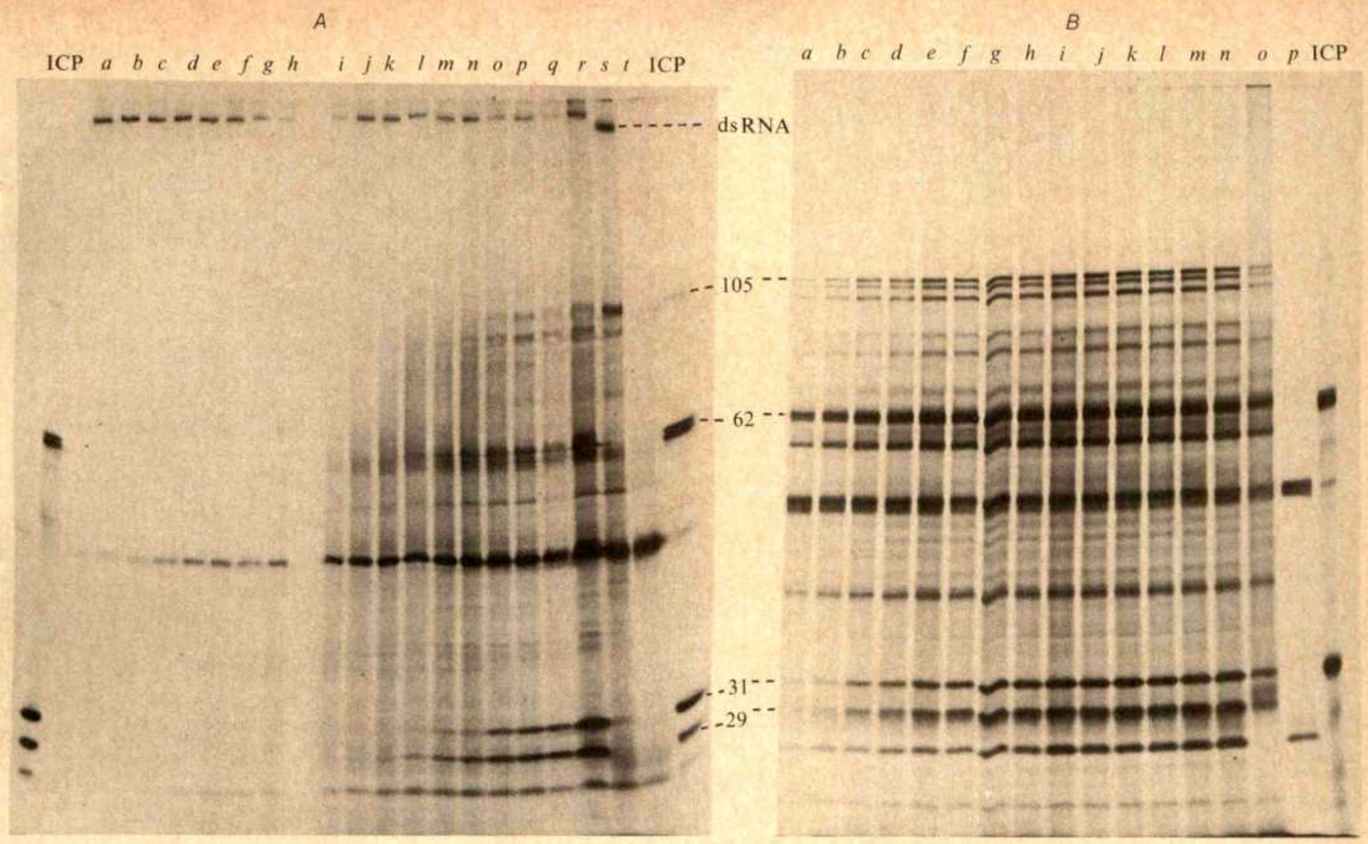

Fig. 3 Analysis of proteins synthesized *in vitro* by translation of denatured IPNV dsRNA in the presence of ^{35}S-methionine. *A*, time course of protein synthesis; cell-free protein synthesis was initiated as described for Fig. 1*E*. At intervals, 2-μl samples were removed from the reaction mixture and denatured by boiling in SDS-containing electrophoresis sample buffer. The labelled products were analysed in 11% polyacrylamide slab gels as described for Fig. 1*E*. *In vitro* translation primed with dsRNA segment A was stopped after the following incubation periods (min): *a*, 1; *b*, 2; *c*, 3; *d*, 4; *e*, 5; *f*, 6; *g*, 7; *h*, 8; *i*, 10; *j*, 12; *k*, 14; *l*, 16; *m*, 18; *n*, 20; *o*, 25; *p*, 30; *q*, 45; and *r*, 60. *s*, *In vitro* translation products from genome segment B, 60 min. *t*, Endogenous product (no RNA added), 60 min. ICP, labelled infected cell proteins as in Fig. 1*E*. (Note the position of ^{32}P-labelled dsRNA segments near the top of the gel.) The approximate molecular weights of the primary gene products are indicated. *B*, pulse-chase experiment; cell-free protein synthesis was initiated as described for Fig. 1*E* using both segments of dsRNA. At various intervals, 5 μl were removed from the reaction mixture, a 1,000-fold excess of unlabelled methionine was added and incubation continued for a total of 60 min. The labelled products were analysed by electrophoresis as described for Fig. 1*E*. Excess unlabelled methionine was added to samples of the reaction mixture at the following times (min): *a*, 2; *b*, 4; *c*, 6; *d*, 8; *e*, 10; *f*, 12; *g*, 14; *h*, 16; *i*, 18; *j*, 20; *k*, 30; *l*, 40; *m*, 50; *n*, 60; and *o*, 60, followed by incubation at 37 °C for 16 h. *p*, No RNA was added (endogenous, 60 min). ICP, labelled infected cell proteins as in Fig. 1*E*.

reticulocyte lysate. The two dsRNA genome segments were separated by preparative polyacrylamide gel electrophoresis (Fig. 1*A*) and recovered by electroelution[10]. Due to trailing, segment A was contaminated with B even after two cycles of electrophoresis, whereas segment B was homogeneous. The results in Fig. 1*E* show that proteins having similar electrophoretic mobilities to the four primary gene products produced in infected cells were also synthesized *in vitro*. Translation of genome segment B produced polypeptide 105K and several smaller polypeptides (labelled *a–f*) which were the result of premature termination of translation, as determined by peptide map comparisons (data not shown). The 105K protein produced *in vitro* exhibited slightly faster electrophoretic mobility than the same protein made in infected cells. This may be due to the addition *in vivo* of prosthetic groups, for example by glycosylation, methylation or phosphorylation, which may have reduced the electrophoretic mobility of ICP 105K. This electrophoretic difference was also reflected in minor variations in the otherwise identical peptide patterns of the *in vivo* and *in vitro* synthesized polypeptide 105K (Fig. 2*A*, arrows). This polypeptide is a minor product *in vivo*[5,6] (Fig. 1*C*), but was produced in large quantities *in vitro* suggesting that not all of the intracellular translational control mechanisms are operative.

Translation of genome segment A resulted in three additional polypeptides having identical electrophoretic mobilities to ICP 62K, 31K and 29K (Fig. 1*E*). Due to contamination of the preparation with the very efficient template B RNA, polypeptide 105K and its incomplete translation products were also found, although in reduced amounts. The tryptic peptide maps of the *in vitro* synthesized proteins 62K, 31K and 29K are identical to those of the equivalent proteins produced in IPNV-infected cells (Fig. 2*A*).

Although rapid protein processing could not be detected *in vivo*[5], the high degree of radiolabelling, and the synchronous initiation of translation achieved *in vitro* prompted us to re-examine the possibility of post-translational cleavage. Analysis of the time course of protein synthesis where *in vitro* translation primed with dsRNA segment A was terminated at intervals between 0 and 60 min of incubation, showed that the order of appearance of polypeptides was 29K, 31K, 62K (Fig. 3*A*). The time for completion of polypeptide chains was proportional to their length, that is, smaller proteins were completed sooner (10 min) than longer ones (16 min). A large molecular weight precursor polypeptide could not be detected. Such a pattern is compatible with three independent initiation sites; it could also arise, however, if the order of polypeptides in a putative precursor were NH_2-29K-31K-62K-COOH and if rapid proteolytic cleavage occurred as soon as the ribosome had passed the 3′ end of a given cistron.

To distinguish between these two alternative mechanisms, we performed the following *in vitro* pulse-chase experiment. Translation was initiated in the presence of ^{35}S-methionine, then at 2-min intervals a 1,000-fold excess of unlabelled methionine was added and incubation continued for 1 h to complete chain elongation. The data in Fig. 3*B* show that all three proteins became labelled even during the shortest pulse

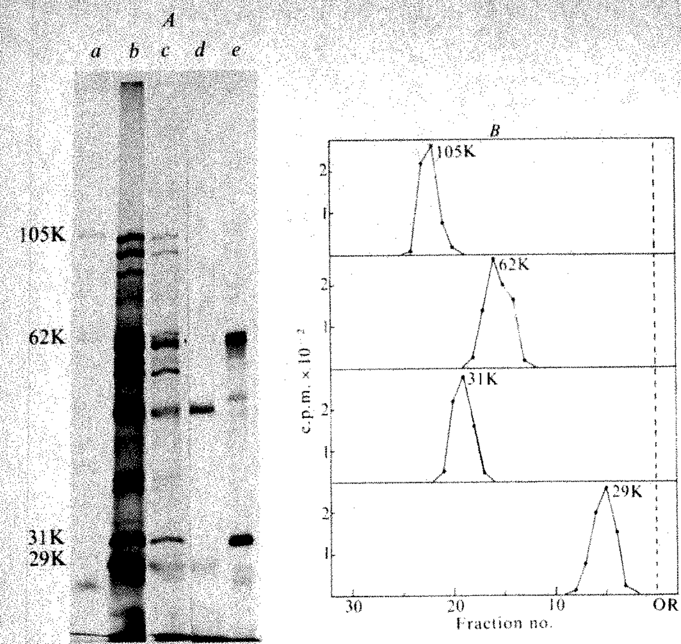

Fig. 4 Analysis of proteins synthesized *in vitro* by translation of denatured IPNV dsRNA in the presence of ^{35}S-fMet-tRNA$_f^{Met}$. *A*, cell-free protein synthesis was carried out using both segments of denatured dsRNA in the presence of ^{35}S-f-Met-tRNA$_f^{Met}$ (as described for Fig. 1*E*). The labelled products were analysed in 11% polyacrylamide slab gels and visualized by fluorography. *a*, ^{35}S-Met-labelled *in vitro* translation product; *b*, ^{35}S-f-Met-labelled *in vitro* translation product; *c*, same as *b* but exposed for a shorter period; *d*, no added RNA (endogenous product); *e*, ICP as in Fig. 1*E*. The molecular weights of the primary gene products are indicated along side. *B*, Thin-layer electrophoresis of the ^{35}S-f-Met-labelled tryptic peptides of polypeptides 105K, 62K, 31K and 29K. Processing and tryptic digestion of fMet-labelled polypeptides were performed as described in Fig. 2 legend. The digests were applied near the anodic end of a thin-layer silica gel plate and analysed in parallel by electrophoresis in pyridine/acetic acid/water (1:10:100 v/v/v) *p*H 3.5 at 450 V for 6.5 h. The dried gel was sliced into 5-mm fractions and each fraction was placed in a toluene-based scintillation cocktail and counted in a liquid scintillation counter. The radioactivity plotted represents net counts greater than twice the background. The broken line marks the origin (OR), where samples were applied. Electrophoresis was from right to left, with the anode on the right.

(2 min). These results are consistent with simultaneous initiation of translation at three independent sites (one for each protein). If initiation had occurred at a single site, followed by cleavage of the nascent chain, then the proteins should have been labelled sequentially from the N-terminus of the putative precursor molecule, with increasing pulse time.

It may be argued that the data are also compatible with the three proteins having common N-termini (overlapping genes), in which case the gene encoding 29K would be situated within the gene for polypeptide 31K, which in turn would be located within the gene for 62K protein. If this were the case, the peptide maps of 29K and 31K proteins would be virtually identical and would show a 50% overlap with that of 62K protein; however, this is not the case as shown in Fig. 2*B* (see also Fig. 2*A*).

When the four proteins were synthesized *in vitro* in the presence of ^{35}S-fMet-tRNA$_f^{Met}$, the N termini of all four polypeptides became labelled with ^{35}S-fMet, indicating independent initiation of translation (Fig. 4*A*). Furthermore, the labelled (N-terminal) tryptic peptides of these proteins exhibited different electrophoretic mobilities when analysed by thin-layer gel electrophoresis (Fig. 4*B*). These results do not, however, exclude the possibility of the three genes initiating and overlapping in the different reading frames on the mRNA.

That intact renatured ^{32}P-labelled dsRNA segments were detected after translation *in vitro* (Figs 1*E*, 3*A*), indicates that there was neither detectable breakdown nor processing of the input denatured dsRNA into smaller monocistronic RNA species. We therefore conclude that the plus strand of genome segment A (that is, the mRNA transcribed from this genome segment) is polycistronic.

Alternative explanations of these results are possible, although in our view highly unlikely. For example it may be argued that (1) IPNV contains more than two qualitatively different RNA segments; however we have shown recently by genetic experiments that the virus contains only two RNA species[7]. (2) One or two splices in the mRNA could result in a change of reading frame without appreciably altering the molecular weight of the RNA, but there is no precedent for this in the case of dsRNA-containing viruses. Although influenza virus Ns_2 mRNA is synthesized from NS_1 mRNA by processing[11], the sizes of the two NS mRNAs are substantially different. It also seems unlikely that the IPNV genomic plus strand would be spliced correctly in reticulocyte lysates *in vitro*. (3) It may also be argued that the *in vivo* mRNA of IPNV is not completely identical to the plus strand of the virus genome and that the two RNAs may behave differently during translation. We believe that only complete sequence analysis of both RNAs can conclusively answer this question, however, partial sequence studies of reovirus indicate that, at least in this case, the viral mRNA and genomic plus strands are identical[12].

Eukaryotic mRNAs usually cannot display more than one initiation site for protein synthesis at a time, even if a second site is present on the mRNA and can be rendered functional by a change in configuration, as in the case of togaviruses[13]. The mRNA of Kunjin virus (a member of the flaviviruses) may contain multiple initiation sites for translation; however, this has not been demonstrated by *in vitro* translation using ^{35}S-f Met labelling, nor has it been confirmed by other investigators[14]. Recently, indirect evidence has indicated that the late 16S mRNA of simian virus 40 is polycistronic, encoding the agnoprotein and VPl (ref. 15).

Although the results given here indicate that translation of the three proteins encoded by genome segment A of IPNV is initiated independently, we have no evidence concerning the relative position of the different cistrons on the mRNA. It is possible that the three coding regions are located in different reading frames and therefore overlap to some extent. Work is in progress to determine the order of cistrons on the A segment of the IPNV genome. We have also begun *in vitro* translation experiments to elucidate the mechanism of gene expression of two other bi-segmented dsRNA-containing viruses, that is, *Drosophila* X virus and infectious bursal virus of chickens[16].

This work was supported by the Natural Sciences and Engineering Research Council of Canada. We thank Drs F. Brown, C. Payne, D. Rowlands, D. Sangar and R. Macdonald and Mr B. Underwood for helpful criticism during the preparation of this manuscript.

BOOK REVIEWS

The games mathematicians play

C.W. Kilmister

Winning Ways, for Your Mathematical Plays. By Elwyn R. Berlekamp, John H. Conway and Richard K. Guy. Two vols, pp.850. Vol. 1 *Games in General*, hbk ISBN 0-12-091150-7, pbk ISBN 0-12-091101-9; Vol. 2 *Games in Particular*, hbk ISBN 0-12-091152-3, pbk ISBN 0-12-091102-7. (Academic: 1982.) Each volume hbk £31.40, $64.50; pbk £10.80, $22.50.

THE business of games is too serious to be left to the players, and this is the main message of *Winning Ways*. It is in the long tradition of Rouse Ball, Dudeney and Lucas, but a great deal further along the line. Some years ago one of the authors, John Conway, published *On Numbers and Games* (Academic, 1976). The first half of that book contained a highly idiosyncratic foundation of the number-system, generating the integers, rationals and reals by a single process which yields them in other than the usual order. There was also an extension of the system to other than "usual" numbers. The second half applied this almost as an afterthought to certain games; but Conway claimed that this second half was really the main part of the book. *Winning Ways* generously redresses the balance. It is hard to characterize the content, except to say that it is mathematical games, understood as broadly as possible, and with a good deal of mathematical lessons deduced from them.

The first part of Vol.1 discusses the types of game described in Conway's earlier book. In these games two players move alternately (often from a particular starting position) according to rules allowing options, until a player loses by being unable to move. There is complete information — both players know what is happening. So this is precisely *not* the "Theory of Games", and no intervention of chance is allowed. Nim is the prototype of such games. (Elsewhere in the book some of these conditions are relaxed, but never the restriction to complete information and no chance.)

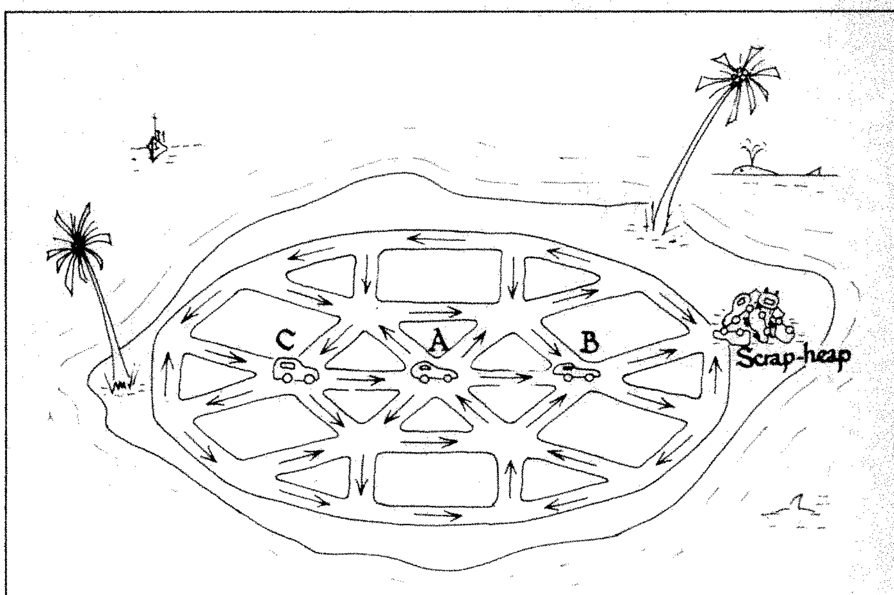
There are two foci of interest: the technique of attaching numbers to positions in games to assess their values, and the analysis of the structure of new games formed from the sums of known and analysed ones. The first of these is so simple as to excite (initial) disbelief. If in any position P the two players have options leading to positions of values, a,b,c . . ., or d,e,f . . . respectively, the value of P is written $\{a,b,c\ \ldots \mid d,e,f\ \ldots\}$. This value may or may not be a number. If a,b,c . . ., d,e,f . . . are all numbers, the value of P is the simplest number (to find out exactly what simplest means you have to buy the book), if it exists, strictly greater than a,b,c . . . and strictly less than d,e,f . . . . The beauty of this system is that it needs no start; for $\{\ \mid\ \}$, in which neither player has a move, is a zero position i.e. $\{\ \mid\ \}=0$. Then $\{0\mid\ \}=1$, $\{1\mid\ \}=2$, . . . , $\{\ \mid 0\}=-1$, . . . $\{0\mid 1\}=\frac{1}{2}$. When the value of P is a number, it has an immediate interpretation as the number of moves advantage. (Then ½ would correspond to a one move advantage in two copies of the game played together — and this leads on to the idea of the sum of two games, in which they are played side by side, and each player, when he moves, may choose to move in either game.) But even if the value is not a number, and so belongs to a natural extension of the rational numbers including infinitesimals, the ordering can be extended to say something useful.

The second part of the book, which concludes Vol. 1, goes on to games where some conditions are relaxed: you can move in several components of a compound game, or must move in all, or there are infinitely many positions, or the game may not stop. The main part of Vol. 2 applies these ideas to games of various kinds with coins, pencil-and-paper or on a board.

The approach is typified by noughts-and-crosses, of which a concise yet complete analysis is given. As the authors say:

> We have no doubt that most of our readers were bright enough as children to discover that [a tied game] always happens when the game is properly played, and only the authors of books like *Winning Ways* retain sufficient interest to study the game in any detail.

But they go on, with approval, to quote Martin Gardner's implied castigation of "many players [who] have the mistaken impression that because they are unbeatable they have nothing more to learn". These two views summarize the attitudes and lessons of the book, applied to many



An example of the games — and humour — in *Winning Ways*, taken from Vol.1. Above is a view of Corrall Island, which was a Charming Antipodean Beauty Spot before the Corrall Automotive Betterment Scheme, financed by the island's three wealthy landowners, built those expensive new super-highways. The island's two political parties (Left and Right) are now running for election and the gallop polls predict a walk-over for whichever party puts the last car on the scrap-heap. The parties have already enforced the one-way system indicated and each will alternately bribe a chauffeur to drive his car along one highway (in the proper direction) to the next intersection. You will see that there is no legal move away from the scrap-heap. How should we advise the ruling party, which must make the first move?

more complex games.

Finally, in Vol. 2, are two chapters on one-person games, and a final one on a no-person game. This is Conway's famous "Game of Life" about which a lot of recent news is here available: for example, that every sufficiently well-posed mathematical question can be converted to a question about the ultimate destinies of some Life configurations, so that Life is as insoluble as mathematics. Again, to quote: "Many computers have been programmed to play the game of Life. We shall now return the compliment by showing how to define Life patterns that can imitate computers". One of the one-person game chapters is solitaire and its extensions, the second on puzzles (the Tower of Hanoi, eight concise pages on Rubik's cube and so on).

The books are elegantly printed and written in a light-hearted vein, with a high density of puns per page, some outrageous but all appropriate. There is a wealth of illustrations — many of them are in colour — for which particular praise is deserved. A good index begins with an essential glossary of symbols.

If you make a practice of playing mathematical games this book is a must; you dare not play again without it. But even if you are not among those who indulge you ought to read it, as evidence of the insights into mathematics and physics you're missing. □

C. W. Kilmister, a Professor in the Department of Mathematics at King's College, University of London, is totally incompetent at any of the games mentioned. He has, however, used the material in Conway's earlier book to try to provide a combinatorial reformulation of quantum mechanics.

Uncovering discovery

I. Bernard Cohen

The Social Basis of Scientific Discoveries. By Augustine Brannigan. Pp.212. Hbk ISBN 0-521-23695-9; pbk ISBN 0-521-28163-6. (Cambridge University Press: 1982.) Hbk £12.50, $24.95; pbk £4.95, $9.50.

MOST of this new book by Augustine Brannigan is devoted to a review of theories about the nature of discoveries in science. The author begins with a description of various psychological theories of scientific discovery, limiting himself to the work of philosophers of science and not really investigating the accounts of psychologists. He then switches to the "emergence of a social model of discovery", which leads him into the fundamental question of heredity versus environment, nature versus nurture.

For convenience, Brannigan begins with Francis Galton's *Hereditary Genius*, intended to show the way in which extraordinary talents ran in families. In antithesis to this, he presents the work of the anthropologist A. L. Kroeber, who stressed the importance of social environment, noting how great periods of history "emerged as a function of cultural development". In particular, Kroeber emphasized the significance of multiple discoveries in science as proof of the importance of the general intellectual or cultural milieu as opposed to that of individual acts of genius. Recently the argument about multiple discovery has been advanced and developed by Robert K. Merton and his students and co-workers. Brannigan further develops Merton's ideas in a most interesting and incisive manner and then contributes a thought-provoking analysis of the work of Mendel in relation to its alleged multiple rediscovery.

This leads Brannigan into an account of the nature of discovery itself and of what he calls "folk reasoning" concerning the theory of scientific discovery. There is a concluding discussion of the sociological features of discovery, where the author develops his own views of the subject and includes a model in which "the normative considerations described by Merton" are enlarged by consideration of the "cognitive grounds" for disputes associated with multiple discoveries. The author can only be applauded for this attempt to add a new dimension to the current debate, but it is greatly to be regretted that this important idea is not developed by fully worked-out examples. And it is the same for the author's programme for analysing "the rhetorical and organizational status of methods in science". It is very frustrating that in the final page or so he no more than hints at research concerning "aspects of the scientific community, its productivity, its stratification system, and factors which influence these things". He introduces a number of suggestions, but they are shot forth with rapid fire, not illustrated or developed.

Indeed, one of the great criticisms to be levelled against this book — and against so many works of this type — is that there are passing references to many individuals and episodes in the development of science, but nothing more. Only in the case of Mendel does Brannigan attempt to do any serious history. He does, to be sure, introduce some aspects of the discovery of oxygen, but even here there is no attempt to go deeply into either the primary sources or the major scholarly investigations which could have further illuminated this topic, both for himself and the reader. As a result, the book will appeal more to those interested in theoretical questions of the sociology or philosophy of science, than to scientists or those whose primary concern is science itself. □

I. Bernard Cohen is Victor S. Thomas Professor of the History of Science at Harvard University.

Too reproductive

Colin Stern

Reproductive Immunology. Edited by Norbert Gleicher. Pp.492. ISBN 0-8451-0070-X. (Alan R. Liss/Heyden: 1981.) $86, £68.

THIS curious volume was cobbled together from some of the papers given at the first S.B. Gusberg Seminar on Reproductive Immunology, in June 1980 in New York, and from contributions solicited after the event which give it a strange chiaroscuro feel. The editor seems to have aimed at obstetricians and perinatologists, as well as immunologists and developmental biologists. There are several very good contributions but also some appalling ones. The book begins with three introductory chapters: two, on immunogenetics and immunoassay are good; the third, "Introduction to Immunology", is dreadful. It opens with a reasonable historical introduction, but the rest is full of errors of fact and misconceptions too numerous to detail. One is left asking whether this was necessary and why the author, an obstetrician whose knowledge of immunology is patently sketchy, was asked to write it.

There follow an excellent discussion of V-gene activation, solid contributions on immunoglobulin synthesis and lymphoid cell ontogeny, and a poor chapter on the development of the fetal immune system: how could the authors fail to discuss the acquisition of self-tolerance? The next part, "Pregnancy Immunology", begins with a brilliant overview of the immunobiology of the materno-fetal relationship by Rupert Billingham: clear and well-written, it makes much of the rest of the book seem redundant. There are other informative chapters here, however, on syncytiotrophoblast, uterine lymph node reactivity, maternal lymphocyte reactivity and breast milk. The next section starts well — Bill Pollack's chapter on Rhesus haemolytic disease — which makes further comment (from Cherry) unnecessary.

As is typical of the uneveness of the book as a whole, the following section contains two good contributions, on SLE in pregnancy and trophoblastic disease, as well as two frightful ones, on common denominators of pregnancy and malignancy and on the immune system in gynaecological malignancy. The last 95 pages, however, on fertility immunology, would have merited publishing on their own. All nine chapters are worth reading, particularly Bigazzi's excellent review of the immunological effects of vasectomy.

There are virtually no new data in this book. Out of 32 chapters, twelve are fair to good, nine bad to ghastly and the rest average. Reading it is likely to make the obscurity of pregnancy immunobiology darker yet, at a time when the relative importance of syncytiotrophoblast antigens, the maternal responses to them,

and the basic genetics of human pregnancy and its diseases are beginning to make a discernible pattern. Half of the contributors come from New York, which may be why some chapters have an insular feel — the authors are seemingly unaware of work going on elsewhere in the world. I cannot imagine that anyone would want to buy this book for themselves, as all the information it contains is already available in cheaper and better presented forms. □

Colin Stern is a Consultant in Paediatrics at St Thomas' Hospital, London.

Lymphokines for the nineteen eighties

Dudley C. Dumonde

The Lymphokines: Biochemistry and Biological Activity. Edited by John W. Hadden and William E. Stewart II. Pp.437. ISBN 0-89603-012-1. (Humana/Wiley: 1981.) $59.50 in the United States, $69.50 elsewhere.

IN 1982 the serious student of immunology need no longer doubt the existence of lymphokines: he has only to consult the literature. As non-antibody protein products of lymphocyte activation, lymphokines act as mediators and regulators of many aspects of lymphocyte function. After a slow start in the 1960s the pace of lymphokine research began to quicken. Semantic barriers were broken down: between mouse-doctors studying "help"; guinea-pig doctors studying "delayed-type hypersensitivity"; and human doctors studying "disease". By the end of the 1970s two international conferences on lymphokines had been held, a special review journal devoted to the subject had been launched, and lymphokine research had become one of the most vigorous fields of molecular and cellular immunology.

Now in 1982, gone are the days when sceptics viewed the term "lymphokine" as having merit only in so far as it could be used both as a noun and as an adjective. The application to lymphokine research of brighter biochemistry, supplemented by techniques of cell hybridization, cell cloning and gene cloning, has even awakened venture capital: not only is there a ferment of lymphokine literature but also a ferment of medical interest in the diagnostic and therapeutic potential of lymphokines. Accordingly the lymphokinologist of the 1980s will find that Dr Hadden and Dr Stewart have edited a book which must be compulsive reading and which must be compulsively purchased given the current pressures of information retrieval.

In *The Lymphokines* the discerning consumer will find his favourite item delicately positioned between an appetizing prologue by Byron Waksman and a satisfying epilogue by Barry Bloom. Considerable effort has been made by the contributors — all authorities — to emphasize what is known about the physicochemical nature of lymphokines and the biochemical events that attend their production and action. This theme is well illustrated in the first half of the book by chapters on chemotactic, migration-inhibitory, macrophage-activating, cytotoxic, thymocyte-stimulating and colony-stimulating lymphokines. A most useful feature is the inclusion of two chapters on the confusing subject of helper and suppressor factors (though at the time the book was finally edited, the term "interleukin" would seem to have only just been coined). There is a chapter on interferons by Dr Stewart himself; here I would like to have seen a more critical discussion of the relationships between interferons and lymphokines.

Having dealt with what we all regard as "lymphokines", the second half of the book is comprised of chapters on leukocyte transfer factor, immune RNA, macrophage secretion products including prostaglandins, monocyte/granulocyte haemopoiesis and thymus hormones. To this extent the book is heterogeneous, though the student of lymphokines cannot afford to ignore current knowledge of other factors apparently regulating lymphocyte and leukocyte function. The general standard of production is satisfactory, though the subject index lacks details and there are quite a number of typographical errors.

Yes! This is a useful addition to the lymphokine literature, although it is not necessarily the "key resource" on the subject. If the aim of the book is to relate lymphokine biochemistry to biological activity, then it must be regarded as premature, simply because much of this research remains to be done. In fact, it seems to be this very theme that runs through many of the contributions, as if the authors were aware that whilst they were writing their reviews someone else was busy cloning the mRNA of interleukin 2 in *Xenopus* oocytes, or copying the gene for γ-interferon in *E. coli*. Can one capture at any moment the pace of a fast-moving scientific field with all of its genetic, biochemical, biological and clinical implications? Drs Hadden and Stewart, together with their well-known contributors, have sallied forth where some others may have feared to tread. The result is appealing. □

Dudley C. Dumonde is Professor of Immunology and Head of the Department of Immunology at St Thomas' Hospital and Medical School, London.

Oceanography from space

John R. Apel

Spaceborne Synthetic Aperture Radar for Oceanography. Edited by Robert C. Beal, Pat S. DeLeonibus and Isadore Katz. Pp.216. ISBN 0-8018-2668-3. (The Johns Hopkins University Press: 1981.) $29.25, £17.

THE US spacecraft Seasat, launched in June 1978, carried among its instrument complement a synthetic aperture imaging radar, SAR, operating at a radar wavelength of approximately 21 cm. During the satellite's short, three-month life, this instrument provided about 1.5 million km of imagery, mapped in a 100-km-wide swath at a resolution in excess of 40 m. The high resolution imagery represents a new and important vantage point for viewing phenomena occurring near the surface of the sea. This volume, stemming from a symposium held at The Johns Hopkins University Applied Physics Laboratory in the spring of 1980, presents the first broad, coherent publication of results and understanding of radar imagery of the ocean surface.

The SAR has provided images of the sea that often exhibit puzzling and varied features which must be interpreted in terms of changes in the small-scale roughness (near 30 cm length) of the surface. The original function of the Seasat SAR was to provide imagery of long-length surface gravity waves, from which one might derive a badly needed quantity, namely two-dimensional surface wave spectra, via Fourier transform techniques. The ocean surface as seen through the radar's eye has proved to be marvellously more complicated than anticipated, however, with such additional features as internal waves, current boundaries, eddies, wind stress variations, rainfall, oil slicks and shallow bottom topographic features appearing in the radar image. While surface waves with lengths greater than perhaps 100 m can often be seen in SAR images as periodic modulations, the functional relationship between the power spectral density obtained from the film and the surface wave psd is essentially unknown. Indeed, there is much discussion in the book of the basic hydrodynamic mechanisms that allow long waves to be imaged via variations in 30 cm wave energy. It follows that the theory of the imaging process for the ocean surface is in a relatively rudimentary state.

The book opens with generalized discussions of surface wave characteristics by Phillips and Kitaigorodskii, followed by a theoretical exposition on SAR imaging mechanisms by Harger and a review of the state of our understanding of oceanic winds by Pierson. A number of more detailed research results are presented next, classified according to winds, waves and circulation. These are punctuated by dramatic examples of SAR images, most of which are of regions off the US east coast (thereby revealing the geographical orientation of the contributors to the book). The clear emphasis of the research papers is on geophysics, not radar technology. Then follow reproductions of some 21 full-swath SAR images of the western North Atlantic, New England and the central Atlantic states, prepared by the symposium organizer Robert Beal; these illustrate the myriad of land and ocean features that characterize Seasat radar images.

This volume represents the first organized exposition of the oceanic results from SAR and, as such, should be available to anyone interested in this phase of the subject. Beyond this audience, however, there should be considerable interest on the part of oceanographers, marine meteorologists, and forward-looking civilian and military users of the sea. The results presented here are so unusual and compelling that the future will almost of necessity see additional imaging radars in space; however, a great deal of research work remains to be done before maximum use can be made of such instruments.

John R. Apel, now Assistant Director for Planning in the Applied Physics Laboratory at Johns Hopkins, was until recently at the Pacific Marine Environmental Laboratory of the National Oceanic and Atmospheric Administration, Seattle.

Explosion in palaeobotany

W. G. Chaloner

Paleobotany, Paleoecology, and Evolution. Edited by Karl J. Niklas. Vol.1, pp.297, ISBN 0-03-059136-8; Vol.2, pp.279, ISBN 0-03-056656-8. (Praeger: 1981.) Vol.1 $37.50, £31.25; Vol.2 $36, £27.

PALAEOBIOLOGY has, in its own jargon, undergone a recent evolutionary explosion. Twenty years ago the study of fossil plants consisted largely of investigating their structure, and where possible reconstructing the whole plant from its variously preserved fragments. In the past two decades, however, the science has linked up with a number of bordering disciplines to encompass the development, reproductive biology, biogeography, biochemistry and a range of other aspects of past plant life. These two volumes contain a collection of papers by workers in the United States, which illustrate this diversity of new approaches. They were presented at a symposium held in Cornell University to honour Professor Harlan P. Banks on his retirement. The theme is very fitting, since over some 35 years of research and lecturing Banks has contributed uniquely to giving fossil botany an image not only of a challenging and rigorous science, but of an exciting one for students to enter.

The volumes comprise 14 articles dealing with topics ranging from Pre-Cambrian microfossils (E. S. Barghoorn) and palaeoecology (A. H. Knoll), through Devonian plant structures (C. B. Beck) and Carboniferous swamp ecology (T. L. Phillips and W. A. DiMichele) to various aspects of gymnosperm (T. N. Taylor) and flowering plant evolution (G. Retallack and D. L. Dilcher; J. A. Wolfe and W. L. Crepet). Two chapters deal largely with extant plants in the context of their evolutionary history — T. Swain and G. Cooper-Driver with biochemical strategy of primitive land plants, and R. M. Schuster with liverwort evolution. Three deal with a broader perspective of evolutionary processes, B. H. Tiffney reviewing changing diversity through the history of land plants, T. J. M. Schopf the process of genomic change, and A. M. Ziegler and others the biogeography of plants through the Palaeozoic.

Evidence for the interaction of plants and past environments is a recurrent theme. The study of microfossils is still very young, and the prospect of unravelling their ecology, novel. But Knoll is able to demonstrate convincingly the correlation between environment of deposition and various aspects (species diversity, association) of Precambrian microfossils. The occurrence of this "horizontal" variation between different assemblages, in addition to the well-documented "vertical" changes, is important for two aspects of Precambrian work: if such microfossils are to be used in dating rocks, the environmental control of assemblages must be understood; equally, if we are to interpret this early phase of plant history, it is important not to confuse migration in response to environmental change with evolutionary innovation. A different aspect of palaeoecology is reviewed by Phillips and DiMichele in a quantitative review of the vegetation of the Carboniferous coal swamps, preserved in a three-dimensional state in coal balls of the American Mid-West. These give quantitative data on biomass, species diversity and succession. Remarkably few genera constitute the dominant plants in the assemblages, in contrast to present-day humid tropical forest. Little evidence of directional succession emerges, and abiotic factors (water level, salinity) were evidently

overriding controls.

Crepet considers the reversion from insect- to wind-pollination in the catkin-bearing trees early in the history of flowering plants. This apparently occurred in the seasonally dry tropics, so that the present-day association of this group with temperate deciduous forest is misleading as a guide to its origin. Wolfe examines the Late Tertiary replacement of broad-leaved forest by conifers in the Pacific north-west. For those overwhelmed by the complex interactions of environmental factors, it is refreshing to learn that the "sole factor" in the assumption of dominance by conifers in that region was the declining summer temperature.

Perhaps the most far-reaching contribution is Schopf's reconciliation of molecular and palaeontological approaches to evolution. He concludes that "speciation may be so instantaneous geologically that many such events might well occur within the best possible resolution of the fossil record". He argues that even if our record of past life is the product of gradualistic change, the process of its formation puts its own punctuated stamp upon the picture. Which brings us, appropriately, back to Darwin's reservation over the "imperfections" of the fossil record. □

W. G. Chaloner is Professor of Botany at Bedford College, University of London.

Room for giants

Janet V. Watson

Igneous Rocks of the British Isles. Edited by D.S. Sutherland. Pp.645. ISBN 0-471-27810-6. (Wiley: 1982.) £55, $132.

FOR more than three thousand million years, melting in the outermost parts of the Earth has been an unusual event taking place only when and where temperatures rose to abnormally high levels. Igneous rocks formed by the consolidation of silicate melts therefore appear in the geological record as indicators of anomalous disturbances which are almost always related in time and space to major structural changes in the Earth's crust and mantle.

A book designed to document the record of igneous activity in the British Isles must therefore aim to throw light on the dynamic evolution of the entire crustal province if it is to be more than a source-book. From many points of view, there is a real need for a work of this kind. As Dr Sutherland notes in her editorial preface, no general synthesis has been published since Geikie's *Ancient Volcanoes of Britain* appeared in 1897. The literature which has accumulated since that date is vast, chaotic and often contradictory. Embedded in it are the outlines of fundamental ideas on the genesis, differentiation and emplacement of magmas which have become classics used all over the world. Encouraged as much by the exceptionally attractive dust-jacket as by the table of contents, geologists will therefore open this book with thankfulness and hope.

Much care has been taken to make it as useful as possible as a work of reference. The treatment is broadly chronological and each of the seven parts opens with a general scene-setting chapter. The distribution of igneous suites and the structure of individual complexes are recorded in many clear maps, well-designed for their purpose. The descriptive chapters conform to a fairly consistent pattern which makes for ease of reference. Chemical analyses, geochronological data and petrographical details are segregated in appendices (the petrographical appendix living up to a hallowed tradition that goes back to J.J.H. Teall). All these are excellent features, due, no doubt, to good planning and editing.

The contents of the descriptive chapters vary in scope and style according to the kind of information available and the predilections of individual authors. The Tertiary province comes off best, with a cluster of chapters covering the volcanics, the centres, the dykes and the petrogenetic story collectively building up a coherent picture in which details fall easily into place. Elsewhere, there are some unexpected gaps (why does the best-exposed British ophiolite, in Shetland, rate only a passing mention?) and a number of thin patches not all of which can be put down to paucity of evidence.

More disturbing, however, is the apparent shapelessness of the sections covering the central event of British geological history, the Caledonian orogenic cycle. The decision to deal separately with volcanic and "plutonic" assemblages bears especially hard on these sections where the progression of tectonic events through subduction to collision and uplift is almost lost sight of. Though defensible in terms of convenience, the separation leads to absurdities such as the allocation of the Glencoe ring complex and the ignimbrites erupted in this complex during cauldron subsidence not only to different chapters but even to different parts. The British Caledonides emerge from this book as untidily as they do in the field. One longs in vain for the authoritative touch that might have shaken this sprawling orogen into shape. The Tertiary province has never lacked giants who measured up to its challenges. There is still, on the evidence of this book, something left for giants to do in the older parts of Britain. □

Peat and prehistory

A. G. Smith

The Archives of the Peat Bogs. By Sir Harry Godwin. Pp.229. ISBN 0-521-23784-X. (Cambridge University Press: 1981.) £25, $49.50.

IT HAS probably come as a surprise to many a young scientist to realize that scientific work is as much about people as it is about science. This is amply illustrated in Sir Harry Godwin's book. It is also an adventure story. Through it all runs a sense of compelling interest and excitement. Above all, however, the author illustrates the way in which ideas about the nature and importance of peat bogs have flowed down the generations of scientists. It becomes, incidentally, an interesting contribution to the history of science.

In 1935 we find Godwin confessing "my ignorance of bog ecology was vast". But he began to learn his trade in the "magical Irish countryside" (acting as chauffeur of a model T Ford) on an excursion to Ireland with Hugo Oswald and A. G. Tansley. They chanced to meet, in Roundstone, another group including Knud Jessen, the great Danish Quaternary scientist, and one of his students, G. F. Mitchell. This group had just embarked on their studies of Irish bogs. We are treated to an enduring cameo of one of the fruits of this meeting: the party slowly sinking into the mire as they listened to an apparently interminable discussion between Jessen and Oswald, in interminable Irish rain, on Von Post's concept of soligenous bog.

From this encounter came the idea among the younger workers of pooling their experience to work on an uninvestigated British peat bog. Thus in 1936 began the classical work on the stratigraphy and ecology of Tregaron Bog in Dyfed, now a National Nature Reserve, which is briefly reviewed. The story continues with Godwin's adventures in the Somerset Levels and Borth Bog (Cors Fochno), Dyfed. The first scientific investigation of this now famous bog (again a National Nature Reserve) was apparently nearly frustrated by the presence of a wide drain. Having thrown their impedimenta over it, Godwin and his companion (D. H. Valentine) had no alternative but to undress and swim for it.

It is apparent that Harry Godwin soon fell in love with British peat bogs, not only as archives, but because of their flora. This he affectionately describes, treating the various species as the *dramatis personae* of the historical pageant. In his descriptions of the bog plants he takes care to show how they can still be recognized after their preservation in the peat. These tricks of the trade are one of the many valuable side-lights of the book.

The ability to recognize the sub-fossil remains of bog plants is of course of fundamental importance in understanding

the history of the bogs themselves. The recognition of distinct layers of the remains of the giant sword sedge (*Cladium mariscus*) and their relationship to the prehistoric trackways in the peats of the Somerset Levels enabled Godwin (working initially with A. R. Clapham) to piece together their basic history. The substantial part of the book given over to this work is not only a compelling detective story: it also includes a rather charming love story for good measure! The treatment of the Somerset Levels is particularly valuable. It brings together in an easily digestible form material from a number of scattered papers. Like the work as a whole, this account can be read with equal pleasure and profit by the research student and the general reader with interests in natural history and archaeology.

The latter part of the book deals with the discovery of the effects of prehistoric farmers on the vegetation of Britain, and the impact of the new technology of radiocarbon dating on the subject. There is shorter coverage of climatic influences and sea-level changes, the origin of blanket bogs and their subsequent erosion.

Godwin's account ends intentionally at about 1960, though with most of his topics he does allude to subsequent work. How happy it is that he has been inspired to write it as a personal story. In doing so he has in no way compromised his science. The book is a pleasure to read: a book to be re-read and re-enjoyed, not only used as a work of reference. □

A. G. Smith, a former research student of Sir Harry Godwin, is Head of the Department of Plant Science at University College, Cardiff.

Scene in New Guinea with characteristic animals (from the *Geographical Distribution of Animals*, 1876), showing Wallace's selection of Papuasian animals to contrast with the Sundaic animals. Left to right and top to bottom: a tree kangaroo *Dendrolagus inustis*, the fairy lory *Charmosyna papou*, the twelve-wired bird of paradise *Seleucides melanoleuca*, the common paradise kingfisher *Tanysiptera galatea*, and a crowned pigeon *Goura cristata* (*coronata*). In the companion plate to illustrate the Sundaic fauna, Wallace chose the western tarsier, flying lemur, pentail treeshrew, Malay tapir and lesser mousedeer.

Drawing the line

Peter D. Moore

Wallace's Line and Plate Tectonics. Edited by T.C. Whitmore. Pp.91. ISBN 0-19-854545-2. (Oxford University Press: 1982.) £15, $39.

IT WAS in a letter to H.E. Bates, written in 1858 from the Malay Archipelago, that Alfred Russel Wallace first drew attention to the two distinct and rigidly circumscribed faunas which are found in that region. They are as different, claimed Wallace, as the faunas of Europe and North America, yet there is no obvious geographical reason for their separation. Often the line of demarcation passes between islands lying close together.

The cause of this biogeographic discontinuity has provided much fuel for debate and the area featured strongly in the proposals of Wegener in support of his theory of continental drift. With the modern developments in plate tectonics much of the mystery has been removed from the subject, but the area remains one of the clearest demonstrations of the biogeographical consequences of moving continents. This book is a collection of essays by various authors setting forth the current state of knowledge concerning relationships between various plant and animal distribution patterns and the tectonic development of the area.

An historical background to the subject is used as an introduction and emphasis is placed on Wallace's own indecision regarding which side of the islands of Celebes his line should lie. As a result of a succession of faunal and floral analyses during the past 120 years, the line has often migrated in the minds of men. Two essays trace the continental movements leading up to the establishment of the discontinuity, and are accompanied by some detailed cartographic reconstructions. On the basis of geological data, Audley-Charles considers that the line of convergence of the Australia–New Guinea plate with Asia actually runs through the island of Celebes, thus explaining its biogeographical complexity.

The collision was a relatively recent one, occurring about 15–5 × 10^6 years ago, but there has still been considerable time for floral and faunal migration, mixing and even evolution, and the remainder of the book consists of a series of analyses of the biogeography of specific groups of organisms (vertebrates, palms, and other plants) in the light of recent palaeoclimatic and palaeoenvironmental reconstructions.

The papers presented in this book are concise, clear, well-illustrated reviews of a variety of specialist subjects, all of which impinge upon the modern view of Wallace's line. □

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences, King's College, University of London.

nature

27 May 1982

Time to chart Europe's future

Britain is once more the black sheep of Europe, after another row about agricultural policy, but the event is also an opportunity. Somebody should seize it.

This is turning out to be a bad year for the European Community. After what should have been a cheerful twenty-fifth anniversary (see *Nature* 25 March, p.278) that had most member governments asking "What have we done wrong?", a quarrel redolent of the turbulent 1960s has broken out between Britain (assisted by Denmark and Greece) and the six other states. The issue is that which has dogged the Community since it began — the price to be fixed for agricultural products in the year already under way. British unwillingness to agree to price increases exceeding 10 per cent had been well advertised in advance, as had the British government's insistence that this year, as in the past two, it should pay less towards the common budget than the rules of the Community require. With other things on its mind (see below), the British government obviously failed to sense that if it stuck to its position, the convention that any member state can veto any proposal would not save it from being voted down. This, in the event, is what happened. In the next few weeks, the member states will be looking for some way of picking up the pieces.

That will not be easy. Ever since it joined the European Community in 1972, the British government has been grumbling about the common agricultural policy, in effect a device for paying European farmers well so as to produce more food than Europe can consume. For much of that time, the British have been chipping away at the policy, and not always in the most high-minded spirit. Only a few weeks ago, a British agriculture minister was boasting to the House of Commons how he and his colleagues had managed to dip British hands into the pork barrel, winning more than a quarter of a new subsidy on suckling cows and virtually the whole of the novel subsidy for sheep. The difficulty, which successive British governments have been slow to recognize, is that the common agricultural policy, the constant but of their complaints against the Community, is as much a political necessity for other member states as is the right to veto any proposal judged to touch a vital issue is for Britain. These are eminently circumstances that call for compromise and self-restraint. Pretending that the truth is otherwise will lead nowhere. The ideal is that the common agricultural policy should wither, perhaps because it is overtaken by farmers' recognition that, in the modern industrial state that Europe seeks to be, there are more interesting and profitable things to do than till the land. What the Community should be looking for, in the rowdy weeks that lie ahead, is some means of making that ambition come nearer.

The difficulties are nicely illustrated by the grand French plan to do something within the Community about the commercial challenge from Japan in the electronics industry (see page 257). The obvious objection to the French plan for the revivification of the French electronics industry is that it is a national plan, and one based on the substantial investment of government funds. Even if the enthusiasts for the scheme were able to recruit the funds they seek, and if their use of them were wise, the result would merely be to make the electronics industry in the rest of Europe even more hard-pressed than at present. The result of that would be to renew the clamour that national governments should do even more than at present to help their own domestic manufacturers, perhaps by putting more business their way. The end result would be a system not very different from that now embodied in the common agricultural policy — a European electronics industry protected from the outside world by high tariff barriers, selling its products at prices that are too high and competing fiercely with itself. That is not a recipe for meeting the challenge from outside but, rather, a recipe for continued failure. The government of France seems not to appreciate that the Japanese success in electronics has been founded on an accurate appraisal of the international market, and that the only effective counter — admittedly only a first step — is to make the European market in electronic products thoroughly international. So will the French, and their Community partners, give up their present policies of channelling public contracts towards their domestic companies? Not, the guess is, without a struggle.

That, however, is precisely the struggle on which the British government, blackballed last week in Brussels, should now embark. The fact that the electronics industry in Europe is closely linked with defence, specifically exempted by the Treaty of Rome from the rigours of the open market, is not the stumbling block it seems but rather the opposite. It is foolish that half of the ten governments in the European Community should be spending large sums of money on the solution of essentially similar problems, hoping to recover part of the cost by sales of advanced military equipment overseas. Why should not each of them spend less on research and development, selling the products to each other in the first place? The result could well be that member states' strategic independence would be compromised, but is it seriously suggested that the constant rows within the European Community imply that one day it may be necessary for the members to attack each other? The pretence of military independence in which the member governments of the European Community at present luxuriate is belied by what their electors know — that culturally the Community is already so much of a piece that unscrambling it would be literally unfeasible. The advantage to the British government of taking the initiative on this issue of electronics and, where necessary, defence, is that it could throw those who baited it last week onto the defensive, yet hope to emerge with a prize to offer its own people that would be at least as valuable as the cost of the agricultural policy.

Rules for limited war

The Falkland Islands conflict marks a step towards the automation of conventional war.

The politics of the Falkland Islands war is outside *Nature*'s bailiwick, but the technology is not. For what is happening now in the South Atlantic is probably a foretaste of what may happen all too often in decades to come. First, it is a limited war in which neither side seeks the comprehensive capitulation of its adversary. Second, it is a high-technology war in which the combatants are equipped with virtually automatic weapons developed against the possibility of conventional conflict in Europe, but now being used in a mercifully remote part of the world, one so distant that other states are unlikely to be drawn in. What lessons, spine-chilling and otherwise, can be drawn from what is now going on?

That limited wars, out of fashion since the eighteenth century, are still feasible should not be a surprise. The Yom Kippur war of 1973 was limited in the sense that the Israeli objective was the capture of a tract of territory, the Sinai desert up to the Suez

0028-0836/82/210253-02$01.00

Canal, and not the destruction of Cairo or of the Egyptian state. This self-imposed restraint was not based on high-minded principle but on a calculation of what might be accomplished without dangerously broadening the conflict, reinforced towards the end by the discovery that Egypt was well-equipped with surface-to-air missiles. (We are all lucky that the calculation was not disproved.) Similarly, the involvement of the United States in the long war in Vietnam was limited; it was tacitly understood that nuclear weapons could not be used without triggering off a broader conflict that the United States did not seek. The same is true in the Falkland Islands. The United Kingdom has a modest stock of nuclear weapons, some conveniently carried on submarines, but their use is unthinkable and has not been mentioned. Even the wild talk in Britain that it might be necessary to attack airfields in Argentina has quietened as the sober realities of conflict have dawned, and as the importance of public and political opinion elsewhere in South America has been appreciated.

What this implies is that limited wars are possible only with the tacit agreement, however grudging, of other interested parties. And because other states' opinions can change, the combatants must spend a substantial part of their energy persuading everybody who is prepared to listen that they are acting reasonably, or at least as reasonably as is consistent with their resort to violence. This, no doubt, explains why the Falklands conflict has so far been conducted with extraordinary civility. The substantial British community in Argentina has not been unduly harassed, while in both capitals journalists go normally about their business (although three British journalists have been wrongly locked up in Argentina for six weeks, and three others kidnapped for a day). In Britain, the only untoward incident has been the decision last weekend by the Tottenham Hotspur football club that its talented Argentine player should be dropped from Saturday's cup final. Both sides have an interest in continuing like this, for to behave otherwise would weaken the cases they are putting to their friends.

Against this background, the British government has made two important errors. First, it has unnecessarily sought to keep to itself news of what is actually happening in the Falkland Islands. Second, no member of the British government has yet made the conciliatory speech that circumstances demand, making the simple point that the traditional links between Britain and Argentina need not be jeopardized by what is going on and even that the present Argentine government, while not democratically elected, is less fiercely repressive than its predecessor. Indeed, it would be entirely consistent with the notion that the Falklands war is strictly limited that even now the British government should be prepared to negotiate the kind of settlement it will be prepared ultimately to countenance. For the time being, both sides are stuck on the abstract concept of sovereignty; sooner or later, they will have to settle among themselves some kind of monetary price at which that concept could be made more flexible (see *Nature* 8 April, p.480). One of the tricks in fighting a limited war is to help opponents to give up the struggle at the earliest opportunity.

Technologically the Falklands war is far from limited. Reports that troops under air attack are unnerved not to see the attacking aircraft but only the missiles sent automatically to bring them down are vivid and credible, but that is what conventional warfare has become — a technicians' war. The past few weeks have shown that vehicles carrying people, whether ships or aircraft, moving in an environment in which radar detection at long range is technically straightforward, have become exceedingly vulnerable to attack. As missile ranges lengthen, they will become more so — which should give pause to the now-vociferous British naval lobby. Long-range attacks on ground targets are for the time being more difficult and still require human intervention, but the development of conventional battlefield weapons in the past decade suggests that even that relative immunity will not persist indefinitely. It does not, of course, follow that people will cease to matter. On the contrary, their roles as gatherers of intelligence and as communications links between pieces of equipment will become more important while their numbers shrink and as their skills increase. This inexorable trend points to several circumstances. First, limited war becomes more feasible as the chances of large numbers of military personnel being killed diminish. Second, the cost of military preparations is bound to increase. Third, there is a limit to the extent to which the depersonalization of conventional warfare can be carried without the combatants deciding that they must force a decision by using civilians as hostages of a kind. None of these prospects is cheerful.

Rothschild rides again

Lord Rothschild's report on social science research is predictably intelligent and subversive.

Once upon a time, the story goes, there was a wicked fairy called Sir Keith Joseph, Secretary of State at the Department of Education and Science in the United Kingdom. One day last year, soon after his appointment (some say demotion) to that office, Sir Keith took the daring step — it was at least unprecedented — of cutting half a million pounds from the recommended budget of an innocent but youthful mainstay of British academic life, called the Social Science Research Council or SSRC for short. Anxious to dissemble the extent of his wickedness, Sir Keith said that he would leave it to Lord Rothschild, a scientist and merchant banker who acquired in 1971 a fearsome reputation for angering academics, to recommend whether or not this stripling outfit should continue to exist. Thanks to the journal *New Society,* it soon became known that Sir Keith had been dutifully promising the Chancellor of the Exchequer (by definition wicked) that *something* would be done about SSRC. Thunder and lightning occurred.

Wicked fairies have no luck. How could Sir Keith have known that his chosen companion in malevolence had earned his reputation for wickedness by his flair for telling the truth and doing it deftly? Lord Rothschild's report on the issue last week (*An Enquiry into the Social Science Research Council,* Cmnd 8554, HMSO, £6.50) is in that tradition. For as nice a statement of the case for social science, and a neat dig at Sir Keith in the process, what could better the fifth paragraph of his report?

> Einstein is reported to have said that "Common sense is a deposit of prejudice laid down in the mind before the age of eighteen". Yet to the layman — the man in the street — many of the problems on which social scientists work are either too far fetched or do not need further work because common sense answers are already available. Common sense tells us that:
> (1) Capital punishment deters potential murderers;
> (2) The import of foreign cars should be drastically curtailed;
> (3) There should be more small hospitals and fewer large ones;
> (4) Horror comics make children violent (USA).
> Are we sure that common sense is right? Might there not be a layer of prejudice or even ignorance?

So, this is how the story goes, Lord Rothschild turns out not to be a wicked fairy's hatchet-man, but a good fairy in disguise. The youthful SSRC has been misjudged, he says. Too many have expected too much of it too soon, and without a proper understanding of what academic life or the social sciences are like. So the SSRC should be reprieved, first from the burden of being "looked at" for at least the next three years. In gratitude, however, it should be prepared to move to Swindon, should be more (not less) courageous and should defend itself against the single open charge of left-wing bias. Wicked fairies everywhere will be discomfitted by this sane and unchallengable opinion. One of these will be the British Academy, which calls itself "the national learned society representing the interests of the social sciences", and which took the lead in bad-mouthing the SSRC a year ago. Lord Rothschild (who is evidently not unalloyed good fairy) quotes a pompous passage from the academy's written evidence saying (truthfully) that it is incompetent to be the SSRC but promising that it will be "vigilant" in overseeing the council's work. Can everybody live happily after that?

UK plutonium worries US Senate

Alarm at link between civil and bomb uses

Washington

US senators may soon start investigating the fate of as much as four tons of fuel-grade plutonium that the United Kingdom supplied to the United States over several years on the understanding that it would be used only for civilian purposes, but which may have been put into nuclear warheads by US authorities. The plutonium originated in the Magnox reactors of the Central Electricity Generating Board.

Last October the two governments apparently agreed that the United Kingdom would resume providing plutonium to the US Department of Energy (DoE) to help indirectly with the DoE's programme for producing and modernizing US nuclear warheads.

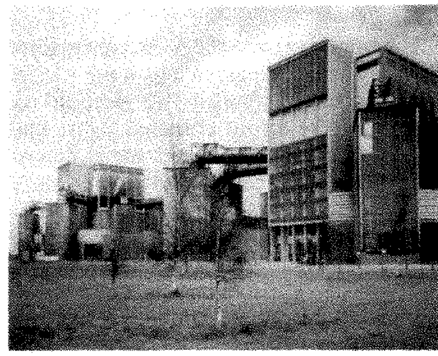
Under a previous barter agreement that ran from 1964 to 1971, the United States supplied the United Kingdom with highly enriched uranium for its nuclear submarine programme and with tritium for UK nuclear weapons. In return, the United Kingdom supplied an unspecified amount of plutonium from Magnox reactors. The terms of the accord have always been secret, but in 1964 a British government spokesman indicated that the United States had no intention of using the plutonium thus obtained for nuclear weapons. Now, however, Senators Gary W. Hart (Democrat, Colorado), Alan K. Simpson (Republican, Wyoming) and George J. Mitchell (Democrat, Maine) seem likely to act on a request from a public interest group that they look into how much plutonium was shipped to the United States between 1964 and 1971.

The Senate investigation reflects a growing concern in the United States about DoE's plans to link civilian and military nuclear programmes, a move away from the historic separation between "atoms for peace" and "atoms for war". Recently, DoE has announced that there is a "shortage" of plutonium (DoE designs and builds nuclear weapons for the Department of Defense). So it plans to take plutonium from spent fuel from several civil research reactors to fashion more weapons grade material.

DoE also wants to convert the 17.8 tonne stockpile of fuel-grade plutonium now destined for the breeder reactor at Clinch River, Tennessee, for weapons use. This stockpile may well include much or all of the plutonium supplied under the barter agreement. "Either it is in the US nuclear weapons already, or it is in the stockpile meant to fuel the breeder, but now destined for weapons," says S. Jacob Scherr, senior staff attorney for the Natural Resources Defense Council Inc.

According to the Natural Resources Defense Council, existing US nuclear weapons utilize about 90 tonnes of plutonium (plus or minus 15 tonnes). Current weapons-grade plutonium production by DoE has run about 1.4 tonnes per year, but DoE wants to step this up to 2 to 3.5 tonnes annually. In October, the UK government allegedly agreed to send more plutonium to the United States. The British plutonium may be going to fuel the breeder at Clinch River so that fuel otherwise destined for the breeder can be diverted into nuclear weapons. John Moore, Parliamentary Under-Secretary of State at the UK Department of Energy, was questioned about the plan in March.

DoE seems likely to continue to press the United Kingdom for more plutonium, because Senators Hart, Simpson and Mitchell have succeeded in cutting off another possible source — by a vote of 88 to 9, on 30 March, the Senate voted for an amendment to prohibit DoE from using spent fuel from commercial reactors for its nuclear weapons programme. In a debate in the House of Commons on 21 December 1981, Mr Moore emphasized that civil plutonian sold to the United States would be subject to international safeguards, but he implied that military plutonium transferred under the defence agreement would not be so restricted.



The Magnox at Berkeley in Gloucestershire — source for US bombs?

DoE has also decided to proceed with the Laser Isotope Separation facility at Lawrence Livermore Laboratory, which would cost an estimated $560 million and which the Natural Resources Defense Council claims has no justification other than to enrich plutonium from civil reactors to weapons-grade material. DoE also seeks to build a decladding plant to utilize fuel from noncommercial plants, such as the Fast Flux Test Facility at Hanford, Washington.

The issue at stake is not only the historic separation between civilian and military nuclear programmes, but also the precedent that DoE is setting for other countries. Critics of DoE's plans argue that if the United States starts taking civilian spent fuel from its weapons programme, it will not have a leg to stand on when it tries to dissuade other countries from doing likewise.

Oak Ridge up for grabs

Washington

On 3 May, the Union Carbide Corporation, which has run government atomic facilities at Oak Ridge, Tennessee, since the Second World War, announced that it no longer wants to do so. Union Carbide is not seeking to renew its option to manage Oak Ridge when the present contract expires on 30 September 1983. Recognizing the dislocation that its decision could cause, however, the company says it will stay on for up to three years longer if necessary.

The names Oak Ridge and Union Carbide have been almost synonymous in government science circles and in the Tennessee Valley region since the first gaseous diffusion plant was built there, amid great secrecy, during the Second World War. At that time, the company was heavily involved in manufacturing carbon products, but has since grown (its 1981 sales were $10,000 million) and diversified into batteries, antifreeze, car care products, even salmon farming and ferroalloys. But earnings have been down of late, and the company has been divesting itself of activities which are not central to its purpose. So it is shedding Oak Ridge.

Union Carbide is one of the most respected corporate managers of any government laboratory in the nation. It actually runs four facilities — Oak Ridge National Laboratory, the Oak Ridge gaseous diffusion plant, the Oak Ridge Y-12 plant that makes nuclear weapons components, and the gaseous diffusion plant in Paducah, Kentucky. Union Carbide's act will be hard to follow.

The government spends about $1,000 million a year on these facilities, paid through the company, which has 18,000 employees working there on its payroll. Its fee for the operation is $8 million per year, from which come some expenses. The Department of Energy, which holds the contract with Union Carbide, may decide to open four separate bids, one for each of the facilities, rather than ask a single company to follow in Union Carbide's footsteps. As a side effect, this might hasten changes in the mission and role of the Oak Ridge laboratory itself, which is under White House review, along with the other departmental laboratories.

Hamburg elections

Power politics

Heidelberg

Nuclear power and the environmentalists will play a crucial part in next week's local elections in Hamburg. The election on 6 June will be a four-cornered fight. The looseness of the traditional social democratic grip on the Hanseatic city state reflects the party's national difficulties. Mayor Klaus von Dohnanyi may well be returned, but with a minority in the senate. Proposals for a *gross Koalition* between the Christian Democratic Union (CDU), the second largest party, and SPD have been dropped. The Free Democrats (FDP), aligned to SPD, are fighting for the 5 per cent vote needed for survival under the proportional representation rules. But the crucial minority, likely to get 8–10 per cent of the vote, is the Grün-Alternative Liste (GAL), an umbrella party of some 150 groups based on issues ranging from citizens' protection and women's rights to environmentalism and opposition to nuclear power.

Mayor Dohnanyi would apparently be willing to attempt a minority administration with GAL cooperation. Despite the difficulties of arriving at even an internal GAL consensus, and despite its preference for a role in opposition, GAL may agree. But its terms include rejection of the new *Energiekonzept*, the controversial product of long hard bargaining between Hamburg and the Hamburgischen Electrizitätswerke (HEW).

These plans, announced on 27 April and heralded as classic reforms, involve going ahead with what is probably the country's most disputed nuclear reactor, at Brokdorf, and also the construction of four conventional coal-fired power stations with heat-coupling. Under the previous plan, 70 per cent of Hamburg's electricity was to have come from nuclear reactors; this has now been reduced to 25 per cent with the possibility of extra conventional capacity that would allow Brokdorf to be abandoned by the year 2000. HEW will invest DM3,000 million for the electricity-heat project and DM2,500 million for Brokdorf. DM50 million will be contributed by the federal government, which sees the plan as a pilot project for integrated energy supplies in built-up areas. A third of a million homes will be heated, 1,500 jobs created, 140,000 tonnes of oil saved, and pollutant emissions significantly reduced.

The plan provides ammunition all round. GAL insists on withdrawal from nuclear power plants at Brokdorf, Brunsbuttel and Krümmel. Nor is the prospective advent of a friendly neighbourhood coal-fired power station, however smart, pleasing to that diverse conglomeration. Within SPD, nuclear power is strongly supported by the federal government but rejected by both Social and Free Democratic Parties in the north. The local Hamburg SPD voted last year for withdrawal from Brokdorf and the previous mayor, Hans-Ulrich Klose, resigned on the issue. The new plans split Dohnanyi's home base and may well drive SPD left, nearer to the "Greens".

Despite Dohnanyi's sleight of hand, his attempt to back the nuclear power issue both ways may leave him stranded. The Christian Democratic mayoral candidate, Walther Leisler Kiep, has attacked the financial basis of the project and the move from clean environmentally favourable nuclear energy to coal, predicting higher energy prices and an electricity gap if local objections slow construction of the coal-fired power plants.

Peter Glotz, party executive secretary, compares the social democratic response to the unwieldy manoeuvres of a tanker. If Hamburg's "Greens" reach the bridge, the Dohnanyi *Energiepolitik* may go overboard and the national supertanker be on course for a dry dock. **Sarah Tooze**

East–West energy trade

Pipeline ploy

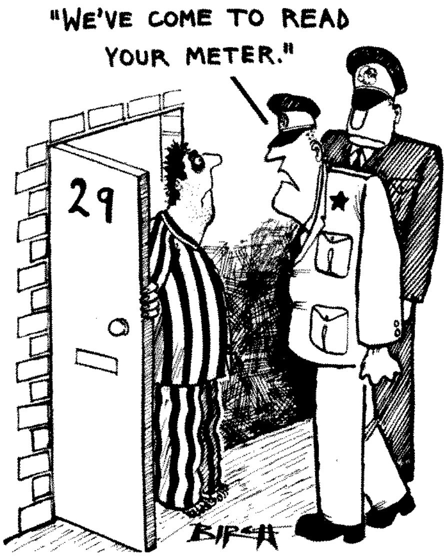
President Reagan's visit to Europe next month will include major talks on the future of East–West trade. The immediate issue is that of the interest rates to be demanded of the Soviet Union. The Americans' wish to increase them is opposed by some West European countries, notably West Germany, which feel that if the Soviet Union is reassessed, several other countries should be treated likewise.

The Soviet Union has a chronic shortage of hard currency. One possible means of repaying loans would be a counter-trade in fuel, particularly natural gas, which during the 1980s will increasingly replace oil as the Soviet Union's major fuel export. French and West German contracts for deliveries of gas from the Urengoi field originally caused the Americans considerable concern. Of late, however, they appear to have accepted European arguments that the amounts involved (10,500 million cubic metres for West Germany plus 700 million for West Berlin and 8,000 million for France) form only a small proportion of the energy budget, and do not constitute dependence. However, the signing of a contract last week for the supply to Switzerland of 360 million cubic metres of gas annually for 30 years suggests that other West European customers for Soviet gas might not follow the comparatively small demands of France and West Germany.

The transfer of technology, heavy-duty pipelines and compressor equipment, as part of the initial Western investment in the pipeline, continues to worry the Americans, although little or nothing is involved that had not been made available to the Soviet Union ten years ago.

A recent survey of East–West energy trade, however, suggests that the lack of a coherent Western policy could considerably weaken the position of the NATO countries in the changing energy situation of the 1980s. The survey's author, Jonathan Stern, describes a dual energy scenario for the 1980s.

On the one hand, Stern says, an endemic energy shortage will develop in Eastern Europe which will only be made good by purchases on the hard-currency market. Under present agreements, the Soviet Union cushions increases in the price of oil and gas to the Comecon countries, but only up to an agreed amount, leaving an increasing gap to be filled from the world market. Unless the Comecon countries can agree with the oil producers to purchase oil and gas with soft currency, foreign debts will escalate and political and economic tensions will increase.



On the other hand, gas exports are an attractive hard-currency earner to the Soviet Union. Construction of the pipeline, in spite of the delays imposed by the US sanctions after the military takeover in Poland, is likely to go ahead, and once the pipeline is in operation, further contracts with the West are likely.

A coherent Western policy, Mr Stern urges, should therefore be worked out, based on the following criteria:

- Are other gas suppliers a more acceptable security risk?
- Are the security risks outweighed by related contracts?
- What would the Soviet Union achieve by cutting supplies (granted that it would lose more than 50 per cent of its hard currency earnings by doing so)?

Lack of such a policy, Mr Stern argues, would not only allow the Soviet Union to claim a political victory (by pointing out cracks in the Western alliance), but would also weaken the Western bargaining position in dealing with the other aspect of the East European energy problem — the efforts of the energy-poor countries of Eastern Europe to top up supplies on the world market. **Vera Rich**

Information technology

Send more bits

The age of electronic mail is about to dawn in Europe, not traditionally the leader in new information and communications technologies. Before the year is out, most European telecommunications administrations are expected to introduce a new international standard that will allow word processors to communicate with each other through existing telephone and data transmission networks.

With its penchant for confusing names, the information technology community is calling the new service "teletex". It is, however, a far cry from teletext, the broadcast information service. Teletex is either a sophisticated form of telex or a standard that allows computer terminals to communicate with each other.

The teletex standard was adopted by CCITT, the international telecommunications standards agency, at the end of last year. Europe's enthusiasm for it stems from the present difficulty of linking incompatible word processors over telecommunications links. The United States, which might be expected to be the largest market, is reluctant to adopt the standard, chiefly because the already-large word processor market makes it worthwhile for manufacturers to adopt their own communications standards.

Theoretically, it should be possible to write teletex-compatible communications software for any type of word processor. The practical difficulties, however, have persuaded manufacturers to design specific teletex machines. Among the leaders are Siemens of West Germany, which already produces teletex equipment compatible with the German data network. Other companies, either selling teletex machines in some countries or promising them soon, include Philips, ITT Creed and IBM.

Teletex's chief attraction is that, in many instances, it can deliver documents much faster and more cheaply than the ordinary telex or the post. As it is basically a word processor, it can also relay information in different formats, unlike telex. Most telecommunications administrations will be introducing services with transmission rates of 1.2 kbits per second, doubling this later on. Using the lower data rate, a typical A4 page of text (*Nature*'s page size) will take roughly 30 seconds to transmit.

The cost of using the service will depend on the charging policy of the different telecommunications administrations. British Telecom, for example, will be making a "small" service charge but will thereafter charge for time at the ordinary tariff. At current rates, one A4 page would cost 12.9 pence to send a distance of more than 56 kilometres between 8 a.m. and 1 p.m. over the public telephone network. Forty-three A4 pages, however, could be sent within the same city after 6 p.m. for only 4.3 pence. These charges should be compared with the cost of a first class stamp, now 15.5 pence.

The capital cost of equipment is still uncertain, but manufacturers expect teletex machines to cost no more than sophisticated word processors.

The service to be launched throughout Europe this year will be relatively simple, but a facsimile standard is expected later. British Telecom's service will initially be suitable only for communicating between teletex machines through either the public telephone or packet-switched data networks. However, the service is expected to expand in 1983 to allow communications from teletex to telex machines.

West Germany, which introduced its own teletex standard in part compatible with the international standard, has already launched a service. Manufacturers that have supplied to the West German market, however, may not be able to sell their equipment in other countries without first modifying it for other networks.

US companies showing an interest in teletex seem to be those with a strong interest in Europe. IBM is planning a teletex version of its display writer word processor and Western Union is also apparently developing teletex. Canada, however, is not showing its neighbour's reluctance. It also plans to introduce a service this year. **Judy Redfearn**

French electronics

Rushing ahead

Has the French electronics plan come too late? M. Abel Farnoux and his team at the Ministry of Research and Technology in Paris have laboured for eight months to produce a grand plan for the whole French electronics industry, from primary materials right through to consumer products and computer components. Its coherence and grandeur are marvellous to behold, but news is still awaited from the Council of Ministers about the scale on which it will be financed. Twelve months ago the new government was full of expensive plans; more recently, the finance minister reckoned up the bill.

Nevertheless, Farnoux and his chief — science minister Jean-Pierre Chevènement — are pushing the plan strongly. The plan must be implemented "within a year" to be effective, they say.

Alongside industrial expansion, it would increase research and development in electronics and related fields by two-thirds, relative to the 1980 figure of FF 12,000 million, to FF 20,000 million in 1986. The strategy would cover the whole industry and not just the present strong points of telecommunications and telematics, and it would be aimed at bringing France closer to the levels of the United States and Japan. (Electronics for the French defence industry, third in the world's armaments league after the United States and Soviet Union, is also included in the strategy but has been omitted from published versions for security reasons.)

Nevertheless the published report says that electronics is a "basic technology at the heart of our defence and communications systems". Strength in electronics would also permit "indispensable gains in productivity" in other industries; open up vast consumer markets; contribute to energy conservation in new energy technologies; directly and indirectly reduce the French trade deficit; and (a point added for Mitterrand?) play a major role in "cultural" affairs.

The industry (or *filière*, as the French call a collection of industries taking a raw material to a product) must be treated as a whole, says Farnoux; for him it is all or nothing. Japan and the United States must be met head-on: it is no answer to manufacture American and Japanese products under licence, says the report. European cooperation should be sought, particularly in the development of new micro-electronic consumer products.

Division of the world electronics market, according to the recent French report

Country	Production ($\$10^9$)	% Of world production	Trade balance ($\$10^9$)
USA	134	46	+4
Japan	46	16	+13
West Europe	76	26	−6
(Germany	23	8	0)
(France	17	6	−0.2)
(UK	15	5	−0.2)
Others	35	12	−11

In France at least, a big training programme will be necessary: up to 1990 the report envisages the creation of 75,000 "engineer-researchers", 25,000 senior technicians and 400,000 skilled workers.

If the report were adopted in full, there would be 14 national projects, including a large French scientific and industrial computer, chip manufacture, electronic publishing, computer translation and others. M. Chevènement has announced the setting up of working parties on each project, independently of the report's adoption by the Council of Ministers.

On research, new units would be set up combining both academic and industrial interests. Government investment in research would rise (50 per cent of the French electronics industry is now nationalized, with 30 per cent in American hands and the rest in private French ownership) but mechanisms would have to be found to give a better return on each franc. The weak areas in current research are seen to be information and communication science, solid-state physics and chemistry. Mathematics and robotics are considered well advanced.

One final recommendation may not be well received by M. Chevènement, however. After a long exercise in gathering the instruments of technology politics under one roof, the minister is now faced by a proposal to create a secretary of state for electronics. **Robert Walgate**

0028-0836/82/210257-01$01.00

Science in US Congress

Fair winds

Washington

The apparently pro-science and technology mood of Congress this session, particularly in matters involving private industry, is indicated in much of the routine business of bills introduced, of bills reported out of subcommittee (which means that a small number of congressmen agree something should be done), of bills reported out of full committees (which means that a larger group of congressmen agrees), and by bills actually voted by either the House or the Senate.

True, Congress is not rushing through sweeping reforms. Indeed, it is unlikely to do much — in terms of legislation passed by both houses that then becomes law — that will change the face of US science. The Republican party dominates the Senate; Democrats have a majority in the House. Democrats are preoccupied with the budget battle, while the Republicans tend to be thinking of the next election.

One measure with a chance of passing is a patent reform bill (the Uniform Science and Technology Research and Development Utilization Act or S. 1657 in the Senate). This would extend to most organizations performing government research the patent reforms enacted last year for small businesses, non-profit institutions and universities. It would also unify the patent policies of the various government agencies. The long-standing question has been when a researcher using government funds is entitled to hold the patents arising from the work, or when patent rights should go to the government department that sponsored the work. The present congressional mood includes greater consensus that federal shackles be removed, allowing researchers the greatest incentive to market their products.

Another bill, the Joint Research and Development Act (HR. 6262 in the House), is a response to the US high-technology industry's complaint that other countries allow industries to pool talent on research problems but that, in the United States, such pooling risks violating antitrust laws. The bill would allow the government's lawyers to issue a certificate permitting joint research and development in selected cases, and protecting the companies from antitrust prosecution.

The Senate has passed the Patent Term Restoration Act (S.255) whose counterpart is now in the House Judiciary Committee, but may not emerge before Congress adjourns in September. It tries to help industries that the government regulates to recoup more money from patents, to compensate for the costs of regulation. At present pharmaceutical companies file for a patent as soon as a new compound is discovered. The patent runs for 17 years, of which several are used to develop the compound into a marketable drug. Then the firm must file for permission to market from the Food and Drug Administration. By the time the drug is approved for marketing, which can take up to 10 years, the company has only a few years left in which to recoup its investment. The pharmaceutical industry claims that this delay can cost $70 million for a single drug. The new bill would extend the lifetimes of certain patents by up to 7 years.

In the Senate especially, legislators seem concerned with freeing industry and assisting US high-technology trade. A resolution has been introduced to guide the imminent talks in Geneva concerning the General Agreement on Tariffs and Trade (GATT), that refers specifically to US high-technology trade needs. Another bill, passed by the Senate, would fund a special clearing-house to help move the government's enormous store of technical information into the private sector. A further measure introduced in both houses would offer tax credits to manufacturers of computing equipment which give hardware to schools. The measure was promoted by one of the founders of the US home computer company, Apple Computers.

If sentiment were more like that of ten years ago, when faith in federal government intervention was far stronger, Congress might now be designing large federal programmes to "rescue" the US high-technology industry, or greatly increasing spending on federal research and development. Instead, there is a feeling that government is not very good at picking winners and that the congressmen want to encourage promotion of technology in the marketplace. This attitude, particularly prominent among Republican senators, is in contrast to past enthusiasm for heavy federal involvement and big government development and demonstration programmes. Basic research has benefitted from the change — both those who favour more federal intervention and those wanting to promote technology in the marketplace view basic research as an essential government investment.

Likewise, the cause of improving US science education in the schools has support from both sides. Senator John Glenn (Democrat), the former astronaut who has made science and technology a main plank of his political activities, has introduced a bill (S.2421) to set up a council in the National Science Foundation to suggest a cure for the "technological illiteracy" of the nation. It would be given $5 million to come up with the plan, and $50 million per year for four years to implement it. A similar bill has been introduced in the House by Don Fuqua (Democrat) and Doug Walgren (Republican). Neither bill is likely to get very far. But the momentum these congressmen are giving to the issue of science education may promote a change of heart from the Reagan Administration, until now opposed to a major federal role in science education. **Deborah Shapley**

Computers for free

The US computer industry is joining the ranks of those crying for improvements in education in science and engineering offered in US schools and colleges. As a result, the National Science Foundation (NSF) is expected to announce in early June that five computer companies will be donating many hundreds of individual computers to help solve the growing problem of "technological illiteracy".

It all began when two computer companies — as yet unnamed — each tried to donate 100 machines to NSF for distribution to schools. This gift, however, set NSF bureaucrats worrying whether it was legal to accept this largesse. As it turned out, NSF, unlike some other government agencies, has specific statutory authority to accept gifts that are for the purpose of furthering NSF's missions.

But NSF did not want to be seen to favour these two computer companies over any rivals for the honour of giving away their machines to the government. So they went through a moneyless bidding process, and invited gifts from all companies. Now, NSF sources say, five companies will be making the donations, although the terms, the nature of the hardware, and the insitutions they will be given to have not yet been revealed.

Why is the computer industry so eager to provide free samples to young people in the schools and colleges? One answer, of course, is that a student who learns an elementary computer tongue at school will outgrow it and ask for another model. Company sales would not be hurt. **Deborah Shapley**

British universities

More misery

Hopes that the British university system would be spared some of the government's economy measures were dashed last week, when the University Grants Committee made public the recurrent grants to individual universities for the academic year 1982–83. There is no substantial change from the provisional allocations of a year ago, although the University of Salford, one of the most seriously afflicted then, has been given an extra year in which to reduce its establishment.

The coming academic year will be the second of the three in which government subvention for the universities is to be reduced by 8.5 per cent. The sum now offered to the universities is, however, larger than the amount advertised last year because allowance has been made for inflation (4 per cent on salaries, 9 per cent on other costs) and because the University Grants Committee has been given more

0028-0836/82/210258-02$01.00

than £100 million extra to compensate universities for the reduction of fees for home students.

For many British universities and academics, last week's announcement will seem to bear directly on the pay negotiations now under way between the universities and university teachers, represented by the Association of University Teachers. For the grants committee's letter does formally confirm the UK government's intention that the university grant for the coming year should include only 3 per cent for salary increases. While there have been some suggestions, at the University of Aberdeen for example, that academics might forgo pay increases in the present round of pay negotiations, the union nationally is asking for 14 per cent, 12 per cent to compensate for price inflation in the past year and 2 per cent to make good the erosion of academic pay.

The allocation of funds for the coming academic year has apparently been made in the light of universities' accounts of how they plan to adjust to falling budgets. The grants committee is apparently planning to keep back some £20–30 million of the total government grant to finance the more interesting of universities' intended innovations. The new letter to universities pleads, however, that universities having to reduce costs should not take the knife to easily eliminated but academically important minority departments.

The committee has also shared out among its dependent universities the annual government grant for equipment and furniture, fixed last month at £83.6 million. While the Department of Education and Science said last week that the grant is "consistent with the aim of maintaining standards . . .", the grants committee seems strongly to hold that the grant is at least one third too small.

For the more distant future, the grants committee seems to expect that there will be a return to "level funding" after the present contraction is over in 1983–84, but does not know whether the provisional budget for 1984–85 published in the government's expenditure white paper in March will be adjusted upwards if inflation exceeds the supposed 5 per cent a year.

The grants committee itself plans to spend much of the coming year studying possible changes in the social function of universities, especially in continuing education. It remains unclear what will befall those universities which fail to meet the grants committee's targets for reduced student numbers by the end of 1983–84. The sentence in last year's letter suggesting that universities failing to meet their targets would be penalized is not echoed in those sent out last week, but the committee is apparently guessing that if the government should be disappointed with the universities' performance, and should cut the total budget by the extra cost of student maintenance, the budgets of the universities responsible will also be cut.

London medical teaching

Merger fever

While the rest of the University of London continues to agonize about its future, the undergraduate medical schools are at last beginning to implement a plan designed to save 10 per cent of the university's medical education bill by 1983–84. The outlook for dental education also looks brighter since the five dental deans recently agreed to move the school at the Royal Dental Hospital from its premises in Leicester Square to one of the university's four other dental schools. But the future of the postgraduate medical institutes, whose finances have been particularly badly hit by the shortfall in the number of overseas students, will not be tackled until July.

After almost two years of often bitter wrangling, the undergraduate medical schools, collectively the largest source of trained physicians in the United Kingdom, finally agreed on a plan at the end of last year. The dispute began after a committee chaired by Lord Flowers, rector of Imperial College, recommended at the beginning of 1980 that the university's 34 medical and dental institutions should amalgamate into six large conglomerates.

That debate was overtaken by events. The government's announcement at the end of 1980 of large cuts in university education concentrated minds. The plan adopted was designed to increase opportunities for pre-clinical students to choose between medical and multi-faculty schools, and provide access to certain major disciplines, clinical pharmacology, therapeutics and community medicine.

Three of the medical schools, those at the Royal Free, St George's and St Mary's hospitals, are to remain much as they are. The others are to form some type of association either with another medical school or with a multi-faculty college. Thus the medical schools of Charing Cross and Westminster hospitals are to merge. So too are those at the Middlesex Hospital and University College. The schools at St Thomas's and Guy's hospitals are to form a united medical school next autumn and those at St Bartholomew's and the London hospitals are to work towards formation of a joint school. The school at King's College Hospital is to be administered from King's College in the Strand.

The outstanding problem is whether the plan can be implemented in time to make the necessary savings. Schools that must merge will be combining courses, departments and administrations and reorganizing accommodation. St Thomas's and Guy's hospitals, however, will retain their separate schools but merge administration.

The merger of the London and St Bartholomew's schools will take longer. The promise by the University Grants Committee to finance new accommodation for the joint school at Queen Mary College, a multi-faculty institution, still stands. But the grants committee is now looking for existing buildings which may become available when Queen Mary College has itself trimmed its operations to match its reduced grant.

The reorganized medical schools will be expected to maintain their aggregate student population. But the reorganization alone will not by itself yield the necessary savings. So student:staff ratios are to decline from the present 1:7.4 in pre-clinical studies to 1:10 by 1983–84 and from 1:6 in clinical studies to 1:7.

Judy Redfearn

Polish sciences

Nothing to read

Poland's endemic hard-currency problems are posing a major threat to Polish science. The purchase of Western scientific journals is virtually impossible, and according to the Warsaw daily *Zycie Warszawy*, last year no subscriptions were paid to foreign suppliers at all, so that by October the country had run up a debt of about US$8 million for journals supplied against invoices.

This year, some $5 million have been allotted for the purchase of journals, but this is only half the quota for 1980 and less than 20 per cent of the 1978 level. Polish scientists have had to resort to various stratagems to keep up with their reading. Photocopies of *Current Contents* were displayed on the noticeboards of institutes and universities and scientists requested a photocopy of articles they required from the Academy of Science or else through interlibrary loan. Martial law, however, meant that very tight security controls were imposed on photocopiers, lest they be used for the production of protest leaflets.

At the same time, their other main source of new publications — offprints and duplicate copies of journals requested from foreign colleagues — has been considerably reduced. Under martial law, the mails are considerably delayed by the censorship, scientific visits to and from Poland have been significantly curtailed, and many Westerners are apparently disinclined to send material to their Polish colleagues for fear that journals arriving from abroad might attract the attention of the security authorities.

So far, little has been done abroad to relieve the situation. The British Council has allotted £25,000 for the purchase of journals for Polish academic institutions; in the United States, however, the view is by no means unanimous that aid would be proper until martial law comes to an end.

But to Polish scientists the situation is a matter of intellectual survival. Letters to Western colleagues emphasize that without an emergency supply of journals to tide them over the current crisis, Polish scientists will rapidly fall behind the world scientific community, and catching up, when dollars become available again, will be virtually impossible.

CORRESPONDENCE

The DNA disease

SIR — This is an account of a disease which has recently attained epidemic proportions. In February 1975 at a meeting held at Asilomar Conference Centre in California, many scientists and the world at large first learned of recent developments which came to be known as the recombinant DNA molecule technique, whereby genetic information initially in one organism could be translocated into another where, with reasonable luck, it might prosper and ultimately find expression. This announcement was followed by a wave of anxiety among the knowledgeable. It was confidently forecast that among the new chimaeras which might thus be generated there would be some that were malevolent. New toxic gene products would be let loose in the world and organisms which had, for millennia, lived in friendly symbiosis would be rudely ejected from their econiches by novel and hostile forms.

The assembled scientists at Asilomar therefore agreed to conduct their experiments under severe constraints of biological and physical containment. The intent of these regulations, drafted as "guidelines" by the Recombinant DNA Molecule Program Advisory Committee of the National Institutes of Health, was to minimize the likelihood of any of the foreseeable catastrophes.

It is now quite generally agreed that the anxieties which were initially generated were without much substance. Curiously, however, the one serious damage to our ecosystem which has now been observed to occur as a result of application of the recombinant DNA molecule technique was totally unanticipated in 1975.

The problem has arisen as a result of the discovery that some of the gene products derived from recombinant DNA experiments commanded a high market value. The gene which was enhanced was that for venality and the unanticipated gene product was money — sometimes in the form of shares in an entrepreneurial company — sometimes in the form of stock options. This gene product to which many investigators had not previously been exposed might well have been contained had the experiments been conducted under appropriate physical containment such as that in a bank vault. However, the new disease proved to be quite contagious, spreading rapidly even to the administration of the institutions in which these scientists were housed. With great eagerness, everyone wanted a piece of the action.

Among the symptoms of the disease most prominent has been a deterioration in communication, both verbal and written, on the part of those affected. They simply will not tell their friends and neighbours what they are doing or what they intend to do. Both teacher and student have schooled themselves to be close-lipped lest the competitor discover the name of the new product or the means to its production.

Concurrently, a change was noted in the dissertation problems assigned to graduate students. Whereas these formerly always contained an element of new *knowledge*, now the stress is more towards a new *product* and preferably a marketable one. The student may not be assured of what would formerly be termed an excellent graduate education, but he is more or less guaranteed a well-paid job at the end of the road. In some instances, if the entrepreneurial company is remote from the campus at which the professor is nominally employed, the academic chair which he is expected to occupy may be vacant much of the time. Science gives way to technology, research to development and publication to patent. Lip service, of course, is still paid to basic research, but clearly the product is the thing. For what is an entrepreneurial company without a product?

The prognosis for this epidemic is, at present, unfavourable. So far no treatment for the disease has been forthcoming; and whereas measures to prevent its further spread can be imagined, no one seems to have the strength or the authority to impose the rigid quarantines that would be necessary. Readers of the *Arabian Nights* may recall what happened when, inadvertently, the genie was allowed to escape from the bottle. Having allowed the venality gene to escape, we cannot foresee how the matter will ever be put right again.

Turkish rights

SIR — As a foreigner who has studied and taught in Turkey for about eight years, I found your version of Dr Ögelman's case lacking rationalism and credibility (*Nature* 25 February, p.638; 18 March, p.186).

I was a member of the faculty of the Middle East Technical University at Gaziantep during the academic years when the internal political strife and violence on the Turkish campuses and in the streets was at its peak. It is no secret that some of the faculty at our campus, and indeed at every other campus, were openly involved in supporting the extreme right or left. As a matter of fact, during those days it was almost impossible and certainly very dangerous not to take sides, which meant inviting the wrath and enmity of both sides. At our university, where the leftist students and the faculty had the upper hand, anyone trying to be neutral and reasonable was branded as a fascist, which made the foreign faculty members, like myself and other North American and West Europeans, very vulnerable and insecure. My office and classroom were heavily pelted with stones for just beginning a lecture on the date when some leftist student had been jailed or hanged in the past. There were daily incidents of bombing and stabbing inside and outside university campuses and everyone lived in an atmosphere of terror.

Active collusion of a part of the faculty with the criminal elements of both the right and the left frustrated the efforts of the university administration to bring about normalization. The police, who could not enter the university premises without prior authorization from the university, usually waited outside as passive and helpless observers while mobs of unruly students of a majority group kept the other students outside the university grounds.

I am neither familiar with the facts of Dr Ögelman's case nor is it my intention to defend the policies and/or practices of the Turkish government. It is, however, a known fact that Cukorova University, which was only a couple of hours drive from us, was the scene of repeated violence and had to be shut down frequently. You state that "Dr Ögelman has been prosecuted not because she is a physicist but because of her part in an organization intended to secure rights for women in a society in which these have recently been denied".

I am afraid that the basis of your above statement as well as your advocacy for the cause of freedom for the Turkish scientific community need to be re-examined objectively and impartially. First of all, the rights of the Turkish women are solidly entrenched in the constitution. I have made several inquiries here and no one seems to know what rights the Turkish women have been denied recently and how Dr Ögelman's organization is planning to restore those rights. In this connection, it would have been helpful if you had included the name of that organization also. From my own experience and knowledge as a resident of Turkey for almost eight years, I have no hesitation in saying that the Turkish women enjoy more rights and have far greater opportunities for advancement than the women of North America.

As a scientist living and working in a free society, I appreciate and support your efforts in publicizing the plight of fellow scientists under oppression, but such incidents must be presented along with credible evidence which, in my opinion, has not been done in Dr Ögelman's case.

M.H. SADAR

Middle East Technical University, Gaziantep, Turkey

SIR — Your article "Turkish illiberality" (*Nature* 18 March, p.186) is a completely erroneous interpretation of the liberality in Turkey today. Being the co-author of the research paper published in the same issue of your journal (p.231), I must protest strongly at your misinterpretation of the situation of people with limited freedom in my country. Above all, the fact that you equate the Turkish martial law authorities with the Polish and Argentinian martial law authorities has driven me to think that your long established, serious and scientifically respected journal is taking advantage of its position by resorting to cheap politics.

As you should know, Turkish women gained their rights in 1923 under the great leader Atatürk. The women's organization mentioned in your article has attempted to give a misleading impression of the Turkish community, which consists of wholly liberated women. Scientists are human too; they can commit wrongs and rights, and can be condemned or set free.

The martial law authorities in Turkey have not limited liberality and democracy, but on the contrary have created an atmosphere of pleasantness and friendship between people who were enemies before the present regime took power. Above all, their existence has eliminated anarchy and its fatal consequences.

Adana, Turkey

SCIENCE IN WEST GERMANY

Discovery and disappointment

THIS year is a turning point in the development of science in West Germany since the Second World War. For one thing, this will be the first year in which government support for scientific research will not increase in real terms. For most agencies, the shortfall is not serious. In deutschemarks, indeed, budgets will be bigger, perhaps by four per cent. If inflation turns out to be six per cent, the real decrease will be a mere two per cent. But inflation could be greater than that, while, as people elsewhere know, official retail price indices are not an accurate guide to the cost of scientific work.

The budget cuts, although unimportant in themselves, are nevertheless symbolic of questions that have arisen in many minds. In the past three decades of heady prosperity, both the federal and regional governments have backed research generously, and for two reasons: the restoration of German scholarship is as necessary as the restoration of the economy and then, of course, science is an important source of innovation and thus a kind of guarantor that the economic miracle will not fade. So if even the West German economy can be driven into recession, may it not have been a miscalculation to suppose that investment in research would keep economic growth alive? The logic is not very sound, but the question, once asked, cannot easily be suppressed.

To politicians, the question takes the form "Are we getting value for all that money?" Their officials are responding with an energetic campaign to assist the process of "technology transfer". A few spectacular successes could make future budgets safe. But the question echoes another which the scientific community in West Germany seems also to be asking: How well are we doing, anyway? After all these years of effort, why is the United States the place where most of the interesting discoveries are made? Is something wrong?

The most surprising impression left by talks with a variety of scientists and officials is the tentativeness of science in West Germany. People seem to spend an alarming amount of time looking over their shoulders or trying to devise criteria for telling how well they are doing. (Nobel prizes per head per year? Mentions in *Science Citation Index*?) In reality, such lack of confidence is entirely inappropriate. West Germany is not merely crammed with scientific enterprises of various kinds, many of which are internationally known, but the sheer scale of the West German enterprise is breathtaking. Yet even if the state of mind is paradoxical, the reasons why it has arisen may be of absorbing interest.

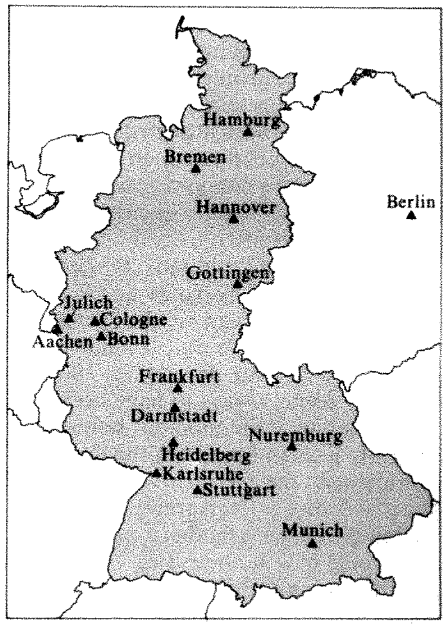
The brief survey of the state of science in West Germany that follows must not be mistaken for a catalogue. It is based on talks with officials of the federal government in Bonn and a string of visits to universities, laboratories and institutions at scattered centres as well as on the lavish use of the telephone. One objective is to investigate an interesting phenomenon in a manner that may interest readers. Another is the hope that it may be easier in future for *Nature* to do justice to an important part of the international scientific community.

As will be seen, much of what follows is concerned with the mechanisms by which public funds are channelled into research in West Germany. For all kinds of reasons but not least the interaction between the federal and the *Länder* governments and the federal government's constitutional compulsion to delegate decision-making to virtually autonomous bodies such as the Max-Planck-Gesellschaft, these mechanisms are more interesting than almost anywhere else. One consequence is that part of the scientific establishment has been able to capture part of the government's machine, and to use it itself.

Especially in these circumstances, why should there be such a general air of self-conscious uncertainty? (One explanation is that the responsibility is almost too great, but few agree with that.) The first thing to say is that these doubts crop up only in places where the objective is basic research, and where people *might* hope to win Nobel prizes even with the restricted definition of science included in Nobel's will. The people in the engineering school at Aachen know they are doing a unique job superbly, and have no recognizable self-doubt. (Chasteningly, one of them also asked "What is this journal *Nature*?")

Nomenclature

THE Federal Republic of Germany (*Bundesrepublik Deutschland*) is referred to throughout as West Germany so as to avoid the use of some set of initials (for example, FRG) that does not translate into German. The German mark (abbreviated as DM) is the unit of currency except when inappropriate. DM1 = £0.24 = $0.43 approximately. People's formal German titles are abbreviated by the omission of references to first degrees (for example, *Dipl.-Ing.*) and by the use of one or other (but not both) of the titles Professor and Dr. Place names are given in the English form when the German names cannot easily be pronounced by English speakers (for example, Munich, Cologne) but Hannover is spelled with two ens, as it should be.



So does the self-doubt have something to do with West Germany? That would not be a surprise. Although well over half of those now living in West Germany were born after the end of the Second World War, the economic miracle has tended to obscure the plain truth that West Germany as it now is was cobbled together by the three Western occupying powers in the late 1940s, became a fully sovereign state only in 1955 and gave up all hope of unification with its other half only in the late 1960s. And there remains West Berlin as a reminder to all who care to notice that the problem to the East was never resolved as intended at the Potsdam conference in 1945. As it is, three hours' driving (West German style) will take you from the Dutch border at the Ruhr to the eastern border near Braunschweig. From Göttingen, further south, you can walk to the border and back within the day. And if such circumstances fail to remind the young that West Germany is a living piece of suspended history, like a fly in amber, there are always people ready to remind them. One young woman in a Hannover restaurant asked whey she had *still* met so much rudeness on a recent visit to Britain. Who knows how to quantify the effects of this on people's confidence at the bench?

More particular versions of this question inevitably arise. What for example were the consequences of the exodus from German universities in the 1930s? And of the Catch-22 trick that in the 1930s encouraged public servants such as university teachers to join the Nazi Party and then, in 1945, denied public service to former Nazis? The result was that the post-war cohorts of undergraduates, now of an age to be laboratory directors, were mostly taught by people who had been unwillingly conscripted into military service. Again the importance of this effect cannot be quantified; the pages that follow will not

0028-0836/82/210261-02$01.00

attempt to answer the implied question.

One startling comment on this conundrum, from an older scientist, is nevertheless worth recording. The exodus should not have mattered, the argument goes. For the people who left during Hitler's time, Einstein and the like, were people who had been attracted to pre-war Germany from countries such as Switzerland, so that their disappearance mostly to the United States should in eugenic terms be strictly irrelevant.

Historically, and culturally, the first half of this century may come to seem an irrelevancy. For can it be simply a coincidence that West Germany has finished up a latter-day replica of what Germany seems always to have been — a confederation of autonomous states, as in the Holy Roman Empire of the thirteenth century and the German Confederation that followed Napoleon's defeat? Certainly neither Hamburg nor Munich now would have it otherwise.

Other manifestations of historical continuity keep cropping up. The past decade's spate of social legislation? Merely an extrapolation of the Weimar Republic's attempt to codify the liberally-paternalistic practices of the mediaeval German princes and their successors, the joint-stock companies of the nineteenth century. Legalism, obsession with laws and their interpretation? But that's straight from the Romans, and anyway you cannot feel free until your freedom has been defined. The tendency towards ideology (purpose shaping action) that prevents those who hold to the concept of the interdependent society from breaking into each other's cars but which tempts a small minority along the Bader-Meinhof path? If Calvin's reformation (when Geneva was still part of Germany) caused such trouble, it could not now be seemly to accept as colleagues people whose motives are misguided, whatever their other virtues (see page 264). And scholarship? Even now, in 1982, few can take up that subject without referring to Wilhelm von Humboldt, the founder (in 1810) of the University of Berlin, who at the same time put out the then-liberal and now supposedly-effete message that good research begets good teaching. Evidently the Third Reich might never have happened. And the West German universities have splendidly played their part in fostering this sense of historical continuity.

But for how much longer? It is clear that opinions in West Germany are deeply divided about the wisdom of what has been done to the universities in the past decade or so. Inevitably, the pessimists are more vociferous than the optimists, but they seem also to have the stronger case. So no apology is needed that much of what follows reflects the anxieties of those who are alarmed at the consequences of reform.

This survey has been compiled by John Maddox with assistance as indicated.

Will the miracle come back?

WHATEVER happened to the West German economic miracle, the phenomenon by which in the 1950s Chancellor Konrad Adenauer and his economics minister, Ludwig Erhard, arranged that West Germany should become the most prosperous of all the states of Western Europe? The most comforting answer is that the economic miracle is still there, just waiting for the long recession to end.

This is probably half true. Economic growth and large trade surpluses persisted throughout the 1970s, while other Western economies were already faltering. Only in the past two years has the growth stopped. Unemployment (once negative in that West Germany in the early 1970s relied on an estimated 2.3 million "guest-workers" for its labour force) had begun to rise in 1973, and is now heading for 2 million. And inflation, somewhat exaggerated by the West German retail price index at an average of 6 per cent a year in the 1970s, has now begun to increase. At least part of the trouble is that West Germany has at long last been affected by the stagnation of international trade in the manufactured goods which constitute some 47 per cent of the country's export trade.

Nobody, however, believes this to be the whole story. For one thing, there is the cost of oil and natural gas, almost all of which has to be imported. Although conservation measures have had a substantial effect on petroleum imports (down from 98 million tonnes a year in 1974 to just over 90 million tonnes a year now), the cost of oil and gas is between a sixth and a fifth of West Germany's import bill. This charge on the economy is not going to go away.

People in West Germany are more alarmed, however, by what seems a sinister threat to future prosperity — the challenge from Japan. The days have long since gone when Volkswagen's beetle swept the world. Now the beetle's successors have to compete in the export markets with cheaper but still well-engineered products from the Far East. The same is also true in electronics. And for other reasons, the West German chemical industry — the other foundation of the post-war export trade — has faltered, financially shackled by expensive investments conceived of when economic optimism was the order of the day. So everybody is convinced that there must now be a new period of creative innovation in West German industry. "Technology transfer" is the slogan. Science may be one of the beneficiaries.

Much less often, people also worry about the possible consequences of the past

Briefing

WEST GERMANY is the quintessential federal state. Its existence springs from the decision of the three Western occupying powers (France, the United Kingdom and the United States) in 1947 that a measure of self-government should be permitted in the west of the country pending agreement on German unification. The "Basic Law" (*Grundgesetz*) adopted at Frankfurt in 1949, for practical purposes the constitution of West Germay, reflects the insistence of the occupying states that political power should as far as possible rest with the regional (*Land*, pl. *Länder*) governments. (West Berlin is an eleventh *Land*, but has a special status.)

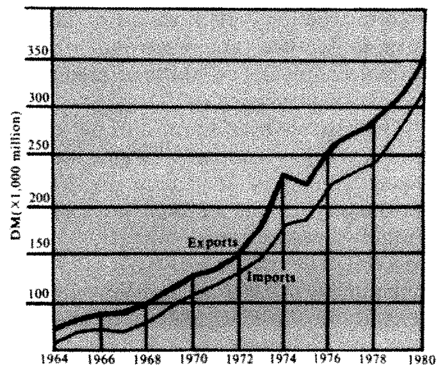
The basic law provides a complicated system of checks and balances by which the powers of the federal government are constrained. The power to take on tasks (such as research) not specified by the basic law requires a formal treaty between the federal and the *Länder* governments. The second chamber (*Bundesrat*) of the federal parliament consists solely of representatives appointed by the *Länder*. The federal constitutional court (*Bundesverfassungsgericht*), based at Karlsruhe, interprets the constitution on demand, and can overturn legislation deemed unconstitutional while also considering, for example, appeals by students against examination results.

The partition in 1945 of Germany and its consequences (east-west migration) have left West Germany with just over two-thirds of the total area (excluding the parts of Germany transferred to Poland in 1945) but four-fifths of the population (now 61 million).

The post-war history of West Germany has been shaped as much by the economic miracle of the early 1950s as by the almost continuous wrangle about East-West relations. Starting from an admittedly low base, for the best part of a decade the West German economy grew faster than any other in Western Europe. Now the Gross National Product is close on US$10,000 per head of population, close to that of the United States.

Since 1969, the federal government has been formed by a coalition of the Social Democrats (SPD) and the Free Democrats (or liberals), with Willy Brandt and Helmut Schmidt as successive chancellors. Now, however, there are signs that the coalition's hold on the federal government (and the cohesion thereof) is weakening. The Chancellor has had trouble within his own social democratic party on nuclear policy (civil as well as military), while the coalition has begun to lose control of some *Länder* governments. The election in Hesse (capital Frankfurt) in September is likely to be crucial to the coalition's future (and to its capacity to govern effectively between then and the *Bundestag* election still two years away).

0028-0836/82/210262-04$01.00



The increase (in actual values) of West Germany's exports and imports. The major exports are all types of machinery, motor vehicles, electrical engineering and chemical products. Major imports are food, drink, tobacco, petroleum and natural gas.

decade and a half of social reform introduced by the Social Democratic Party (SDP). Certainly the past few years have seen a substantial increase in social transfer payments by the federal and *Länder* governments for such things as pensions, student support and unemployment assistance (and the high cost of these statutory payments when tax revenues have been reduced by the recession is the immediate cause of the economies now being enacted throughout public administration). But there is no sign that the SPD government's reforms have in any way impaired the efficacy of the market economy which has been the engine of economic success in the past three decades. Thus the statutory extension in 1976 of the rights of workers to participate in management decisions (at a time when even a British Labour government failed to make headway towards similar objectives) is said even by Christian Democrats to be but a continuation of a tradition going back, in West Germany, to the 1920s.

But may not people's attitudes have changed? The economic miracle was a heroic time for West Germany. People rose to the challenge. Now, some fear, affluence has made the younger generation work-shy, from which point of view the activities of the "greens" (politically active environmentalists) is akin to sabotage of the West German dream. Such gloomy after-dinner musings are probably mere speculation. That they are offered at all as serious contributions to the question of what the future holds is a measure of the extent to which the economic miracle lies in the past. □

Universities reformed to death

By spitting out a peppermint in a dental surgery, does a dental student demonstrate such an ignorance of simple hygiene as to be unqualified for his profession? Last year, after an angry scene with such a student, a member of the dental faculty at Munster took this view, and said that a final examination should be retaken. But the local appeals court has now decided in favour of the student.

This solemn affair illustrates one of the common complaints of academics in West Germany. Legal interpretations of the public duty of academics (who are public servants) take precedence over research and teaching. But of the thousands of suits brought against the universities each year, most come from would-be students seeking to prove that they have been wrongly denied a place.

So what has become of the "Humboldt university", that community of scholars willing to share their learning with anybody who chose to take part? The embittered say that the classical German university has been killed off by the sequence of reforms to which the West German system of higher education has been subjected in the past fifteen years. The reformers agree that the system is still in turmoil.

The underlying trouble is that West Germany has sought to reconcile several irreconcilables — the principle of open access to any university in the country, the doctrine that all universities are equal, the practice that universities are run by the ministries of culture in the *Länder* in which they happen to be sited and the phenomenal increase in the demand for higher education in the past twenty years. Add the West German conviction that the law is the law is the law, and the plain fact that the reforms, consisting as they do of formal agreements between the federal and the *Länder* governments, are public legal documents, and you have a recipe for muddle, even chaos.

Historically, this mess was preordained, After the twelve years of incivility that ended in 1945, what can have been more natural than that the few surviving academics and the army of their would-be successors should have set out to recreate the Humboldt university, with all its blinding virtues and glaring faults?

The principle is admirable. The university is a community of scholars supported by the state (*Land*) as if it were an opera company. The scholars or professors (*Ordinarien,* sing. *Ordinarius*) *are* the university but each year they elect one of themselves (the *Rektor*) to be their head. As public servants, their duties are spelled out (for example, to lecture eight times a week) but they negotiate their salaries with the *Land*'s appointed bagman in the university, the Chancellor. He and not the *Rektor* also decides each professor's allocation of assistants, research expenses, janitors and capital costs. Students do not explicitly enter these calculations. The bright or pushy become unpaid laboratory assistants ("learning through research"). The others move on elsewhere, looking for something more congenial.

This system, which made possible the flowering of German scholarship at the end of the nineteenth century, is obviously open to abuse. Well-favoured professors may acquire delusions of divinity, and may tyrannize their assistants. And since even among scholars, rivalry and even jealousy may from time to time occur, professors in related fields and their respective entourages, organized into separate institutes, may occasionally behave like warring empires.

Great men and good universities usually managed to avoid such dangers. But the universities recreated after the Second World War were faced with a rapid growth in the numbers qualified to be students. By 1960, it was plain that the then-existing universities could not be expanded indefinitely, and that new institutions would be necessary. With Nordrhein-Westfalen in the lead, and with the promise of financial assistance from the federal government, the *Länder* set out to create new universities more or less in the image of the old. But the pace of construction was insufficient, and the replication of universities in the existing pattern could not meet the needs of society, let alone of students.

So what was to be done? By the mid-1960s there was a fierce argument between those represented by Professor Ralf Dahrendorf (then at Cologne, now director of the London School of Economics) who argued that there should be institutions equipped to provide vocational tertiary education (and shorter and more structured courses all over) and those who sought a more radical change in the structure of the university while preserving the cherished notions that all universities are in principle equal and that qualified students may study where they like.

The argument, unfortunately, did little to help the universities overwhelmed by students, some of which began to operate a *numerus clausus* rule — students should be turned away if there were already too many of them in the university or some part of it. This offence against the doctrine of free access was held to be an infringement of people's constitutional right to follow the profession of their choice. The operation of a quota system now, in fields such as medicine and veterinary medicine, is one of the chief sources of litigation by would-be students.

The second wave of expansion in higher education that began in 1970 appears to have given something to both parties in the earlier argument for reform; technical colleges of various kinds, traditionally means by which the graduates of non-*Gymnasium* high schools acquired a vocational education, were enlarged, upgraded and called *Fachhochschulen.* And the new universities established after 1970 (often built around pre-existing technical or teachers' colleges) were "comprehensive" in that they offered courses of frequently vocational study,

A conservative opinion on reform

THE universities are intrinsically conservative, so how can "reform" imposed from outside fail to damage them? This was the gloomy lament of *Rektor* of the University of Munich, Professor Nikolaus Lobkowicz, on the day last month when he had just handed in his resignation to the Bavarian government after being voted out of office.

A touch of bitterness would in the circumstances have been forgivable; that university rectors should be elected every four years is laid down in the federal reform law for higher education. But that suspicion is too dark. Professor Lobkowicz is a political scientist born in Czechoslovakia who has spent most of his working academic life in the United States. His description of himself as a true conservative is relevant.

The University of Munich is the biggest in West Germany, with 45,000 students or thereabouts. Bavaria is the stronghold of the Christian Democratic Union and, Lobkowicz thinks, the *Land* made a tactical mistake in 1969 by trying to preempt the federal law then being hatched by making one of its own. Bavaria overlooked its own long-standing tendency towards "preposterously perfect" legislation.

Lobkowicz — eloquent on reform

Legalism has run riot. In one recent year, the university awarded 1,100 doctoral degrees but had to fight 1,300 court cases, most of them brought by students contesting examination results. Occasionally, the university takes the government of Bavaria to the Constitutional Court in Karlsruhe.

The bureaucracy, the *Rektor* says, is palpably a pain; the damage done to academic standards cannot be as easily assessed. But surely the old system, in which holders of a university chair (*Ordinarien* in the old nomenclature) were treated as gods in their departments, was capable of corruption? So what? is the surprising answer. "Who says that corruption excludes excellence?"

The most serious of the present dangers in Professor Lobkowicz's opinion is that the new system for appointing people as professors of one of the Western world's great universities will ensure that they are "smooth" people, first of all electable and only secondarily capable of scholarship. The drill now is that the senate instructs the *Rektor* to submit a list of three nominees for each professorial appointment to the *Land* government, in order of the "soviet's" preference. (Students and other ranks are represented on these committees, but professors have a majority.)

The minister knows that there will be a row if he fails to appoint the first name on the list, but apparently there have been occasions when a discreet telephone call has persuaded him to take the risk. One of Lobkowicz's own regrets is that he failed to persuade his fellow academics to appoint as an honorary professor a distinguished Marxist philosopher "with whose every word I disagree" but who might have been good for the university. Reform, says Lobkowicz, has made the world safe only for the safe.

The result, he says, is that both scholarship and the scholarly professions have been debased. The great teachers of the old days have been replaced by people on the hunt for material with which to embellish their *curricula vitae*. And the days have long since gone when it was reckoned better to be a university professor than a bishop. So university teaching has become less attractive to bright people, those left are reluctant to welcome colleagues who may be brighter than themselves — and the brightest students are in any case persuaded to opt for courses of study to which entry is restricted, medicine for example.

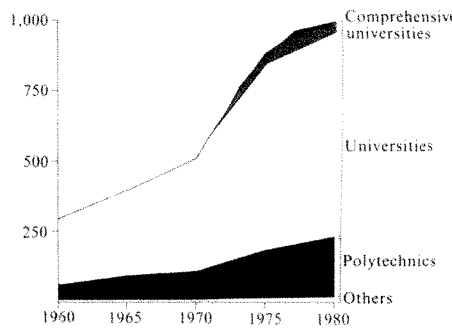
On the state of West German science, Lobkowicz is more puzzled than dismayed. Nobel prizes or the purchase of foreign patent rights are poor criteria of success, he says, while the prevalent academic convention to despise the popularization of scholarship has removed academic scientists from intelligent appraisal by their fellows. He notes the growing tension between university teachers and those working in Max Planck institutes, who have more time for research. He agrees that young people returning to West Germany from a successful spell in, say, the United States tend to lose their sparkle once back at home.

The explanation? The bureaucracy engendered by the reform. Yet Munich has been lucky in its minister of culture — it has dutifully "integrated" the *Pädagogische Hochschule* and only one department has been "ruined" in the process.

Why not, then, reform the reform? The outgoing *Rektor* is despondent even about that. For an amended law would be even more detailed than the present, allowing more scope for legalism. But Lobkowicz says that he differs from his colleagues elsewhere in this opinion and he insists that his is a conservative view. It is, however, eloquent and influential.

used instructional methods other than the formal lecture yet awarded degrees formally equivalent to those offered by the pre-existing universities.

The cap has been set on this pattern by the federal government's "frame law" on higher education, a general prescription for the ways in which *Länder* governments should organize their universities made constitutionally possible by the amendment in 1969 of the West German constitution, which permitted collaboration on "common tasks" between the federal and *Länder* governments on



Student registration in higher education in West Germany from 1960 to 1980 (in thousands).

matters previously reserved to the latter. One objective of this tortuous piece of legislation is the removal of the opportunities for abuse in the classical German university. Departments rather than professorial chairs (*Lehrstühle*) were decreed to be the "basic organizational units", *Rektors* were to be elected for four years rather than one, staff vacancies were to be advertised, and so on.

The crucial and controversial part of the frame law, however, is the declaration that

> . . . the different types of institution of higher education shall be brought together to form a new system of higher education. Institutions shall be extended or merged to become comprehensive universities or, while retaining their legal autonomy, shall be linked together by the establishment of joint bodies to form comprehensive universities. Where it is not, or not yet, possible to establish comprehensive universities, cooperation between institutions is to be assured.

The zeal with which these principles have been prosecuted varies from *Land* to *Land*. Although the deadline for decision specified in the act was 1979, the system is still in flux. Observers from outside must marvel at the confusion that results. Here is one list of what seems to be awry:

- A university cannot match student registration to its capacity to teach unless the *Land* government has formally declared a shortage of capacity, in which case only the Central Office for the Allocation of Study Places can decide which students shall be taken in. In practice, quotas apply principally in medicine and related courses. The law specifies that two-thirds of the available places should be allocated according to

grades in high-school leaving examinations, but the number of years spent waiting for a place should count in the allocation of the remainder.

- The time spent by universities and their academics in providing information about the way they spend their time (essential if a university is to defend itself against law suits brought by students who argue that they have been turned away when they could have been taken in) is an intolerable intrusion that makes the "effort reporting" required of grant-holders in the United States seem benign.
- While entry to restricted courses is to some extent determined by school-leaving grades, the recent reform of the *Abitur* system makes possible a degree of specialization at school, but there is no means of linking that with the course chosen at university; whence the complaint that school-students plump for easy options when their real aim is to enter a medical school.
- The attempt to modernize the content of university courses, and to ensure national uniformity in deference to the conviction that a degree is a degree (or that all universities are equal) and to ensure transferability from one place to another has the predictable effect of increasing the duration of students' courses, now more like six years than the minimum four. (Students' grants, a liability chiefly of the federal government since 1972, run out after five years.) Yet students' preferences for the older universities suggest that they do not regard the universities as equal, so the newer universities are, through no fault of their own, under-used.

The consequences of all this for the conditions of the research enterprise are only indirect. The mechanisms for financing research in universities are enlightened (see below), and almost entirely in the gift of the research community itself. But in the universities that remain popular with students, the teaching load has become intolerable (research during vacations only), and the nature of academic life has changed in such a way that people are likely to find the Max Planck institutes even more seductive than they already are. Doubts persist about the way in which students are being taught.

The past few years have, however, seen a more immediate problem. The federal and *Länder* governments, linked financially together by the taxation system, are being forced to live within their means. In many places there is a moratorium on filling academic places, and a 7.5 per cent reduction of all public posts is likely by 1986.

In Nordrhein-Westfalen, the spearhead of educational expansion in the 1960s, the problem is more acute. By being first in the movement to establish comprehensive universities, the *Land* has saddled itself with educational facilities still under-used, as well as with institutions such as the great medical school at Aachen (see page 267) whose future must be problematical. The result is that the word went out from Dusseldorf (the state capital) at the end of March that there must be reductions of the scale on which the traditional universities operate. In a form reminiscent of what has been happening in Britain in the past few years, the Minister of Culture has recommended that this or that department must be closed. The University of Bonn, now bursting at the seams with 35,000 students (including 5,500 law students) in buildings fit for half that number, has been told that it must lose part of its teacher training programme, and its institutes of egyptology and Scandinavian studies. Dusseldorf's immediate target is to save 400 jobs at Bonn. Nobody knows how many of those posts are intended to finish up at places such as Aachen. Indeed, it is still possible that the overcrowded universities will be able successfully to resist what Dusseldorf has in mind. If the issue is settled before the mid-1980s, when the falling school rolls will have worked their way through to higher education, giving some relief to the overcrowded universities, everybody will count himself lucky. □

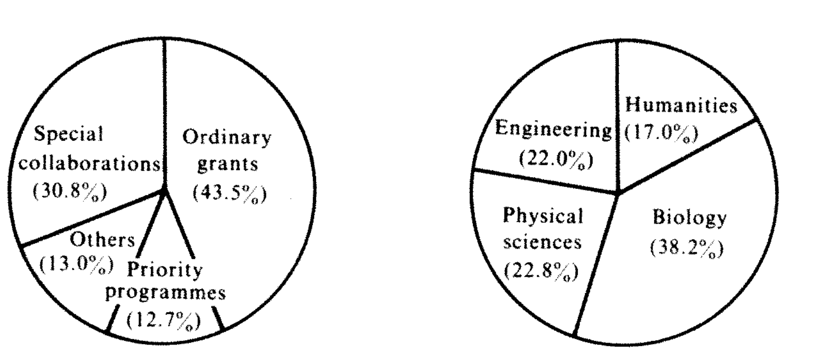
Where to get research grants

PLURALITY is most academics' defence against the peer review system, but not in West Germany. For there is just a single agency for supporting research in higher educational institutions — Deutsche Forschungsgemeinschaft (German Research Society) or DFG. Curiously, however, this single organization is not the monolithic enterprise that might be feared; grant applicants speak well of what it does, even if university administrators complain of having to sign several identical pieces of paper for each grant application.

Part of the explanation for the respect accorded to DFG is historical. There has been a device of some kind for helping academics to carry out research since 1920, when Max Planck and Fritz Haber persuaded the then *Reich* to put money into such an enterprise. After the Second World War, DFG was formed by a merger of two similarly intentioned organizations as the result of a treaty between the federal and the *Länder* governments.

The legal constitution of DFG also helps. It is not a government agency but the strict equivalent of a "not-for-profit" organization in the United States or an operating charity (a company limited by guarantee) in the United Kingdom. And those responsible for its operations are not people but a motley collection of legally autonomous academic enterprises — many (but not all) of the universities, some (but only a few) of the national research centres and a sparse sampling of learned and scientific societies. The result is that even though the funds for DFG's operations come from the federal government and the *Länder* governments, which are all represented on various high-level committees, these same committees provide such a complicated system of checks and balances that the potential beneficiaries of DFG have a real sense of making policy, particular and general.

At the same time, DFG has many of the functions of what are elsewhere known as national academies. Thus it pays the West German contribution to bodies such as the International Council of Scientific Unions, looks after the exchange of scientists with other countries in Europe and elsewhere, worries about scientific libraries (and such questions as computerized information services), carries out studies at the behest of government and runs the "Heisenberg programme" — West Germany's device for helping people who would in other times walk straight into academic jobs but who are now, in a period of relative stagnation, kept waiting on the sidelines. It differs from a learned academy, however, in the scale of its operations — the budget is close on DM900 million — and in not electing people to any fellowship. Naturally, German culture being what it is, DFG looks after the whole of scholarship, both Protestant and Catholic, theology included.



Left: Expenditure by DFG (in 1980) on the various forms of grant support. "Others" includes central facilities, administration and so on. Right: Distribution of DFG grants (in 1980) between fields of research. "Biology" includes medicine.

0028-0836/82/210265-02$01.00

Another Catch-22?

THE West German government, a great believer in economically counter-cyclical devices, was among the first to introduce (in 1978) a scheme for catering for younger scientists for whom there would in normal times have been empty academic posts, but who in present circumstances are likely to be forced out of research. How well is this Heisenberg programme working?

By the beginning of 1982, 246 people had been awarded fellowships, which can run for five years. The scheme was devised by the West German Rektors Conference, is supported financially by the federal and *Länder* governments, and administered by the DFG.

Those elegible for support must be qualified (by means of the *Habilitation* process), for appointment as a tenured university professor. One striking proof for this necessity is the frequency with which visiting cards refer to this qualification, unknown outside West Germany.

However, the DFG is apparently not able to spend all the funds at its disposal for this purpose — enough for 150 new fellowships each year. The problem is that selection committees are anxious that those awarded Heisenberg fellowships should be people who could, without disgrace to themselves or anybody else, move into a university post should one become vacant. But those are also the people who are likely to be snapped up by Max Planck institutes, industry and, even in these straightened times, the universities.

What seemed, only a few years ago, to be an imaginative solution to a widely recognized problem has thus turned out to be another Catch-22.

As a grant-making organization, DFG does business in a variety of ways. At one end of the scale is the standard procedure by which academics can apply for research funds to employ research assistants, to travel abroad, to be freed from teaching and research for a year and even to prepare (over a period of no more than two years) for qualification as a full university professor (*Habilitation*). DFG spends close on half its budget on these activities, and makes more than 5,000 grants a year with an average cost of about DM80,000 each. Half of the cost is met by contributions from the *Länder* and federal governments.

As in Britain, grants of this kind are made on the assumption that university applicants already have access to the essential tools of research. Hitherto, the *Länder* governments appear to have been generous in this respect, partly from regional pride, partly because well-equipped universities are better able to compete for centrally administered funds. But DFG is alarmed at the signs that have become apparent in the past two years that many applicants are no longer able to satisfy their sponsors on this point. With misgivings, DFG is now paying for some equipment that it would previously have expected the university to provide; the fear is that too much of this will erode its capacity for making grants.

Larger projects are financed by different mechanisms. A group of researchers at a university can apply to be financed as a research group, and there is a "priorities programme" that enables groups of academics anywhere in West Germany to collaborate on a research topic considered by DFG to require special attention.

West German participation in the Deep Sea Drilling Project has been in part made possible by a priorities programme grant of more than DM20 million to a research plan coordinated by Dr Helmut Beiersdorf from the Federal Geophysics and Natural Resources Laboratory at Hannover, which involves some 36 investigators at 14 universities (most of whom have used DFG funds to buy equipment). More recently, nationwide collaborations on this pattern have been set up in gene technology and the mechanical engineering of miniaturization technology.

The most distinctive of DFG's mechanisms for supporting academic research is, however, the scheme for providing long-term grants to university departments prepared to concentrate their research in some specified field. This *Sondersforschungbereich* programme supports projects as different as the University of Bonn's continuing interest in radioastronomy (see page 274) and a variety of clinical projects scattered through West Germany. Since the beginning of the programme in 1968, about 180 of these special collaborative projects have found their way onto DFG's books. The scale of support appears to range from DM1 million a year or less up to DM12 million a year (for the marine construction project at Hannover), with the average cost at about DM1.5 million. Unlike DFG's other grant-making activities, the costs of this programme are not shared equally by the federal and *Länder* governments but, rather, are divided in the ratio 3:1.

While it seems that DFG has frequently brought such projects to an end, there has been a tendency over the years for the number of current projects to increase. But now DFG is constrained by a recommendation of the Wissenschaftsrat that these projects should not normally last for more than 12 or 15 years. With 40 current projects going back to 1968, the next few years will see rapid change. This is part of the reason why the theoretical mathematics *Sonderforschungbereich* at Bonn is being converted into a Max Planck institute. Elsewhere, some discreet renaming of research projects may be necessary.

At the Max Planck institutes, DFG operates a formal and stringent system of invigilation for deciding whether support for one of these special programmes should continue. Every three years or so, a team of people in the field spends two days interviewing the members of each collaboration, raising awkward questions about the inevitable gap between aspirations and achievement. The invigilators pride themselves on being tough.

Broadly speaking, DFG seems confident that, despite this year's interruption, its previously steady growth will soon be resumed. Between 1981 and 1982, the budget grew by just six per cent, the equivalent of inflation, but the prospect is that next year's budget will be only four per cent greater than now — an increase less than the probable inflation rate. The general secretary of DFG, Dr Carl Heinz Schiel, expects that DFG's budget will continue to grow at least until around 1990, when demographic change may imply that the university system begins to shrink.

As an essential component of what would elsewhere be called the dual-support system for the universities, perhaps the most immediate threat is that, as in Britain, regular support for the universities may be so cut back by the *Länder* governments that DFG's grant-making capacity will be undermined. Inflexibility is another difficulty. Because of the different degrees of the involvement of the *Länder* governments in DFG's general and special programmes, the transfer of funds from one part of the budget to another is constrained. Moreover, because new *Sondersforschungbereich* projects have to be approved in advance by the Wissenschaftsrat, speed cannot be assured nor political interference ruled out.

What seems most conspicuously to be missing from the pattern of DFG's activities is some mechanism for supporting substantial programmes of research by the younger members of academic faculties. The Heisenberg programme (see box) is intended to keep some such people in an academic orbit when they might otherwise be frozen out, but the needs of young and potentially daring researchers seem to fall between the two stools of modest individual support as part of the standard grant mechanism and the much larger programme grants in which large groups of people, many of them senior scientists, are simultaneously involved.

The consequence may be the explanation given by one academic molecular biologist, a member of one of DFG's research groups, for his fatalistic expectation that the next dramatic development in his field would be made by some American group. But why not you? "Well," he said, "our hierarchy is more rigid than theirs, we are less mobile and our communications with each other are less good." Add to that the teaching load, which keeps senior academics away from the bench except during vacations, and you have a recipe for being second. □

A little knowledge

If *wissen* means "to know", then *Wissenschaft* means "knowledge", and since German culture makes no distinction between different branches of knowledge, *Wissenschaft* accordingly includes "science" as one of its English meanings. But this English legend does not correspond with present usage.

A further complication is the use of the prefix *Natur* (meaning "nature") as a qualifier, for *Naturwissenschaft* means "physical science", as distinct from, say, the biological sciences (as in *Biowissenschaften*), but *Naturforschung* appears to mean scientific research of any kind. Confusion is not common, but appears to have led to the common practice of translating *Wissenschaftsrat* as "science council".

That unique institution, made necessary by the federal character of the West German constitution and set up in 1957, has a general influence on the development of the university system and the research enterprise in West Germany. The *Wissenschaftsrat* is a kind of constitutional rubber stamp. Its general assembly consists of two constituencies — one appointed by the federal government and one representing each *Land* equally — with equal voting power. There are also outsiders from universities and business who do not vote. Technically, the council is advisory to the federal and *Länder* governments. Recommendations require a two-thirds majority, which means that the federal government can have its way if four *Länder* support it.

For the first decade and a half of its existence, the council was creatively influential; and even now it would be imprudent of the federal government or one of its agencies to think of doing something new without the council's agreement. Thus proposals that public money should be spent on a new laboratory, or that some new university should be established, are at some stage cleared with the council.

The agenda for discussion has shrunk since the constitutional amendment of 1969 that gave the federal government a role in higher education. Even so, it retains a life of its own. In the past two years, it has for example argued successfully that the *Deutsche Forschungsgemeinschaft* (DFG) should not make long-term programme grants for more than 12-15 years (which advice appears to have been taken seriously). The council was more recently influential in the decision that the new Alfred Wegener research centre for polar research should be located at Bremen rather than at Kiel.

The most accurate translation of the council's German name may therefore be "the council for the politics of scholarship".

Aachen's other cathedral

THE great *Klinikum* of Aachen stands in relation to the city at which Charlemagne was defeated as did the opera house to Sydney a decade ago: it is too soon to know whether it is one of the wonders of the modern world, a white elephant or both. But the now-estimated cost of DM 1,700 million of what may yet become the world's most gargantuan teaching hospital has already so cramped the budget of Nordrhein-Westfalen that the repercussions will be felt next October in all the *Land*'s universities from Bonn to Bochum.

Like Aachen's cathedral (probably the loveliest of them all), the *Klinikum* lies in a hollow but towards the west of the city, within sight of the Belgian and Dutch borders. Like all cathedrals, the *Klinikum* is huge, with a usable physical capacity of 130,000 m^3 and a gross volume (including air-conditioning plants and the like) of half as much again. If ever completed, it will house 10,000 people, including 1,500 patients, 2,500 medical students and up to 500 dental students. Like many mediaeval cathedral projects, the *Klinikum* has been plagued by subsidence — some parts of it have sunk by as much as 5 cm.

Like any cathedral, the *Klinikum* is the physical expression of somebody's vision — in this case, that of Mr Hans Wertz, once financial controller of the city of Aachen, who, when finance minister of Nordrhein-Westfalia in the early 1960s, appears to have wished on his native city and on the university (the Rheinisch-Westfälische Technische Hochschule) which the *Land* "owned" there, the promise of a building in which physicians could make their dreams come true, together with an accompanying blank cheque.

Although RWTH, as it likes still to be known (see page 275), now seeks to distance itself from the huge cost of the *Klinikum*, at the outset it was a willing accomplice.

This distinguished institution, best known for its contributions to the health and wealth of the West German machine-tool industry, acquired a medical faculty only in 1965, three years before the notion of the *Klinikum* was hatched. Even academics would have known that most other universities with medical schools could largely finance them from the payments made by the insurance companies with which West German workers are compulsorily insured.

During the past fifteen years of construction, the dream has faded in several ways.

- The hope that the Aachen *Klinikum* could become a truly European hospital, drawing patients from Belgium and the Netherlands as well as West Germany, has been frustrated because insurance companies' payments are no more transplantable now than in the 1960s (and because the Dutch have closed their border since terrorism became rife).
- The discovery that the infective organisms of legionnaires' disease flourish in the humidifiers of air-conditioning plants has made it necessary to modify the design of the large single plant.
- There was a successful prosecution in 1976 of a suit in the West German courts by complainants holding that work-people should not be required to spend more than four hours a day in rooms without windows. The result has been a three-year delay while the architects, Weber, Brand and Partners of Aachen, arranged that the internal partitions between the 6,600 rooms of the largest of all man-made caverns should be replaced by glass (which has, in turn, often been covered by venetian blinds).
- The main contractor for the *Klinikum*, the non-profit organization *Neue Heimat Städtebau*, set up as a cooperative of labour unions in the construction industry, has been involved in a generalized upheaval so widespread it may yet turn out to be the biggest socio-political scandal in the short history of West Germany. (The investigating commission has not yet reported.)

The result is that the *Klinikum*, surrounded by between 5 and 10 square kilometres of still-empty car park, remains unused. But the building is already being

Inside Aachen's great Klinikum *— but will the patients come?*

0028-0836/82/210267-02$01.00

used for teaching physiotherapists and it is hoped that 80 third-year dental students will arrive in October.

Academics on the Nordrhein-Westfalia payroll half snigger when asked "Why did you let this happen?" "Nothing to do with us", they say, "and anyway the *Klinikum* at Munster also cost a packet". But responsibility does not all lie in Dusseldorf. The university senate was willing enough to take over the city *Klinik*, offering to turn it into a medical school. The architects at Aachen were given not merely an opportunity to build a latter-day cathedral but a chance to try out a theory — the belief that construction and planning could proceed simultaneously.

Some of the immediate consequences are absurd. The new medical faculty is having to teach in the old *Klinik*, now hopelessly run down. And as the day approaches when the hospital may have real patients, perhaps in 1983, the university is alarmed that the *Klinikum*'s history (and appearance) will frighten off the patients from whose health insurance policies the operating cost must come.

The *Klinikum* is thus a monument to the economic optimism of the 1960s. Of the three medical centres then planned by the government of Nordrhein-Westfalia for its bemused and then fast-growing university system, that at Munster has been completed and that at Essen abandoned. And nobody knows whether West Germany needs all the physicians now being trained, some 5,000 a year. □

Where the power lies

IF there is a power centre in the federal government, with sway over the conduct of science, it must surely be the BMFT. It has a bigger budget than the education ministry, a more personable minister (Dr Andreas von Bülow) and a cleaner brief: spend money and make things happen. BMFT also finances the Max Planck Gesellschaft (see below), the most powerful but the most contentious basic research enterprise in West Germany. The trouble, unfortunately, is that not even the BMFT is as free as it likes to think.

Part of the problem is that the ministry is a tiny organization (and nine of that small number of posts were abolished when last autumn's draft budget was revised in February this year). Taxpayers paying taxes outside West Germany would be alarmed at the prospect of entrusting such small groups of people with such large sums of money. They would also be surprised to learn how civil (in the sense of being open) civil servants become when saddled with the responsibility.

Another part of the problem of telling where the power lies is how that power is distributed. The *Länder* governments have a lot of it. So too do the committees that have been given some kind of constitutional blessing by means of formal agreements between the federal and the *Länder* governments. Although the influence of the *Wissenschaftsrat* has declined since 1968, its formal recommendations must still be considered.

People also matter. West Germany being the place it is, a speech by some establishment figure, say the president of the DFG or of the Max Planck Society, will carry a great deal of weight. West Germany's preoccupation with the quality of research stems from a public speech by distinguished people who have left the public service and then made their misgivings public.

So science policv is determined in West Germany much as elsewhere, by accretion. The civil servants will defend the existing budget, but will leap at whatever opportunities for innovative expenditure are approved of by the councils of wise men.

Thus the BMFT is the sponsor of West German interests in space, energy, information technology, marine and polar research, while through its sponsorship of the national laboratories (see page 279) it is also directly responsible for much fundamental research, especially in particle and plasma physics. From one year to the next, it is possible to add or subtract relatively small amounts from these large programmes — this year, for example, an extra DM12 million for biotechnology (a 28 per cent increase) and an extra DM40 million for information technology (a 42 per cent increase on last year). More radical changes would be difficult. □

Centres of excellence

THE Max Planck Society (Max-Planck Gesellschaft zur Förderung der Wissenschaften) is internationally the best-known of all West German research organizations. *Everybody* knows *somebody* working at one of the 49 institutes scattered through the country. And that is one of the most frequent complaints about the society: if anything, the "Max Planck" is too successful, providing scientists with opportunities for research far better than those at the universities, for example.

But this is inevitable, given the constitution of the society . Historically, it is the post-war replacement for the Kaiser Wilhelm Gesellschaft, the organization established in 1911 whose Berlin institute provided Einstein with a base in the 1920s. The underlying objective is frankly elitist — to provide distinguished researchers with resources sufficient to support a group of younger colleagues, and to provide all concerned with the security and the equipment necessary for high-quality research.

On many occasions the Max Planck institutes have amply justified their founders' faith. The institute of biophysical chemistry at Göttingen for example, is where Professor Manfred Eigen's use of pulsed lasers pointed the way to novel techniques for following fast chemical reactions (and won a Nobel prize).

Flexibility is plain. The Göttingen institute has grown to the point at which there are nearly 400 people, many of them visitors from overseas, while the research programme has diversified enormously. This illustrates the Max-Planck contention that once an institute has been established, those in charge are within reason free to follow their changing interests.

Elsewhere, new institutes seem to spring up by mitosis. Thus the clutch of physics institutes at Garching, near Munich, can be traced back to the unique arrangement by which Professor Werner Heisenberg's Institute of Physics was financed in the years immediately after the war. By a succession of fissions, there are now for practical purposes five descendent institutes, one of them the huge plasma physics institute (see page 271) and the others concerned with physics, astrophysics, extra-terrestrial physics (see page 274) and quantum optics.

The Max-Planck Gesellschaft claims also to be vigilant in bringing institutes to an end when they have outlived their usefulness. Again (as with DFG) there is a system of formal invigilation every two or three years, with scientists from elsewhere included among the visiting party. But the list of casualties among institutes is not long — five have disappeared since 1948, while the thriving coal research institute at Mülheim (in the Ruhr) has become virtually self-financing by means of contract research.

While some Max Planck institutes are from time to time riven by internal disputes deriving from the way in which the direction of the larger institutes is the collective responsibility of senior people — the radioastronomy institute at Bonn seems to have been unlucky in this respect — the most obvious danger is that a group of people who age together will become less sparkling than at the outset of their enterprise. Proof is necessarily hard to come by, although Dr Dieter Raft, general secretary of the Max-Planck Gesellschaft, acknowledges that "we are not satisfied".

Most complaints against the institutes, however, are concerned not with the quality of the work but with the effects of the institutes on other research organizations. By offering security and freedom from teaching to talented younger scientists, does the system unfairly deprive the university system of talent? And should not the institutes be more closely integrated with their local universities? In reality some Max Planck institutes are closely integrated with universities, others are unnecessarily separate (see page 274).

0028-0836/82/210268-01$01.00

Money to spend

By any criterion, West Germany spends more on research and development than any other state in Western Europe. But the question keeps cropping up, "Are we getting value for money?"

Telling who pays how much for what, however, is complicated by the division of financial responsibility between the *Länder* and federal governments. The *Länder* governments are wholly responsible for the direct support of university research through recurrent budgets, contribute 50 per cent to the costs of DFG and some Max Planck institutes but only 10 per cent to the cost of large research establishments. Industry, of course, is separate.

In 1981, the total spending on research and development is estimated to have been just over DM41,500 million, something like DM750 per head of the population. The absolute amount is greater than that spent on research and development elsewhere in Europe. *Per capita* spending is close on twice the annual spending on research and development in Britain and, with the exclusion of defence research, more than is spent by government and industry in the United States.

Industrially financed research, mostly in industrial laboratories, accounted last year for more than half the total — DM22,490 million. Some officials suspect that this figure may be inflated. Government support for industrial research is estimated at more than DM5,000 million, mostly from the federal government.

There is similar doubt about the contribution of the *Länder* governments to research in universities, this was estimated last year to be DM5,380 million, but this is to some extent to be based on notional divisions of university expenses between teaching and research.

Among the government sources of finance, the federal ministry of research and technology (Bundesministerium für Forschung und Technologie, or BMFT) is dominant. This year (1982) the ministry had DM6,578 million to spend, apparently a real increase over the last year's DM6,073 million. But this year's total includes DM280 million for special programmes of research support in microelectronics, iron and steel and optical communications technology. Thus the funds available for continuing last year's programmes will increase less quickly than inflation.

BMFT is the source of support for most high technology in West Germany. Nuclear energy remains the biggest drain on the budget, with space activities and information technology of growing importance. More significantly, the technology ministry is the channel for the federal government's support of the Max Planck Society.

Centre of confusion

Argument about the future of the West German Cancer Research Centre at Heidelberg continues. The next landmark in the laboratory's turbulent contemporary history will be the special meeting of the governing body (the *Kuratorium*) arranged for 21 June, when the staff of the laboratory plans to reply to the criticisms of the report by the investigating commission under Sir Michael Stoker, published at the end of March (see *Nature* 8 April, p.481).

Professor Otto Westphal, previously director fo the Max-Planck Institute for Immunobiology at Freiburg, and director of the *Krebsforschungszentrum* since March this year, nevertheless hopes senior members of the staff will keep a pact he has made with them that there will be no public discussion of events of the past few years until after the *Kuratorium* meeting.

He does, however, say that the Stoker report was in some ways superficial, and too dismissive of the political nature of the problems that have plagued the centre. Referring to the resignation of his predecessor, Dr Hans Neurath, last summer, he says that it is now plain that there were faults on both sides — Neurath looked for too much change too soon, but was not adequately backed by government officials.

The cancer research centre has willynilly been caught up with politics because both the federal and the *Länder* governments have looked to it for advice on questions raised in the *Bundestag* and elsewhere on the incidence of cancer in West Germany. In the absence of formal channels for these consultations, differences of scientific opinion at the laboratory have been magnified into political differences — a circumstance further complicated by the election of a Christian Democrat government in Baden Würtemburg.

Westphal says that the effectiveness of the cancer research centre has hitherto also been impaired by a poor working relationship with the university clinic, part of which is in the next concrete and glass block. He says that there is already a more constructive relationship between the two establishments, partly because of the openness of some of those recently appointed to the university's medical faculty.

On the centre's role in medical research, Westphal says that West Germany is surely big enough to support a centre able to understand and acquire skills in new methods of treating various forms of cancer elsewhere in the world. Thus, he says, the complaint that the laboratory is not a centre of excellence across the board does not mean that it should be scrapped. In any case, its recent record is far from discreditable, particularly the work on new chemotherapeutic schedules and methods of analysis for the detection of small doses of carcinogens.

Perhaps the laboratory's most valid boast is the use of advanced image processing techniques for the accurate three-dimensional mapping of tumours (using some form of tomography), followed by the design of radiation sources (based on a specific implant of radioisotopes) which are optimized to destroy, say, a brain tumour but not surrounding tissue. The centre has the resources to deal with three such cases a week but depends on Heidelberg's neurosurgeons for implantation.

The somewhat down-to-earth character of those achievements is entirely consistent with the original concept of the institute by Professor K.H. Bauer, himself a Heidelberg surgeon and a personal friend of the first West German Chancellor, Konrad Adenauer. The hope in the 1950s was that applied research could help with the treatment of cancer. At first constituted as a foundation (*Stiftung*), the *Krebsforschungszentrum* became one of the research centres supported by the Ministry of Research and Technology as recently as 1976.

The centre's immediate difficulty is shared with the other major research centres dependent on the federal government — staff has to be cut across the board by 7.5 per cent in the next five years. If it is eventually decided that the pattern of the centre's work should be radically changed, the specificity with which the proposed cuts have been defined (so many scientific posts, so many cleaners) and the fact that half of the centre's original research groups are still in being will be a hindrance.

Westphal's own future is unclear. He relishes having brought a measure of calm to the laboratory at which, only a few months ago, one institute director (division head) told his boss at a committee meeting that he would fight him until one or the other went. (In the end, both went, the subordinate after an incriminating letter had been posted to Heidelberg in the wrong envelope.) It is a fair guess that Westphal will be looking for a measure of independence and an assurance of government support.

For the federal government, the problem is more serious. The *Krebsforschungszentrum* fits awkwardly in the clutch of major research laboratories financed principally by the Ministry of Research and Technology. (Its closest relative is the biotechnology laboratory at Braunschweig, west of Hannover.) In reality, however, the existing federal grant-making agencies are conspicuously unsuccessful at supporting clinical research — some say because physicians are so busy making money. With an election two years or less away, will the federal government have the stomach for the long process of consultation, with the *Länder* and everybody else in sight, that might eventually lead to an effective medical research organization? □

0028-0836/82/210269-03$01.00

Particle physics goes ahead

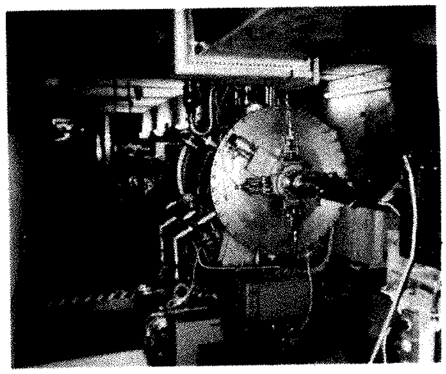
BEFORE the Second World War, German electron physics and technology was already strong. And despite the flight of physicists from the Nazis, it remained strong afterwards, partly through the influence of the "father of quantum mechanics" Werner Heisenberg and his colleague Heinz Maier-Leibnitz. The tradition has been maintained in one place in particular: the Deutsches Elektronen-Synchrotron in Hamburg.

DESY, as it is called, has become the only national high-energy physics laboratory in Europe which is unquestionably of world class. So much so, that a couple of years ago there was a distinct possibility that DESY would upstage CERN, the big joint European high energy laboratory near Geneva, and go ahead independently to build the next big machine for Europe (the 27-km circumference large electron–positron collider, LEP).

How has DESY managed to become so strong? The laboratory owes much to the canniness of DESY directors in raising money within Germany; and also to good, cost-cutting design of accelerators, rather in the legendary style of Fermilab's Bob Wilson in America. It is not exactly the spirit of Göttingen again: more like German technology and good management. Also it has been luck. DESY is an electron laboratory, and electron physics has come to the front of the stage, as the electron is now seen to be elementary, in contrast to the other commonly accelerated particle, the proton, which contains three quarks. DESY got into the excitement of charm, and the *Land* of Hamburg (which contributes 10 per cent of DESY's budget) and the federal government in Bonn now look on the place as a little German jewel. The previous director, Professor Herwig Schopper, whose political lobbying in Bonn and Hamburg was so effective, is now director-general of CERN, but his successor, Professor Volker Soergel, although a more private and very different man, has taken over all of Schopper's tactics — in particular, internationalism.

Soergel has attracted the largest American high energy physics experiment ever to be undertaken in Europe: \$4 million of equipment and 30 American physicists will stay at DESY for upwards of three years to make a thorough investigation of the interactions of the bottom quark (the one that came after charm). According to Elliot Bloom, the Stanford University spokesman of the group, there is "tremendous support" at DESY. Bloom hopes to match and perhaps outgun the only equivalent "bottom" investigation in the world, at the CESR facility at Cornell University, New York.

Bloom will use as the collider DORIS, the electron–positron collider that first put DESY on the map during the charm era of 1974–76; but now it has been completely rebuilt, and should do for the higher mass of "bottom quark" what the old DORIS (and the Stanford machine SPEAR) did for charm.



Superconductivity success at DESY — an accelerator cavity which works on a storage ring.

The other big machine at DESY is PETRA, which shares with PEP at Stanford the accolade of being the highest energy electron–positron collider in the world. However, both PEP and PETRA

More neutrons may cost too much

Is neutron scattering "Big Science"? It is at a price of DM850 million (about £220 million), which is the current tag on a spallation neutron source (SNS) being proposed in West Germany. The idea is to produce a high flux of neutrons, particles which can be used rather like X-rays to analyse the structure and dynamics of many kinds of material, by bombarding a target of uranium with a pulsed beam of protons. Broadly speaking, fluxes much greater than those currently available with "high flux" nuclear reactors can be created in that way, so spallation neutron sources are now seen as the second generation sources in the field, just as synchrotrons have replaced X-ray tubes in X-ray work.

However, spallation sources are not cheap. Only HERA, the electron–proton collider planned by the national high energy physics laboratory DESY (see above), comes close to the SNS in price among major capital projects currently before the ministry of research, and even that is cheaper. But the SNS would provide for a much larger community of scientists than HERA, and it could be built in two half-price stages. Which to buy, HERA or the SNS? Or is there money for both? The decision is due sometime next year.

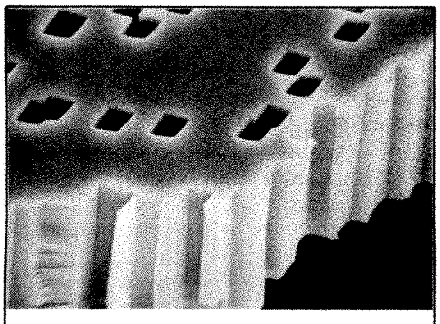
For the moment, the two interested communities are playing a kind of poker game. The minister for research and technology, Dr Andreas von Bülow, has asked them to assume that the government would fund both projects, but to stretch the construction schedules of their machines so that the net annual cost would not be too high. However, von Bülow has omitted to say what "too high" would be; so the communities are now competing both against each other and against an uncertain ceiling to pare their costs to the minimum. Nevertheless there is some hope that a recent government commitment to make a major investment in the economy in the middle of next year (at the expense of increased borrowing) may see money being spent on both projects, if only to help the construction industry. This was just how DESY first got the money to build PETRA (see above) some years ago.

The only firm decision so far is that the SNS, if funded, will be built at the Jülich nuclear centre near Cologne, where Professor Hans-Heinrich Stiller is the project leader. (Karlsruhe, an early competitor for the site, has been eliminated.)

The SNS would be bigger (and come on line considerably later) than the only other similar machine in the world, the British SNS under construction at the Rutherford laboratory — which will first become operational in 1984. The German SNS would not be likely to be ready before 1991, even if it got early approval; but then it would produce more than three times as many neutrons (peak flux) as the Rutherford SNS in the first stage, or 25 times as many in the second stage. The corresponding figures for mean intensity are 25 times and 200 times the British SNS — an indication of how sophisticated and complex the German technology would have to be.

On both the British and the German sides the open question is how much collaboration can be established on the two projects. Money for the British SNS is agreed, but a lot more cash is needed for the complex instrumentation (spectrometers and so on) which must accompany a neutron source if it is to be a success. (A major reason for the pre-eminence of the high-flux reactor, the Institut Laue-Langevin at Grenoble, in this field can be traced back to an early and effective emphasis on instrumentation for the institute.) So Britain would be happy if Germany could contribute a few instruments to the SNS. Then, perhaps, if the British economy had improved, there might be some British support for the German machine in the 1990s. Very preliminary discussions are already under way on such matters. But a likely fate for the large-scale German SNS might be that it will not be built at all, unless much wider international collaboration can be set up to support it.

Robert Walgate



A molecular sieve (see article on GSI, right).

have suffered a trick of physics: the energy region has proved so far to be relatively barren of spectacular results. Nevertheless, PETRA has found evidence for gluons (the photons of the interquark force), and has more recently demonstrated "interference" between the electromagnetic and weak interactions — which indicates the existence of the neutral intermediate vector boson, the present holy grail of particle physics.

Another DESY success (in collaboration with Karlsruhe) was demonstrated only this month: "our little present for LEP", as it is described at DESY. It is a superconducting accelerator cavity, which can reduce the electric power required to drive an electron accelerator by a very large factor (up to tenfold) or, equivalently, raise the energy that the machine can reach for the same power input. Since CERN's likely power bill for LEP is a major headache, the demonstration of working, cheap and reproducible superconducting cavities would be a great step forward. Two weeks ago a single Karlsruhe-DESY cavity successfully drove PETRA to 5 GeV. The cavity has some unique features, and could be produced industrially, but so far it is too expensive: to equip PETRA fully with the devices would cost DM50 million, DESY staff estimate, for a present electricity bill saving of DM2–3 million a year. Nevertheless, savings at LEP would be much greater, and it is clear the design is approaching being practical.

DESY is again looking abroad to raise the finance for HERA, DESY's big (DM600-million) project for the 1990s. (HERA would collide 30 GeV electrons with 820 GeV protons, to probe the lepton–quark interactions. It would use superconducting bending magnets. If for some reason LEP failed, it could be converted to create the intermediate vector boson.) A DESY spokesman said recently that negotiations are already well-advanced if not with governments, with laboratory directors elsewhere, with hope of raising around DM200 million of the cost of HERA abroad. Hamburg has already committed itself to its 10 per cent (DM60 million) which would then leave Bonn with only DM340 million to find — cheaper than the first stage of the spallation neutron source with which HERA might be in competition for Bonn resources (see opposite).

Robert Walgate

An element of risk

The Gesellschaft für Schwerionenforschung (GSI) at Darmstadt (south of Frankfurt) is riding high. It has one brilliant feather in its cap — the artificial production of element 107, the heaviest so far. And its director, Professor Gisbert zu Putlitz, has ambitious plans for bigger and better experimental equipment.

GSI, the only dedicated heavy-ion laboratory in Europe, lives by its equipment for accelerating heavy ions — even uranium ions — in several stages. At the end of last month, the laboratory inaugurated an extension to its UNILAC accelerator that will double the maximum energy of the ion beams produced to 20 MeV per nucleon. But zu Putlitz is already looking beyond that target.

Element 107, represented by the isotope with 155 neutrons, was made at GSI last year by the collision of accelerated chromium-54 with a target of bismuth-209. As with all experiments of this kind, the chief difficulty is to demonstrate that the intended element has indeed been produced. The team at GSI used a novel arrangement of electric and magnetic fields to demonstrate their few nuclei of element 107 and thus to break the near-monopoly on the creation of heavy elements which the Lawrence Radiation Laboratory in the United States has enjoyed in the past few years.

More intriguing, however, is the demonstration of a novel form of radioactive decay — the emission of protons rather than electrons from nuclei that are deficient in neutrons. By the collision of a beam of nickel-58 ions with a target of ruthenium-96 for example, it has been possible to synthesize the isotope lutetium-151 which has 24 neutrons fewer than the stable isotope of the element. (The isotope thulium-147 is also subject to proton decay.) Plainly this novel form of nuclear instability has been a great fillip to nuclear physics — and not merely in West Germany.

The laboratory says, however, that it is not merely a nuclear physics establishment but a practical place. By way of evidence, it cites the use of molecular beams for producing molecular sieves. What better than a beam of heavy ions to punch holes of molecular dimensions in a synthetic membrane? So filters are being made for instruments that measure particulates in air and models constructed for studying the permeability of biological membranes.

So what of the future? Professor zu Putlitz clearly regards the present energies at which heavy ions can be produced as only a modest beginning. Ultimately, there will be a need for ions with energies of 500 MeV per nucleon or even 10 GeV per nucleon. Such energies cannot be achieved with a linear accelerator of reasonable cost and size, and GSI has therefore proposed to build two interlinked synchrotrons, presently called SIS 12 and SIS 100. The smaller one, SIS 12, would use UNILAC as an injector and would accelerate ions to about 1 GeV per nucleon. The next synchrotron (SIS 100) would take over from there and further accelerate the beams to the maximum energy of about 10 GeV per nucleon.

Enough land is available for both machines. The cost, just under DM90 million for SIS 12 and just over DM 150 million for SIS 100, is the stumbling block. But SIS is high on the government's list of major projects; zu Putlitz is optimistic. Indeed, if funds are short, he would prefer to start by building SIS 100. Time alone will tell whether he will be able to follow this more imaginative but no doubt risky approach.

Konrad Guettler

Research without responsibility

Professor Klaus Pinkau, director of the Max Planck Institute for Plasma Physics at Garching-near-Munich, is a square-jawed square-built man with a shock of grey hair and a ruddy complexion who exudes enthusiasm. He thinks he knows something of what is wrong with the state of science in West Germany.

First, he says, people are needlessly depressed by what is in effect an illusion, what he calls the "echo-effect". Everybody must accept that the United States is now the chief source of scientific discovery, and American scientific journals the chief medium for the announcement of new developments. Inevitably, however, this implies that papers by West German scientists are referred to less frequently, and less fulsomely, than their merit would demand. Worse still, there is a tendency for science journalists and even scientists themselves to take note of some development in West Germany only if it is first applauded, or approved of, in the United States.

In reality, Europe (and West Germany) has more to boast about than anybody acknowledges. Has not the COS B gamma-ray satellite (switched off last month after seven years of operation) been a unique and successful demonstration not merely of the technique but of the capacity to formulate an adventurous project?

So what else is good in West Germany? Pinkau echoes the common response by referring, first of all, to "Eigen's group in Göttingen". But his main impression is that West Germany has done best in those

0028-0836/82/210271-02$01.00

fields in which there were enough people still active after the Second World War to provide a nucleus of active research. Perhaps nuclear physics, especially the work with heavy ions at Darmstadt (see page 271), is representative of the best.

Professor Klaus Pinkau: "We do second-rate research rather well".

Like others, Pinkau thinks that bureaucracy has had a baleful influence. Why should it have been left to a committee of the *Bundestag* to decide, last December, which six posts at his laboratory should be abolished? But the irritation caused by such happenings is less important than the way in which the bureaucracy's existence undermines the sense of responsibility that professional scientists should enjoy. If everybody knows that, in the last resort, distant committees of officials will make the most detailed decisions, how can working scientists shoulder the responsibility implicit in their promises?

Pinkau shares the common concern about the reform of the universities, but in a novel way. The problem is that the universities have also lost their sense of responsibility. He agrees with the opinion that "we do second-rate research rather well". He is doing what he can, personally and by encouraging his colleagues to follow his example, by teaching regularly at the technical university at Munich.

The lack of responsibility — the freedom to act independently — is here again Pinkau's main worry. "The government", he says, "must realize that by restricting the independence of scientists, they are killing science". He acknowledges that the Max Planck Society has an enviable reputation for not being bureaucratic, although his own institute is in the significantly different position of being financed directly from Bonn.

But even with this proviso, Pinkau answers a firm "yes" to the question "Should the Max Planck institutes be merged with their neighbouring universities?". That would be good for research, but in any case there is too much tension between university and Max Planck scientists for comfort. □

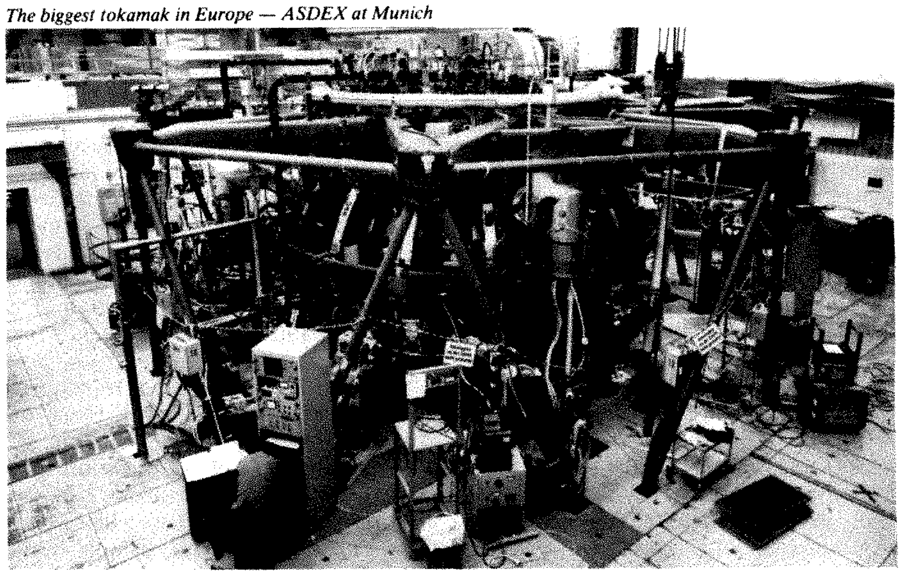
New ways with fusion

In 1978 the European decision to build the Joint European Torus (JET) at Culham in the United Kingdom rather than at Garching in West Germany seemed a blow to the German plasma physics community. For JET is the principal experimental facility in the Euratom plasma physics programme, and for when national programmes have to compete for funds with collaborative international experiments whose funds are necessarily committed in advance, there is always a danger that they will be squeezed.

The main plasma physics research laboratory in West Germany, the Max-Planck-Institut für Plasmaphysik (IPP) at Garching near Munich nonetheless continues to run a thriving national programme. But the generally less favourable economic climate of the past few years has taken its toll; an initial multitude of experiments has gradually been reduced to two main lines of research. One of these is centred around ASDEX, the biggest tokamak machine in Europe, which was commissioned in 1980 and has already yielded important scientific results.

What excites the people at Garching about ASDEX are the diverter coils which produce a magnetic field allowing for control of the level of plasma impurities. The stability and lifetime of any contained plasma is severely limited by the impurities introduced through interactions between the plasma and the wall of the container. The diverter chambers of ASDEX significantly reduce the level of metallic impurities and lighter species such as

The biggest tokamak in Europe — ASDEX at Munich



Jülich's jewel

"Come and see our jewel", said the man behind the wheel, pulling up outside a hanger. The jewel in question is the fusion experiment called TEXTOR, a machine recognizable as what it is from its toroidal shape but with the advantage that it can be separated into two halves so that the interior can be rebuilt.

TEXTOR, partly financed by the European Community as part of the joint programme of thermonuclear experiments, has so far cost DM110 million, with close on DM50 million still to go. With its discreet constructor's label, Krupp, the machine is as nicely engineered as it could be.

The torus is intended for the study of problems that may crop up in thermonuclear reactors thirty years from now. It is a small tokamak designed to examine the interaction between a hot plasma and the containing walls, the behaviour of wall materials under neutron irradiation and the processing of tritium, the necessarily radioactive component of likely thermonuclear fuel. Everybody is delighted with the way it works.

For a nuclear research centre such as the Kernforschungsanlage Jülich, set up in 1956 by the government of Nordrhein-Westfalen but since 1970 supported to the tune of 90 per cent by the federal government, a long-term project such as this must be a comfort.

The establishment is best known for its development of a high-temperature reactor, an experimental version of which went into operation in 1967, producing 46 MW of heat. The prototype of that design being built at Hamm-Uentrop nearby will function only in 1985 (seven years late), producing 300 MW of electricity.

The technical problems are those of making reactor components that will operate reliably at 950°C for years on end, but the costs are also high. So Jülich is pushing hard a scheme for long-distance energy transmission in which fast reactors would convert methane (and water) into hydrogen and carbon dioxide for reconversion at some distant point.

0028-0836/82/210272-02$01.00

oxygen. The mechanical devices used elsewhere in tokamak machines are said to be comparatively ineffective.

The second objective of ASDEX is to study the properties of plasmas heated by beams of neutral atoms. The original neutral beam injectors are being upgraded to a total power of 2.5 MW which should lead to an increase in plasma temperature from 6×10^6K to 2×10^7K. There are plans to use radio-frequency heating to increase plasma temperatures still further, and to use a deuterium pellet injection system to replenish the plasma particles removed by the diverters.

The ASDEX device will remain the major focus of research for several years, but plans for an upgraded version are already being drawn up with support (in the design phase) from the European fusion programme. As well as being a bigger machine, the distinguishing feature of the version being planned is that the diverter coils will be external to the main toroidal field coils, an arrangement considered to be essential for a fusion reactor.

Most of the research at ASDEX is of direct relevance to JET (also a tokamak machine) and the laboratory says that there are close links between the two establishments. But IPP has not put all its eggs into one basket; it continues its research into the physics of stellarator machines. In the present machine (called Wendelstein VII-A) the peculiar stellarator magnetic field configuration is achieved by a set of toroidal field coils surrounding the inner helical coils. But the laboratory is planning an Advanced Stellarator in which these two sets of coils would be replaced by one, each of them with a somewhat different twisted geometry. The result is expected to be improved plasma stability at a higher plasma pressure. The design phase has begun and the new machine could be working as soon as 1985.

Although the Garching institute is technically part of the Max-Planck-Gesellschaft, its size and large annual (running) budget of DM110 million made it a natural candidate for membership of the association of the large science centres, AGF. The institute's finances are outside the usual Max Planck pattern — a quarter of the budget is derived from Euratom, with the remainder split 90:10 between the federal government and the *Land* of Bavaria.

Not surprisingly, other Max Planck institutes are uneasy at the presence of such a cuckoo in their nest. Fusion research is, however, one of the few European programmes that really work, and it is difficult to imagine how such a successful research centre could be effective on a much smaller scale. Nevertheless, as the size of fusion reactor experiments becomes even larger in the future, it is likely that one of the more applied research centres, such as the huge *Kernforschungszentrum* at Karlsruhe may take a bigger share of the development — its contribution to research at Garching takes the form of technological development of such items as the pellet injection system.

Within the national German fusion programme, the Karlsruhe centre tends to be most active in magnetic field technology and materials study, but the centre is also involved in system design studies. In particular, it maintains a modest presence in two lines of fusion research: inertial confinement fusion using light ion beams and fusion by magnetic confinement in a tandem mirror machine. The light ion fusion studies involve a pulsed high-power ion generator, whereas the tandem mirror configuration is only at the system design stage. Earlier mirror experiments at Lawrence Livermore National Laboratory in California yielded promising results, yet the research at Karlsruhe seems to be the only investigation of its kind in Europe.

Fusion research in West Germany seems thus to have retained an enviable diversity, the commitment to JET notwithstanding. The machines now operating, at IPP and elsewhere, are producing a substantial harvest of data. And with funds secure for the initial upgrading of the major facilities, the institute has a viable programme for the 1980s. Its involvement in the study groups for the Next European Torus (NET) and the international INTOR project should leave it well placed in any competition for a future international facility.

Yet the time scale for break-even fusion power seems to be receding further and further; Klaus Pinkau, director of IPP, is quite frank in saying that two or three steps will be necessary after operating experience with JET, perhaps by the end of this decade. Each step seems to require ten years or so, so that it may not be known until the year 2020 whether fusion is technically and economically feasible. "I'll be dead by then", he says.

Konrad Guettler

Alternative routes to fusion

THERE are other means of inertial confinement fusion which have received considerable attention and funding elsewhere: laser fusion and heavy-ion beam fusion. The main difficulty with the former is the high power output required by the lasers and reliable operation with a high pulse repetition rate. Heavy-ion beam fusion research suffers from the handicap of requiring a very large initial investment in the ion beam accelerator. Some of the relevant ion beam studies are being carried out at the GSI accelerator (see below) near Darmstadt but with low priority. A high-power laser project group originally formed part of IPP at Garching but some time ago it was expanded and elevated to the status of the separate Max-Planck-Institut für Quantenoptik. Although still sharing a site with IPP at Garching, the research emphasis of the new institute is divided between laser fusion, laser spectroscopy and laser chemistry. Its fusion research is carried out with a high-power iodide laser and is aimed at understanding the fundamental aspects of energy transport within the compressed fusion pellet. The emphasis on some restricted topics of research appears to be deliberate, although some foreign concern seems to have been expressed about a much more expanded national laser programme.

Konrad Guettler

An astrophysics star is rising

WEST GERMAN astronomy and astrophysics are neatly parcelled up on wavelength lines: the Max-Planck-Institut für Radioastronomie in Bonn (see next page) looks after the radio-wavelength part of the spectrum, the Max-Planck-Institut für Astronomie in Heidelberg looks after the optical region and the Max-Planck-Institut für Physik und Astrophysik (with its Institut für Extraterrestrische Physik) in Munich deals mainly with the short wavelength domains of UV, gamma-ray and X-ray astronomy. The Munich institute is the major West German institute involved in satellite-based experiments and has an ambitious programme for the 1980s.

The gamma-ray part of the package is perhaps the most distinctive. Balloon-borne telescopes are used for low energy studies, while the high-energy domain has been studied as part of a European collaboration using the COS-B satellite, shut down only in April this year after more than six years of operation. The users are delighted with the way this instrument has performed but also with its conception. "It shows", Professor Joachim Trümper, head of the institute, says, "that European scientists can still be the first with a good idea".

Even so, the prospects for further research in the field now depend on plans for the Gamma-Ray Observatory (GRO) satellite of the US National Aeronautics and Space Administration (NASA) for which the insitute is helping to design one of the telescopes. Its other gamma-ray investigations centre mainly around the Solar Maximum Mission and the ISEE-3 satellites, which are specially equipped to study solar flares and gamma-ray bursts.

The magnetosphere and the interplanetary medium constitute the second major focus of the institute's programme. The Earth's magnetosphere is being

0028-0836/82/210273-02$01.00

investigated with experiments aboard the European GEOS-2 satellite, and the interactions between the magnetosphere and the solar wind with the ISEE-1 and ISEE-2 satellites respectively. While the analysis of the data from these satellites will keep people busy for many years, what excites them most are the preparations for the next mission — a major joint project between NASA and European institutes called the Active Magnetospheric Particle Tracer Experiment (AMPTE). It consists of three major components. The Munich institute is building an Ion Release Module, NASA is responsible for the Charge Composition Explorer satellite and the British Science and Engineering Research Council is contributing a subsatellite equipped for *in situ* plasma diagnostics. The release module will inject artificial plasma clouds into the solar wind and the tail of the magnetosphere, and the two other satellites will measure the interactions between the cloud and the ambient plasma.

For the future, the X-ray astronomy group seems to have even more dazzling prospects. Apart from its own balloon experiments, the institute is a major participant in the EXOSAT satellite soon to be launched by the European Space Agency. But its most ambitious project is ROSAT, a large X-ray observatory designed for launch by the space shuttle in 1986 or 1987. This instrument has been designed to have much better angular and spectral resolution than even the NASA Einstein Observatory which ceased functioning last year.

Primarily a national project, this satellite should give West German scientists a commanding place in X-ray astronomy at the end of the decade. The initial observational programme is a sky survey for the first half-year after launch which should reveal many more X-ray sources, given that the satellite's sensitivity is three times greater than that of the Einstein Observatory. This survey is to be followed by a one-year study of interesting sources. If all goes well, the satellite could even be retrieved after a couple of years by the space shuttle and refurbished.

Although a national project, ROSAT will provide observation time for other astronomers. Negotiations are under way with NASA for a US instrumental contribution in exchange for time, while there is to be an extreme-UV telescope built by a consortium of British universities.

So in the late 1980s the focus of attention in the field will shift from America to Europe. Repeated cuts in the US research budgets have put the competing Advanced X-ray Astronomy Facility further back, even though it has received the highest priority in the recent Field report (see *Nature* 8 April, p.482). And with no successors in sight for the UK Ariel satellites, ROSAT will be the only source of X-ray data for years to come.

Konrad Guettler

Contrasts in Max-Planck styles

MAX PLANCK INSTITUTES seem to come in all kinds of shapes and sizes. The largest and most costly of them is the institute for plasma physics at Garching, but the radioastronomy institute at Bonn is similar in that it owes its existence to equipment so expensive and distinctive that it cannot easily be the property of a single university department. The institute's boast is a 100-metre high-frequency radiotelescope.

At the other end of the Max Planck spectrum is the newly created (1980) Institute of Mathematics, which is closely a part of the University of Bonn and which has the further distinctions that its personnel consist largely of visiting mathematics professors (with graduate students from the university) and that it is the first example so far of a Max Planck institute created from one of Deutsche Forschungsgemeinschaft's special research programmes (*Sondersforschungsbereichen*, see page 266). Although the institute will not become a charge on the Max-Planck-Gesellschaft until 1985, it already has a shiny new name-plate on its handsomely constructed building.

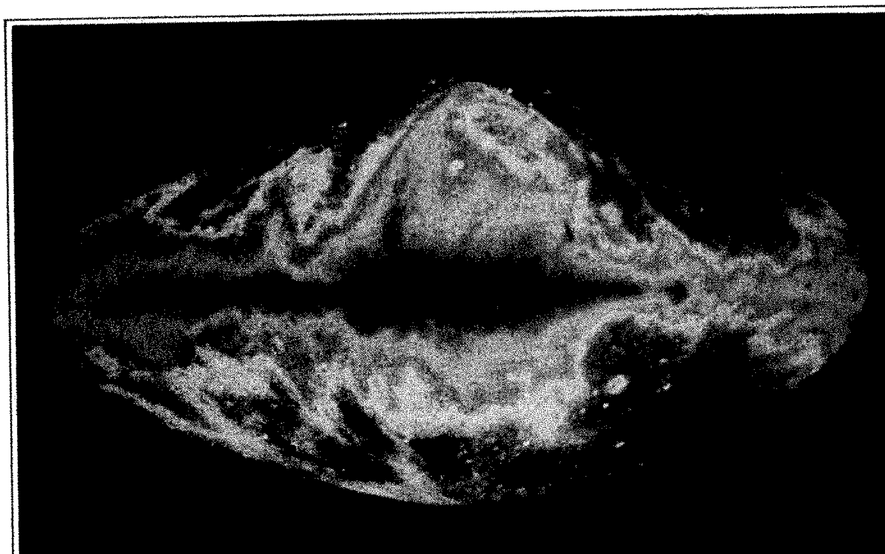
Technically, the radioastronomy institute is inevitably the more spectacular. The 100-metre dish sits in a well-wooded valley at Effelsberg, 30 kilometres east of Bonn. It has been designed to operate at frequencies up to 50 GHz (a wavelength of 6 mm) and beam width at 1.2 cm is reckoned to be 35 seconds of arc.

The total cost of the dish (completed in 1972) and the ancillary equipment was DM 40 million, a substantial part of Max-Planck-Gesellschaft's capital budget more than a decade ago. The staff (including a score or so of visitors) amounts to more than 180 people, of whom a third are scientists. The institute is divided between an office in Bonn and the field station at Effelsberg, and includes a substantial technical effort at both places on the design and construction of detectors for use with the telescope.

Operationally, the telescope has been an immense success, at least in part because of the cleverness with which the structure was designed. The objective is somehow to preserve the parabolic shape of the 100-metre dish whatever the elevation. This has been accomplished in the Krupp-MAN built instrument at Effelsberg by attaching a huge counterweight by a network of struts to the back of the dish so that the dish can distort only into another parabola. The result is a dish that is substantially lighter than rigid construction would have required.

The staff at the mathematics institute is by comparison inconspicuous. The director, Professor Friedrich Hirzebruch, says that he and his two senior colleagues from the mathematics department at Bonn remain on the university's payroll, but that he is relieved of administrative duties (but not teaching) on account of the time spent at the institute. He thinks he may apply to Max-Planck-Gesellschaft for two permanent positions for mathematicians, but the bulk of the budget, roughly DM 2.5 million a year, will still be used to support mathematicians visiting from elsewhere in West Germany and abroad.

In Hirzebruch's view, an institute of mathematics is necessarily a place for peripatetic people. Since his group was formed in 1969, he says that it has acquired an international reputation comparable with, say, those of the groups at the Princeton Institute of Advanced Study, the



A map of radio-sky intensity at 408 MHz compiled at the Max Planck radioastronomy institute at Bonn from data gathered over a period of 15 years at Bonn, Jodrell Bank and Parkes (Australia). Data reduction was by means of a Cyber 172 computer at Bonn. Prominent patches along the mid-line of the sky are the local arm complexes Cygnus X (left) and Vela X (right).

0028-0836/82/210274-02$01.00

Institut des Hautes Études near Paris and the University of Warwick as being places where mathematicians can work on interesting problems with interesting colleagues without having permanently to tear up their roots at the place whence they came. But Hirzebruch also sees his peripatetic working group as a direct benefit to the mathematicians at Bonn.

The links between the institute of radioastronomy and the local university seem much less immediately productive. Professor Richard Wielebinski, the Polish-born Australian immigrant who is now one of the laboratory's two directors (the executive director is Professor Peter G. Metzger) says that the radioastronomy institute is, above all, a national research centre. A substantial part (more than 20 per cent) of the 100-metre telescope's time in the past two or three years has been used for coordinated interferometric observations in which radiotelescopes as far apart as California (Goldstone) in the West and the Soviet Union (Crimea) in the East have been used to produce the intensity of radio emission from distant objects such as the radio galaxy 3C298 with a resolution of 0.5 seconds of arc.

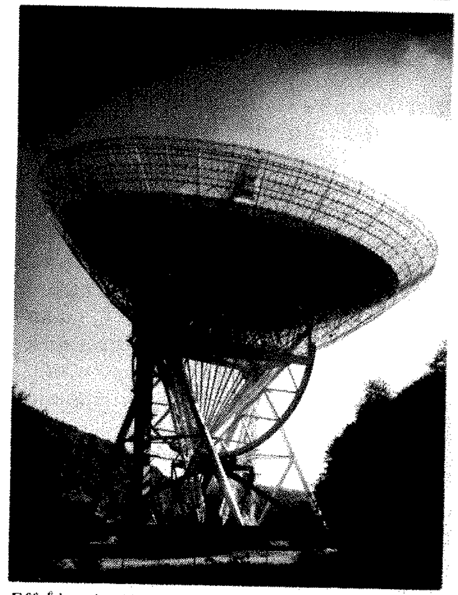
Long baseline operations such as these require long-term planning and the blocking-out in a somewhat arbitrary fashion of other opportunities for observation. Even so, the institute is planning to extend its international operations. The institute is the vehicle for the Max-Planck-Gesellschaft funds being channelled into the construction of a 30-metre radiotelescope being built in Spain to operate at frequencies of 80 GHz and above. This will be for a time, when tested in operation next year, the largest instrument of its kind in this region of the spectrum. The instrument will be used for observations of extragalactic carbon monoxide and continuum radio emission (the latter being one of Wielebinski's particular interests). It is also intended that the Spanish instrument should be used in conjunction with an array of three 15-metre dishes being built near Grenoble in France under a fifty-fifty agreement between Max-Planck-Gesellschaft and Centre National de la Recherche Scientifique, but that agreement has been made at headquarters level.

Off its own bat (but with approval from Munich), the institute has made a fifty-fifty deal with the University of Arizona that will lead to the design and construction of a 10-metre sub-millimetre telescope, to be built in Arizona. That agreement is to be signed in June this year.

What these two institutes therefore have most conspicuously in common (from 1985, in the case of the mathematics institute) is that the money comes from Munich. There is also a sense in which a direct comparison between them is unfair. One (the mathematics institute) is a device for channelling support for old-fashioned scholarship through a talented scholar to a university which, even though founded in 1818 in the aftermath of the Napoleonic wars, is distinguished in this and other fields. The other, the radioastronomy institute, is either a national research centre, intended to put West German radioastronomy on the map, or a national research facility, to be used by whichever West German astronomer has a sensible idea as to how the equipment should be used.

The trouble seems to be that this Max Planck institute pretends to be neither of those things but rather, in the Max Planck rhetoric, to be a free-living community of independent scholars which, nevertheless, by means of its senior people's honorary professorships (at the local university), its downtown location so close to the Department of Astronomy at the University of Bonn that the two institutions can share a library and its willingness to take in graduate students from everywhere, is intrinsically part of the university system. The irony is that the university's department of astronomy seems likely to succeed in its application to Deutsche Forschungsgemeinschaft for the funds with which to build another radiotelescope at a different site.

What follows is a strictly personal impression. First, the two institutes have distinctly different roles. The mathematics institute is not merely a source of scholarship but a way of enlivening mathematics at the University of Bonn, while the institute of radioastronomy, in spite of its links with university astronomers in West Germany and elsewhere, must be judged primarily by its own staff's output of research results. To some extent, of course, these differences are explained by the differences between the subjects — mathematicians are mobile, radioastronomers to some extent tied to their instruments. But there are other ways of organizing the use of large research facilities, with the American pattern of open access through user committees at one extreme and the British tendency to base radiotelescopes in university departments at the other. More concessions at Effelsberg in one direction or the other could not fail to embed the use being made of this splendid instrument more firmly in the scientific community's consciousness.



Effelsberg's 100-m dish: productive but an ivory tower?

Making a business of research

By what trick can a group of only four tenured academics run a department with 400 students, 160 of them doctoral students, spend the best part of DM20 million a year and yet keep the department's well established reputation for being the best academic institution of its kind anywhere in the world? The department is the machine tool institute at Aachen, one of the fourteen specialized institutes in the mechanical engineering complex at the Rheinisch-Westfälische Technische Hochschule (RWTH). The trick is to run the department as if it were a business.

The four tenured academics are university professors. Their formal duties are to lecture to the undergraduates, but each also has under his wing a small clutch of research groups, perhaps three or four. The research groups are run by senior engineers, hand-picked from among those gaining a doctorate in the department and employed as the need arises on short-term contracts.

Of the total cost of the department, no less than eighty per cent comes from outside RWTH, principally from the federal government and its grant-making agencies. The brunt of the research work falls on the graduate students, paid out of project grants, but the department also makes a special point of engaging undergraduates part-time in its research work (and pays them for their trouble). Ten per cent of the successful diploma candidates are kept on for doctoral work, on which they spend between five and eight years (the average is about six). Once their dissertations are completed, they must find a job elsewhere.

That step appears to present very little difficulty. Apart from the institute's high reputation, the Laboratorium für Werkzeugmaschinen und Betriebslehre prides itself on having the closest possible relations with companies in the metal-forming industries of West Germany, many of which play a crucial part in helping to define the department's research programme. But the department will add a project to its portfolio (and apply to some

0028-0836/82/210275-02$01.00

Hard management and software

THE machine tool institute's reputation stems directly from the single-mindedness of its founder, Professor Adolf Wallichs, who in 1906 seems to have taken fright at developments in production engineering in the United States and to have embarked on a research programme in a small cellar. One of his achievements was to persuade German industries to contribute to the cost of a building and the equipment to go with it at the height of the post-war inflation in 1924.

Wallichs was succeeded in 1938 by Professor Herwat Opitz, whose 37-year spell in office saw radical developments in, for example, the design of gear-cutting tools and, after the Second World War, the threefold growth of the institute. Since 1973, the management of the institute has been shared between the occupants of the three full university chairs (*Lehrstuhlen*) among whom the chairmanship of the department rotates. (Metrology is for the time being the poor relation.)

The research programme is now dominated by the application of computers to production processes. Thus the design section is up to its eyes in computer-aided design (CAD). Here and elsewhere, part of the objective is to produce a library of software that can be used by the small to medium sized manufacturers that dominate this sector of West German industry in the optimization of, say, a gear train — and the automatic draughting of the drawings needed. Similarly, using banks of data built up over the years on the characteristics of various cutting and metal-forming processes, computer programs are being designed so as to identify the best way of producing metal parts of various forms.

The search for accuracy and reproducibility is a recurrent theme in the research programme, whence the current interest in real-time measuring techniques. Similarly, computer techniques are being used in the analysis of how machine tool structures are deformed by stresses arising during use.

While all this software is accessible to would-be industrial users, specialized seminars (at Aachen but also at Zurich) are regarded as essential means of propagating the new ideas that arise, as are the biennial international conferences on machine tools, the last of which last year attracted 2,000 participants.

such organization as the Deutsche Forschungsgemeinschaft for funds) only if the outcome of its work can be published in the open literature. Consultancy on specific problems for industrial companies is only a modest part of the department's work.

This unique way of doing academic business has, in effect, made the institute both the research laboratory and the source of skilled engineers for much of an important sector of West German industry. Yet this is one of the smaller of the fourteen institutes catering for the 5,300 mechanical engineering undergraduates now registered at Aachen.

But is this not a narrow way of training engineers? Yes and no is the customary answer. For the first two years of their academic careers, students follow a more or less common course, heavy on mathematics and physics or chemistry as the intended speciality may suggest. On paper, the undergraduate course should take four years, or eight semesters, divided into the two equal halves of *Grundstudium* and *Hauptstudium*. In reality, par for the course is more like six years, although a small percentage of students win their diplomas after 4½ years. Along the way, some 30 per cent of Aachen's engineering students fail to jump one hurdle or another, although it is reckoned that only seven per cent of them fail to complete some kind of first-degree course, perhaps after moving to some other university. Hothouses like the machine tool institute are responsible only for the second half of an engineer's education.

The rigours of Aachen's engineering courses seem not to have deterred school-leavers from signing on. Indeed, business is booming. This year's intake in engineering is up on 1980–81 by between 10 and 20 per cent, according to the field, while the volume of enquiries suggests that there will be a further jump next October. The proportion of women remains negligible.

The apparently steady increase of the length of time needed to win the right to the title *Dipl.-Ing.* is nevertheless a source of some concern. There is an unavoidable conflict between the need to give graduates some marketable breadth in their fields and the objective, still held to, that graduates should know about everything there is to know.

The decline in the knowledge of entering students of mathematics and basic science has also made it necessary for RWTH to provide extra courses in mathematics in the September before the first year begins. Apparently what has happened is that students seeking high marks in the school-leaving *Abitur* are opting out of the extra three hours of mathematics offered each week in the last two *Gymnasium* years.

In this respect, RWTH makes more concessions to its students' needs than many other West German universities, where students are usually left largely to their own devices. Legally, however, it has no control over the quality or even the numbers of those who elect to join engineering courses. The *Abitur* gives anybody the right to sign on for what he chooses, and that is that.

Nor, for the time being, does RWTH appear to have much interest in leavening the education of its engineers with a dash of the humanities (along the lines of the 20 per cent of time students at Massachusetts Institute of Technology are required to spend following courses in the humanities). As it happens, RWTH almost accidentally acquired a philosophy faculty in the heyday 1960s (together with a teachers' training college), and the senate will soon have to decide whether to respond to the financial crisis in Nordrhein-Westfalia by taking the knife to that cuckoo in the nest. The news that the Electrotechnische Institut in Zurich, with which Aachen has close links, is making a few experiments of this kind has unsettled hard-liners.

RWTH seems also to have been comparatively untouched by the wave of recent university reform. In 1968, it was slow to follow other West German *Technischen Hochschulen* in calling itself a university. On reflection, people are glad that they have kept the name first coined in 1870. And while there are student representatives on most committees, their proportions are such that they can be voted down when necessary. □

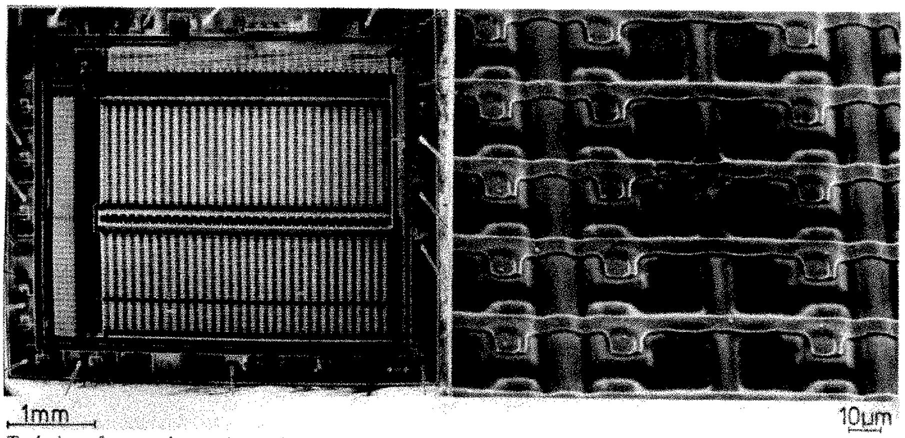
Where graduates make good

SIEMENS AG, the largest employer of scientific manpower in West Germany, is not so much a source of monthly pay cheques as a way of life. The company offers those who work for it attractive fringe benefits such as pensions, while it makes a point of recruiting all its senior managers from within its own ranks. Indeed, the company boasts that the members of its board of directors are almost all technical people who have worked their way up within the hierarchy — and that there are no lawyers, only money people, from outside. The result of all this is that recruits to Siemens who survive the first five years are likely to stay in what has become a remarkable example of a technical enterprise run by scientists and engineers.

So how does Siemens recruit its technical people? Of the 180,000 employees in Germany, more than 26,000 are technically qualified. In recent years, to make good losses and to sustain a growth of 2.5 per cent a year, the company has been recruiting about 2,000 graduates from the universities and the *Fachhochschulen*. What with the recession, this year's intake will be no more than 800, however.

In the German university tradition that students must fend for themselves, university careers offices do not exist. So a re-

0028-0836/82/210276-02$01.00



Technique for non-destructive testing of microcircuits developed by Dr H. Rehme at Siemens-Perlach. Left-hand panel represents secondary electron emission by an electron probe scanned over the surface. Dark areas are at positive voltage. The dark like across the lower half indicates the presence of a defect affecting a whole row of circuit elements and revealed in the electron micrograph (right-hand panel).

cruiting team from Siemens trudges round 20 universities and 60 *Fachhochschulen* twice each academic year. On balance, the company prefers to recruit engineers after the first degree (*Diploma*), simply on the grounds that it is easier to take on people in their twenties (the median age of university graduates in engineering is between 26 and 28) than in their thirties.

With the experience gathered since Werner von Siemens founded the company in the nineteenth century, the recruiting men now know where to go. Of the university recruits, 47 per cent are electrical engineers. Physicists make up 13.5 per cent of the university recruits, while the past few years have naturally seen a rapid growth of the recruitment of mathematicians and information scientists. Briefly, the company has a well-trodden selective path between the good engineering schools in West Germany, but also, interestingly, in Austria. Something like 10 per cent of its skilled labour force is from outside West Germany.

So how well is Siemens satisfied by the performance of the country's engineering schools? The specialization which is now common in the bigger and better schools is in some ways an embarrassment. The University of Karlsruhe, for example, produces graduates in electrical engineering under twenty different labels. Siemens approves of the objective — that a qualified engineer should know all there is to know in his or her chosen field — but wishes that it were possible also to help young engineers to be more flexible.

The consequences of the successive reforms of higher education are not welcomed. Siemens people shake their heads over the plight of some of the new universities such as Bremen, which have buildings and teaching staffs but which have failed to attract students of high quality in the numbers originally planned. They also agree with the widespread criticism of the decision that graduates of both the *Technische Hochschulen* and the *Fachhochschulen* should in future append to their names indistinguishable degrees — *Dipl. Ing.* for all. The result, they say, is that potential employers will not be able to rely on the uniformity of standards hitherto ensured by the various boards of engineering operating nationwide.

The company's chief concern, however, is that the attitudes of young people leaving engineering schools in recent years have been sharply different from those in the more distant past. People have been less competitive than they used to be, less eager to get on. They have also been corrupted by concern about the environment, a distaste for affluence and all that. But, so the argument goes, in the past year or so there has been a change. People are beginning to respond to the challenge presented by Japan. It's vital, said one company official, not just for West Germany but for the whole of the West that the Japanese should be challenged effectively at their own game of innovation.

The most striking feature of the company's use of its technical people is that close on 10,000 of its qualified staff work in research and development in laboratories scattered through the company's six operating groups but also in two central laboratories, one at Munich and one at Erlangen (not far away). The central laboratories are thus an important part of the cement that holds the six operating divisions together.

The scale of Siemens's investment in research and development should be sufficient to give it a sporting chance. For the company as a whole, 48 per cent of sales in 1979–80 consisted of products developed in the previous five years. Inevitably, the contributions of recently developed products are even higher in the company divisions responsible for components and information systems. Research and development cost more than DM3 million a year, exceeding 9 per cent of the company's sales (56 per cent of which are outside West Germany).

The central laboratory at Munich is housed in a complex of Lego-like buildings on the edge of the housing desert of the suburb of Perlach. Its managers say that they encourage proposals for research projects from members of the laboratory staff, and although most projects are oriented towards products that may ultimately be saleable, they insist that they can fairly be compared with the Bell Telephone Laboratories in New Jersey because of their willingness to take on basic research.

The laboratory also boasts of close links with the university system, pointing to its usual loss of one or two senior researchers to university chairs each year. And even the scientists and engineers who leave for jobs elsewhere are not an outright loss — they remain customers for Siemens products, it is hoped. □

No moving parts

ONE of the first instruments whose operation depends on the special theory of relativity is a spectacularly neat gyroscope built at the Siemens research laboratory at Munich-Perlach. Briefly, the device is a circular coil of single-mode glass-fibre around which radiation beams from a single semiconductor laser diode are sent in opposite directions. Rotation of the coil about its axis changes the velocities of the two opposing light beams, and thus the position of the interference fringes produced by recombining them.

The prototype instrument, built by Gerhard Schiffner (now at the University of Bochum), Benhardt Nottbeck and G. Schöner, consists of 2.88 kilometres of optical fibre wound on a 12.3 cm diameter former. To obtain an analogue signal proportional to the rate of angular rotation of the coil, the phase of the counter-travelling light beams is modulated by means of a short length of fibre whose length is modulated by means of a piezoelectric element. The signal produced by the recombined beams at a silicon photodiode is amplified and analysed by means of two lock-in amplifiers, one at the modulation frequency and one at twice that frequency. The ratio of the two signals can in principle provide a measure of rotation rate independent of power output or of the attenuation of the glass fibre.

The obvious rotation rate to measure is that of the Earth — some 10 degrees per hour for an axis pointing north–south at the latitude of Munich. Measurements of this rate suggest that the sensitivity of the prototype instrument is limited by noise to about 0.3 degrees per hour, while drift of the calibration scale may be about 0.5 degrees per hour. Temperature fluctuations (affecting the length of the optical fibre and its optical properties) and even fluctuations of the Earth's magnetic field may contribute to drift.

Siemens has little to say about the potential applications of the instrument, but the attractions of what may be a sensitive gyroscope with no moving parts are obvious. The immediate problem is to achieve miniaturization, using fibre optics elements as means of constructing the interferometer which is the essence of the instrument.

0028-0836/82/210277-01$01.00

Helping small businesses

SMALL business is big in West Germany, respected and much cherished. The best-known companies (Bayer, Siemens, Krupp and so on) are huge, and also big spenders on research and development, but everybody knows that the real strength of West German industry rests with the small and middle-sized companies, often too small to support research and development programmes of their own. What can the governments, federal and regional, do for them?

Quite a lot, it seems. West Germany offers a richer menu for encouraging research on a shoestring than any remotely comparable country. Given the way in which graduates of the engineering schools slide into the management of the small companies (and behind the wheel of the accompanying Mercedes), it is natural that they should first turn for help to the academic departments whence they came.

The volume of direct research contract business at the large engineering schools is, however, small. But the constitution of the universities as dependants of the Länder makes the connection between the universities and local industry a two-way street. A large but unknown proportion of the grant applications to DFG for engineering projects is stimulated by the needs of small business.

The federal and *Länder* governments also support a more formal mechanism for collaborative research — the Fraunhofer Society (Fraunhofer-Gesellschaft zur Förderung der Angewandten Forschung). This organization maintains some 27 research institutes in West Germany, with interests primarily in sold-state electronics (including defence applications), information processing and the construction and woodworking industries.

Contract research is now the most rapidly growing part of the Fraunhofer Society's work, apparently stimulated by the agreement struck between the federal and *Länder* governments in 1975 on the scale of their support (now running at about a third of the total budget of DM250 million).

In the past five years, the research and economic ministries of the federal government have gone even further and have introduced a number of schemes which amount to direct subsidies for research by small businesses. Small companies letting research contracts to some external research organization (which may be a public laboratory) can apply for grants to cover a third of the cost, but up to a fixed amount. And there is also a scheme of grants to cover the costs of approved in-house research, again within a ceiling.

At the same time, the national research centres are being encouraged to take on research projects for small companies — and given the unaccustomed financial pressures to which they are now exposed, seem anxious to respond.

The overwhelming response to the research ministry's offer, at the end of last year, of small grants to help with the development of products incorporating microprocessors is one striking illustration of the willingness of small companies to play their part in what has become a self-conscious crusade for the application of research. Having offered grants amounting to DM300 million over three years (up to a maximum of DM800,000), the research ministry has been swamped with 1,400 applications in the first few months.

The common explanation for this enthusiasm is nothing if not encouraging. What people say is that West German companies, and especially the smaller among them, have awakened to the consequences for them in the present hiatus in the economic miracle and in the challenge from Japan. One small metal-working manufacturer at this year's Hannover Fair put the point simply: he reckons he has at most three years in which to redesign all his products.

Research for sale

MOST stands at the Hannover Fair attract visitors either by means of something that moves or by means of a young woman (rarely a man) sitting at a keyboard hitched to a computer or the like. Dr Jürgen Schulte-Hillen, by contrast, puts himself on show. From morning to night, he sits at a small table seeking to interest potential clients in the services of his small company as an adviser on research and development. Half-way through last month's fair, he was well on the way to laryngitis.

Management consultancy is not, of course, new in West Germany, while organizations such as Battelle (whose Frankfurt establishment includes one of the largest laboratories in West Germany)

Schulte-Hillen predicts a vigorous response to the challenge from Japan

will not merely advise a company on its need for research but will carry out the work on a contract basis. Schulte-Hillen, however, reckons that he has found a unique niche in West German industry.

His small company, now ten years old and employing only 20 people, deals principally with small and medium-sized companies. Its strong suit is to provide advice on how, in a client's operations, research and development might lead to a new product or process. Schulte-Hillen does not himself carry out the work, but will instead arrange a contract between the client and some research establishment, supervising progress much as an architect will breathe down a builder's neck . In the process, the argument goes, the managements of small companies learn what research and development can accomplish — training in research management, he calls it.

So what (if anything) is wrong with the state of science in West Germany? Schulte-Hillen was for six years head of project planning at a national aerospace laboratory (Deutsche Forschungs und Versuchsanstalt für Luft und Raumfahrt, see page 266) before setting up on his own. He believes that the national laboratories and Max Planck institutes are "highly qualified" institutions with deservedly high reputations, but that they are not flexible enough and that they should have closer links with industry or the universities, as appropriate.

Schulte-Hillen also shares the view common at least among those who graduated before the 1970s that the university reforms have been "a great mistake". He regrets that they have created two classes of universities in engineering, Aachen at one end of the spectrum and Bremen (everybody's whipping-boy) at the other.

The Japanese challenge to West German industry is preoccupying but not depressing. The reason for the Japanese success, Schulte-Hillen believes, is that they have set out to make well-engineered products for a mass market. Except in a few fields, German industry, based as it is on medium-sized companies, is not naturally well placed to compete.

But, in Schulte-Hillen's view, the climate is changing. The past few years have been a shock for West German industry, and the West German automobile industry for one is now bent on becoming competitive again by ensuring good design, high-quality and low costs.

Another sign of the changing climate, Schulte-Hillen believes, is the response of West German industry to the federal government's announcement last year of a programme of small grants (up to DM 50,000) to small companies with development projects intended to use microelectronic devices in novel ways. The applications received since January this year apparently already exceed the DM 300 million originally set aside for the next five years — and one suspects that Schulte-Hillen has written many of them.

0028-0836/82/210278-01$01.00

Research labs galore

THE legend, according to one senior official of the federal government, is that those who planned the reconstruction of West German science after the war deliberately decided to take over the conspicuous institutions in what were then the obvious models for the administration of science. So now there are research councils (DFG) on the British pattern and national laboratories, as in the United States. The Max Planck Society, however, is special and indigenous.

Whatever the explanation, large laboratories are now an important part of the West German scene, with the establishments run directly by the ministry of research and technology most prominent among them. Altogether, these twelve establishments employ more than 16,000 people and cost the ministry close on DM1,700 million a year.

The laboratories are a mixed bag, including as they do the Cancer Research Centre at Heidelberg (see page 267) and a centre for biotechnology research at Braunschweig (which employs fewer than 300 people). There is a case for thinking that the Cancer Research Centre would fit more comfortably under the wing of some part of the federal government more directly concerned with medicine.

The biotechnology laboratory, on the other hand, originally founded to meet the needs of the fermentation industries, now has a distinguished group of molecular biologists working on such projects as the transfection of cells in culture by gene fragments including the gene of beta-interferon. The laboratory is likely to be one of the beneficiaries of the DM70 million that the ministry of research has to spend this year on various aspects of biotechnology. It remains to be seen how far and how fast the laboratory will move along the path towards commercial exploitation. (As it happens, the laboratory was founded in 1968 with a grant from the Volkswagen Foundation.)

For the rest, the national laboratories range from largely academic establishments including the particle physics laboratory DESY at Hamburg (see page 270) and the plasma physics laboratory at Munich (see page 271), which is also a Max Planck institute, to the nuclear establishments at Jülich and Karlsruhe and the sprawling aerospace research organization centred on Cologne. They are collectively represented in Bonn by an Association of Big Science Establishments (or AGF for Arbeitsgemeinschaft der Grossforschungseinrichtungen).

As elsewhere, AGF's West German members are having painfully to adjust to changed economic circumstances. As recently as 1980, the laboratories were hatching a scheme for employing 700 younger scientists in specially created posts — a temporary expedient to keep young people in research and the research ministry's equivalent of the Heisenberg programme run by DFG. Now, like other government establishments, the national laboratories are having to reduce their staffs by 7.5 per cent over the next five years. Even so, AGF hopes to maintain the validity of its boast that 350 graduate students from West German universities earn their doctorates at its member establishments.

The process of contraction should not be as difficult as some fear. Natural wastage by retirement, death and so on runs at about one per cent a year, while the rate of resignation by people leaving for other jobs is said to average 4 per cent a year. The question that naturally arises, however, is whether there should be some more radical change in the pattern of this substantial research effort.

Much, no doubt, will depend on the success of these laboratories in persuading the general run of West German industry that developments incidental to what would be called, in the United States, their missions are of commercial value. Beneath an elaborate green tent-like structure at the Hannover Fair this year, AGF orchestrated an impressive display by its members of technology that may have a wider use.

Thus the Karlsruhe laboratory now boasts of a piston-driven pump for liquid helium, the Jülich laboratory of novel ceramic heating units (offshoots of its work on the development of equipment for installation in high-temperature reactors) and the aerospace laboratory claims already to have had success overseas in licensing its designs for fuel-oil burners. (Their high efficiency depends on the way in which droplets of fuel oil are vaporized by combustion gases before being ignited.)

The two nuclear laboratories at Karlsruhe and Jülich are of particular interest because of their close involvement, over past years, in the West German development of civil nuclear reactors. (Other member laboratories of AGF have an interest in nuclear affairs, including the GSF laboratory in Neuherberg near Munich concerned with problems of the geological disposal of radioactive wastes, the Hahn-Meitner institute in Berlin with an interest in radiation chemistry and the GKSS centre at Geesthacht-Tesperhude in northern West Germany which is a monument to enthusiasm in the early 1960s for nuclear-propelled ships.)

Both establishments have long since outlived their original remits. The Jülich establishment, for example, was founded (in 1956) by the *Land* government as a nuclear research facility for the universities of Nordrhein-Westfalen but was converted into a national laboratory in 1968. It is still responsible for the development of the technology of high-temperature reactors, as Karlsruhe is responsible for fast-reactor technology. (The plan is that Karlsruhe will shed 70 of its 270 fast reactor people in five years or so, when the prototype fast reactor at Kalkar should at last be complete.)

The question never far beneath the surface is whether there will be reactor-development projects with which to continue when these come to an end. For the past two years, even the construction of well-established types of reactors has become a contentious political issue — and not merely in the safe SPD country of Hamburg but in CDU Bavaria as well. Although Chancellor Schmidt was able to avoid the two-year moratorium on civil nuclear construction demanded of him at his party's conference in Munich last month, plainly the political climate is one in which new proposals for major reactor development would not be easily accepted, while the electricity utilities, stung by the research ministry's success at persuading them to contribute extra funds to the cost of the fast reactor prototype, are unlikely to be pressing for further initiatives in this direction.

The present plan seems nevertheless to be that these laboratories should be kept alive on more or less the present scale, with the understanding that new tasks should be transferred to them whenever possible. The principle that it is easier to start a new laboratory than to close one down applies in West Germany perhaps even more rigorously than elsewhere, given the close interest (and the 10 per cent financial contribution) of the *Länder* governments.

AGF is not the source of funds for these laboratories but rather a coordinating mechanism for those national laboratories that happen to come under the wing of the research ministry. Other federal laboratories exist more inconspicuously, again but in partnership between the federal government and the *Land* concerned.
